Recent development of boronic acid-based fluorescent sensors

Guqian Fang,^{abcd} Hao Wang,^{abcd} Zhancun Bian,^{abcd} Jie Sun,^{abcd} Aiqin Liu,^{abcd} Hao Fang,^e Bo Liu,^{abcd} Qingqiang Yao^{abcd} and Zhongyu Wu^{abcd}  

As Lewis acids, boronic acids can bind with 1,2- or 1,3-diols in aqueous solution reversibly and covalently to form five or six cyclic esters, thus resulting in significant fluorescence changes. Based on this phenomenon, boronic acid compounds have been well developed as sensors to recognize carbohydrates or other substances. Several reviews in this area have been reported before, however, novel boronic acid-based fluorescent sensors have emerged in large numbers in recent years. This paper reviews new boron-based sensors from the last five years that can detect carbohydrates such as glucose, ribose and sialyl Lewis A/X, and other substances including catecholamines, reactive oxygen species, and ionic compounds. And emerging electrochemically related fluorescent sensors and functionalized boronic acid as new materials including nanoparticles, smart polymer gels, and quantum dots were also involved. By summarizing and discussing these newly developed sensors, we expect new inspiration in the design of boronic acid-based fluorescent sensors.

1. Introduction

Different elements form a rich and colorful world dynamically, and they are in diverse forms of existence through a series of physical effects and biochemical reactions. To accurately understand these processes, we need to give consideration to their existence at the molecular level. The objects of scientists' research vary from single ions to complex and changeable proteins. In order to deeply understand them, scientists have devoted much time to developing effective recognizing tools, and molecular recognition sensors are utilized extensively. Normally, two conditions should be taken into consideration while fabricating an ideal sensor. First, it is necessary to have a specific recognition site that combines with objects such as the human microenvironment of ions, carbohydrates, peptides, *etc.* Second, the dynamic changes made by these combinations can be detected by monitoring environment, and some of the extensively used reporters are optical and electrical.¹ The interactions of recognition originate from noncovalent bonding, such as hydrogen bonds, van der Waal's forces, π - π interactions, electromagnetic effects and so on, extending to

covalent bonds and other sensory systems.^{2,3} In recent years, using boronic acid groups to fabricate a variety of fluorescent sensors have attracted great interest among scientists. Based on the principle that boronic acid forms a reversible five- or six-membered cyclic boronic esters with *cis*-1,2- or 1,3-diols,⁴ the fabrication of boronic acid fluorescent sensor extends from boronic acid-appended molecular sensors to apply unconventional smart new materials, including boronic acid-functionalized polymers, boronic acid-modified nanoparticles, and boronic acid-based electrochemical sensors.^{4,5} For instance, boronic acid-functionalized hydrogels are important smart materials that can be used to fabricate the self-controlled insulin releasing device in the biomedical field.⁶ Hydrogels endows special properties to boronic acid sensors due to their compatibility with organisms to a certain degree.^{7,8} Recently, numerous new types of boronic acid sensors have been fabricated to detect blood glucose concentrations,^{9–13} ionic compounds,^{14–17} traces of water in solvents,^{18,19} hydrogen peroxide (H_2O_2),^{20–22} catecholamines,²³ as well as using boronic acids as biochemical tools for various applications, including tumor cell imaging,^{24,25} enzyme inhibitors²⁶ and cell delivery systems.²⁷ Therefore, the boron-based fluorescent sensor is still hot in today's research. This review summarized the recent development of boronic acid-based fluorescent sensors for carbohydrates, catecholamines, reactive oxygen species (ROS), ionic compounds and new materials. Although numerous remarkable achievements have been mentioned in previous reviews,²⁸ some areas of research have faded and many new and exciting areas have developed. In order to update knowledge of this rapidly developing field, it is worth highlighting their

merits and discussing the remaining shortcomings, as well as the development perspective of fabricating boronic acid sensors. It is also hoped that inspires others to exploit novel sensing strategies.

2. Carbohydrates boronic acid sensors

As the important material basis, carbohydrates widely distribute in the body and maintain the normal operation of life. They are usually divided into mono-, di-, and polysaccharides, which play numerous roles in nature. For example, glucose serves as the primary form of energy for basic life processes such as nervous system regulation, cell proliferation, *etc.* Cellulose endows nature with structural rigidity. Starch and glycogen can serve as energy reserves to sustain life. In addition, they can combine with other molecules to form glycoproteins, glycolipids and so on,²⁹ which play key roles in many biological basic activities such as cancer migration,³⁰ cell fusion,³¹ protein function regulation³² and embryo development.³³ Consequently, the recognition of carbohydrates in the medical, cell biology and other life sciences is of great significance.³⁴

2.1. Chemical basis for the combination of boronic acid and carbohydrates

The initial study of forming reversible covalent bonds between boronic acids and 1,2- or 1,3-diols can be traced back to 1959. Lorand and Edwards compared different covalent bond constants between the phenylboronic acids (PBA) and diols compounds involving saccharides *via* the observation of a pH drop.³⁵ As depicted in Fig. 1, boronic acid interacts with water, resulting in a rapid transformation of the boron atoms from the trivalent plane sp^2 (neutral) form **1** to the tetravalent tetrahedral sp^3 (anion) form **2**, and then releasing the proton. Due to the unique electron configuration of the elemental boron element 5, the electron configuration $1s^2 2s^2 2p^1$ allows the form of three covalent bonds in the sp^2 geometry. In the sp^2 hybrid conformation, boron has only 6 valence electrons and can accept an electron pair, thus it is Lewis acid. Namely, boron has an

“electron hole” that interacts with the Lewis base, thereby forming a covalent bond with the tetrahedral sp^3 geometry. It is an acid–base reaction that applies to the formation of borate ester. Davis *et al.* reported the relative rates of cyclic boronic esters, manifesting that the six-membered rings are thermodynamically more stable than the five-membered rings.⁵ Due to boronic acid and borate are likely to exist in two different hybrid forms of sp^2 or sp^3 , there are three processes in the borate–sugar interaction process, and the equilibrium constant is expressed by K_{trig} . The second equilibrium is the process of sp^3 hybridized borate anions **3** to borate ester anions **4** whose equilibrium constant is called K_{tet} . These two equilibrium constants alone can't really reflect the true situation of boronic acid combined with carbohydrates. Thus the third general combination constant K_{eq} is often used, regardless of the specific hybrid state of boron. Later, Wang *et al.* found that K_{tet} was actually measured by the pH drop method, and K_{eq} was measured by spectroscopy.^{36,37} Therefore, when comparing the literature value, we need to pay special attention to the specific method of determining the binding constant.

2.2. D-Glucose boronic acid sensors

As a basic necessity of organisms, D-glucose plays an important role in biological processes. Humoral abnormal glucose level is a warning signal for medical conditions, and the development of selective glucose sensors for clinical and biomedical applications has become a crucial goal in the field of boronic acid-based chemical sensing. The selectivity of boronic acid for fructose has a higher abundance than glucose, thus reversing the intrinsic binding property has been the focus of early studies.⁴ The selectivity of glucose can be achieved *via* molecular design,³⁸ and this technology is maturing,¹³ and recent developments tend to produce glucose optical responses by inducing nanoscale self-assembly of boronic acid-containing amphiphiles or other materials.³⁹ This section will briefly introduce fluorescent sensors that were fabricated with anthracene, pyrene, heterocyclic ring as fluorescent units, and then the analysis of ribose,⁴⁰ sialic acids,^{25,41} glucosamine,⁴² α -hydroxy carboxylate,⁴³ ATP,^{44,45} amyloid- β plaques⁴⁶ fluorescent sensors are followed. This paper summarized the unique design ideas of these fluorescent sensors, the luminescence response mechanisms and the development perspective in the future.

2.2.1. Anthracene boronic acid sensors for D-glucose (**Table 1**). The first application of boronic acid compounds as fluorescent sensors dates back to 1992. Czarnik *et al.* reported the first anthracene boronic acid sensor **5**.⁴⁷ This work has a great significance in the development of boronic acid sensors. Schwarz *et al.* reported that anthracene has higher fluorescence quantum yields compared to benzene and naphthalene.⁴⁸ It is probably ascribed to the influence of the longer conjugated rigid planar structure. Anthracene has a stronger UV absorption (K band) in $\pi \rightarrow \pi^*$ transition. Therefore, Czarnik devised boronic acid sensor **5** using anthracene as a fluorescent unit, which recognizes D-fructose selectively in aqueous solution at pH 7.4. The sensor **5** belongs to excited state internal charge transfer (ICT), composed of anthracene unit and the boronic

Fig. 1 Transformation of boronic acid to boronic ester.³⁷

Table 1 Key information of anthracene boronic acid sensors D-glucose

Sensor	Structure	Spectroscopic properties (λ_{ex} ; λ_{em})	C (LOD; range)	Functions and applications
5 ⁴⁷		—; 416 nm	—; 3.7 mmol L ⁻¹	pK_a modulation, the apparent fructose dissociation constant at 7.4; providing a tight, reversible association mechanism and a signal transduction mechanism
6 ⁴⁹		348 nm; 416 nm	—; 0–50 mmol L ⁻¹	The adjacent hydrogens influence the selectivity, the binding of catechol is stronger than that of saccharide; illustrating the influence of spatial steric

8 ⁵¹		370 nm; 423 nm	—; 0.3–1 mmol L ⁻¹	Diboronic acid, D-glucose ($\log K = 3.6$); the binding of D-glucose is stronger than that of other saccharide
9 ⁵⁶		377 nm; 427 nm	—; 10 ⁻⁵ –10 ⁻¹ mol L ⁻¹	Diboronic acid, high ¹³ C chemical shifts of the binding of D-glucose; the binding of D-glucose is stronger than that of other saccharide
11 ⁵⁹		358 nm; 418 nm	0.8 μ mol L ⁻¹ ; 0.003–3.0 mmol L ⁻¹	Fluorescence intensity ↑, lower detection limit; successfully applied to glucose detection in human serum samples
12 ⁶²		405 nm; 488 nm	4.4 mmol L ⁻¹ ; 0–55.6 mmol L ⁻¹	Diboronic acid, good biocompatibility; applied <i>in vivo</i> and successfully tracked the fluctuation in blood glucose concentration

acid unit. In ICT systems, heteroatoms or strong-inducing functional groups can lead to an imbalanced electron density in the excited state of the molecule, thereby the favorable dipole–dipole interaction is increasing between the fluorophore and the surrounding solvent shell.¹ Interestingly, they found that sensor 6 has a smaller fluorescence change, ascribed to the influence of the adjacent hydrogens.⁴⁹ Those studies showed that pK_a is a viable mechanism for signal transduction of carbohydrates bindings, providing some experiences for the future design of this type sensor. First, a tight, reversible association mechanism is needed. Second, the fluorescence assay required a signal transduction mechanism.

Subsequently, Shinkai *et al.* reported the anthracene monoboronic acid sensor 7 selectively recognizing D-fructose and the anthracene diboronic acid sensor 8 which selectively recognizes D-glucose.^{50,51} The sensor 7 was combined with carbohydrates to form 7a, and its N–B bond interaction of 7a was enhanced,

which hindered the photoinduced electron transfer (PET) process from the tertiary amino group to the anthracene fluorophore. PET mechanism is generally believed that the aromatic ring electrons can be excited to the vibrational energy level of the first electron excited state or higher excited state after the aroma system is excited by the excitation light, and then it reaches the lowest vibrational energy level of the first excited singlet state after the internal energy conversion or vibration relaxation process. Finally, it returns to the ground state in the form of radiation to produce fluorescence.⁵² If there are nitrogen atoms and other atoms in the molecule, due to the energy of the lone pair electrons is between the ground state and the singlet state, the solitary electrons can transfer to the aromatic ring of the electron deficient and occupy its orbit, resulting that the original excitation of the electrons can't return to ground state, and can't produce fluorescence. Thus this combination brings great changes in the fluorescence

properties that can be applied to detect specific carbohydrates.^{53,54} The discovery of PET mechanism will contribute in the future study of fluorescent sensors. However, the PET mechanism is not consistent with all data based on boronic acid sensors. Recently, Sun *et al.* proposed internal conversion mechanisms supported by three aspects. First, the receptors and its complexes with fructose are solvent-inserted without B–N interaction. Second, these sensors were also verified to not be aggregated. Third, there was no fluorescence response upon binding fructose while the $-\text{B}(\text{OH})_2$ was converted to the $-\text{B}(\text{OMe})_2$ groups in pure methanol.⁵⁵

Similarly, anthracene was used as the fluorescent unit of sensor **8**, but its selectivity was reversed because of bearing multiple boronic acid groups. Based on the above studies, Eggert *et al.* fabricated the sensor **9** that has a better selectivity for D-glucose, compared to fructose and mannose, and its stable complex structure was confirmed by ^1H and ^{13}C NMR data.⁵⁶ However, this was a part of the story. Diboronic acid sensors research was expanded by other groups.⁵⁷ Those studies give us a new insight: the inherent selectivity of boronic acid sensors to specific carbohydrates can be controlled by molecular design to form diboronic acid, which has better fluorescence selectivity through comfortable spatial position between the two boronic acids. Later, Mulla *et al.* took advantage of this feature and fabricated the sensor **10** containing a redox-active tetrathiafulvalene (TTF) unit and two boronic acid groups to selectively recognize carbohydrates.⁵⁸

Recently, Wang *et al.* reported a sandwich boronate affinity sorbent assay (SBASA) for glucose detection. Sensor **11** was synthesized with anthracene group as a fluorescent monomer.⁵⁹ This method has a higher selectivity, a wider linear range (0.003 to 3.0 mmol L⁻¹) and a lower detection limit (0.8 $\mu\text{mol L}^{-1}$). Moreover, it was successfully applied to glucose detection in human serum samples.

With the further improvement of technology, the selectivity of diboronic acid to glucose has been applied to the study of living animals. Takeuchi *et al.* utilized the anthracene boronic acid sensor **12** reported by Shinkai *et al.*⁶⁰ to fabricate injectable-sized fluorescent beads with uniformity and high throughput *via* polymerization. Those fluorescent beads were applied *in vivo*

successfully by implanting fluorescent beads into the ear skin of mice for continuous glucose monitoring. As a result, it was found that the fluorescence intensity successfully tracked the fluctuation in blood glucose concentration from 0 mg dL⁻¹ to 1000 mg dL⁻¹.⁶¹ Subsequently, Takeuchi *et al.* went on further investigation by improving the polymerization technique.⁶² Hydrogel fibers were fabricated, which could stay in mice for up to 140 days. When implanted, they can control and quantify the amount of fluorescence. Moreover, they are easily removed from the body and have better applicability.

2.2.2. Pyrene boronic acid sensors for D-glucose (Table 2).

Pyrene belongs to the fused aromatic ring compounds, having highest fluorescence quantum yields among benzene, naphthalene and anthracene.⁴⁸ And it is often used in the basic theory study in the field of fluorescent sensors. A basic sensor should have three essential components: acceptor units, linker units and fluorophore units.⁶³ Based on this principle and the fluorescence resonance energy transfer (FRET) mechanism, James *et al.* fabricated a new boronic acid sensor **13**. FRET is a nonradiative energy transition phenomenon. When the fluorescent substance is excited, if the energy difference between the ground state of the donor and the vibration energy of the first excited state is equivalent to that of the acceptor or the emission spectrum of the donor is effectively overlapped with the excitation spectrum of the acceptor, the donor will effectively generate the oscillating dipole, resonate with the dipole of the proximal acceptor and transfer the energy of the donor fluorophore to the acceptor fluorophore, resulting in a change in the fluorescence intensity of the system.⁶⁴

As mentioned in the previous part, glucose selectivity can be achieved *via* exquisitely fabricating receptors with multiple boronic acid groups. Such a modular approach to saccharide recognition has been pioneered by James,⁶⁵ Wang,⁶⁶ Singaram,⁶⁷ to name but just a few. The boronic acid sensor **13** contains two PBA groups for selectivity, two different fluorophores units and a hexamethylene unit as a linker.⁶³ They found that hexamethylene was the best linker to obtain D-glucose selectivity. The emission wavelength of phenanthrene **15** (donor) was 369 nm and the excitation wavelength of pyrene **14** (acceptor) was 342 nm. They were overlapped. The conjugate of sensor **13** and the D-glucose was irradiated with the excitation wavelength of phenanthrene (299 nm), and its emission wavelength was further as the excitation wavelength of pyrene. Finally, the fluorescence intensity increased 3.9 times at 397 nm. At 299 nm and 342 nm, the fluorescence enhancement of D-fructose was 1.9 fold and 3.2 fold, respectively. D-glucose complex was a rigid

Table 2 Key information of a pyrene boronic acid sensors for D-glucose

Sensor	Structure	Spectroscopic properties (λ_{ex} ; λ_{em})	C (LOD; range)	Functions and applications
13 ⁶³		299, 342 nm; 417, 460 nm	—; —	Diboronic acid, the binding of D-glucose is stronger than that of other saccharide, K ($142 \pm 12 \text{ L mol}^{-1}$), ↑3-fold; serving as selective glucose sensor, offer FRET mechanism
14 ⁶³		342 nm; 397 nm	—; —	D-Glucose: K ($44 \pm 3 \text{ L mol}^{-1}$), ↑4.5-fold; poor selectivity for glucose
15 ⁶³		299 nm; 369 nm	—; —	D-Glucose: K ($30 \pm 7 \text{ L mol}^{-1}$), ↑1.5-fold; poor selectivity for glucose
16 ¹²		328 nm; 510 nm	0.1 mmol L ⁻¹ ; 0–10 mmol L ⁻¹	D-Glucose: high binding constant, K (1378 L mol^{-1}), ↑3.9-fold; knocked out the interference of D-fructose by PBA and clearly recognize D-glucose

1 : 1 cyclic, while the D-fructose complex was a flexible 2 : 1 acyclic. As shown in the results, the energy transfer from phenanthrene to pyrene in D-glucose complex is more effective than D-fructose complex. Thus D-glucose is responded by sensor 13. This study showed that two points should be taken into account while fabricating fluorescent sensors employing FRET mechanism as a method to enhance sensitivity and selectivity. First, energy transfer in donors and acceptors should have corresponding fluorescence relationships. Second, it is critical in this sensor that the two boronic acids groups have a comfortable spatial position. As such, there are some strict requirements in the use of the FRET mechanism, but it does offer another novel method to fabricate fluorescent sensors. Subsequently, FRET mechanism is widely used in boronic acid-based sensor development.²³

Due to the complex process of improving glucose selectivity by synthesizing diboronic acid groups or multiple boronic acid groups, Huang *et al.* had been exploring novel sensing regimes to improve the inherent selectivity of simpler monoboronic acid sensor 16, as depicted in Fig. 2.¹² It is generally accepted that binding affinity of the boronic acid with fructose is higher than that with glucose. The specific recognition of glucose can be explained by the stoichiometric point of glucose and fructose binding to boronic acid. In the presence of D-fructose, a boronic acid derivative was produced to form an amorphous 1 : 1 conjugates. Highly ordered 2 : 1 fluorescent conjugates were obtained in the presence of D-glucose. This sensor system utilized the selective sensing mechanism both of the interaction of boronic acid with diols and aggregation induced by pyridinium cation-π interactions. The binding constants of PBA with D-fructose and D-glucose were 4365 and 110, respectively, while the binding constant of the sensor 16 with fructose and D-glucose were 353 and 1378, respectively. Huang *et al.* used this kind of property and knocked out the interference of D-fructose

by PBA strongly selective binding to D-fructose in the case of D-glucose and D-fructose mixed solution. Under this treatment, the sensor 16 can more clearly recognize D-glucose.

2.2.3. Heterocyclic boronic acid sensors for D-glucose (Table 3). Due to a traumatic operation of the blood will make some patients have tensional and promote blood glucose, the test results can't correctly reflect the patients' true blood glucose levels. If chemosensors can be used for continuous, non-invasive study of changes in blood glucose levels, it will greatly facilitate the clinical treatment of diabetes and related scientific research. Badugu *et al.* fabricated a water-soluble sensors 17 for non-invasive and continuous glucose detection based on the interaction between the quaternary nitrogen of the 6-methoxyquinolinium nucleus and the boronic acid group. When they are fixed on contact lenses, it is possible to use for the detection of glucose concentration in intraocular liquids.⁶⁸ Due to changes in the process of ICT, these sensors have good fluorescence intensity and suitable spectral properties, which can be excited by inexpensive lasers. In the PET mechanism, the fluorophore and the acceptor are generally joined together by

Fig. 2 Cartoon illustrating the knock-out effect of an excess of PBA.¹²

Table 3 Key information of heterocyclic boronic acid sensors for D-glucose

Sensor	Structure	Spectroscopic properties (λ_{ex} ; λ_{em})	C (LOD; range)	Functions and applications
17 ⁶⁸		299, 342 nm; 417, 460 nm	—; 0–40 mmol L ^{−1}	D-Glucose: ↑4.5-fold; used in the contact lens and sensitive to the very low concentrations of tear glucose
21 ¹³		328 nm; 510 nm	—; 0–5 mmol L ^{−1}	D-Glucose: ↓0.79-fold; the selectivity of glucose binding is modulated by the distance, serving as an “on-off” fluorescence sensor for selective glucose detection

a linker, as the majority of the anthracene boronic acid sensors mentioned above. But an important feature of ICT mechanism is that the fluorophore is directly linked to the acceptor without the part of the linker. Push electrons (electron donors) and electron withdrawing groups (electron acceptors) are connected by the fluorophores of ICT fluorescent sensor to form a strong push–pull electron system, and the push electrons or electron withdrawing groups themselves act as recognition groups or a part of recognition groups. Normally, there is a certain conjugation between the acceptor and the fluorophore, and the whole molecule is a large π system, and electronic groups or electron withdrawing groups can be used for acceptors.

Based on the encouraging research results of Badugu and co-workers, Bruen *et al.* conducted an in-depth study of the affordable, continuous and minimally invasive glucose monitoring system.⁶⁹ The negatively-charged BA groups are capable of interacting with the positively-charged N present in the structure, resulting in fluorescence quenching. In contrast, indirect sensing using BA species has also been explored, such as the selection of fluorescein as fluorophore for pairing with BA species. Due to the electrostatic interaction of fluorescein and 17c, the fluorescence of the fluorescein is quenched. However, with the addition of glucose, the 17c preferentially binds to the glucose, and the fluorescence intensity is restored by releasing the fluorescein.

Brothers *et al.* reported the first O-BODIPY-glucose conjugate, which connected glucose directly to the

dipyrrometheneboron difluoride (BODIPY) dye core by forming two B–O–C bonds, and the boronic acid recognition function and the fluorescence properties of BODIPY were combined into an entity.⁷⁰ The reaction of Cl-BODIPY with glucose in acetonitrile formed a 1:1 α -glucofuranose BODIPY complex 18, a 1:2 α -glucofuranose BODIPY complex 19 and 1:2 α -glucoseptanose BODIPY complex 20. To our knowledge, compound 20 is a novel example of unnatural septanose form of glucose. These fluorescent and hydrolytically stable conjugates open a new paradigm for carbohydrates labeling, sensing, and visualization by connecting strong fluorophores directly to carbohydrates rather than by long-range binding.

Recently, Zhai *et al.* reported the synthesis of a new bisboronic acid sensor using copper catalysed azide–alkyne cycloaddition (CuAAC) reactions and fabricated a new glucose-selective fluorescent sensor 21.¹³ Interestingly, isothermal titration calorimetry (ITC) experiments showed that sensor has higher binding affinity toward glucose than fructose when two linkers with BPA were in the *ortho*-position. It manifested that the selectivity of glucose binding is modulated by the distance between the two boronic acid groups. Based on this principle, they fabricated sensor 21 subsequently. Excitingly, its fluorescent intensity shows compliance with ITC experimental prediction.

In general, diol sensors are identified based on fluorophore-appended boronic acids, and their applications are often limited due to the lack of discrimination and one-dimensional response. However, Axthelm *et al.* designed a strategy that could compensate for this defect.⁷¹ The combination of fluorinated boronic acid-appended pyridinium salts **22** with ¹⁹F NMR spectroscopy enables the screening of a library of 59 biological analytes including monosaccharides. It is worth noting that these receptors are highly sensitive, selective and water-soluble. In addition, their ¹⁹F-NMR analyte fingerprint is pH-robust making them particularly suitable for medical applications. For example, in a 188 MHz NMR spectrometer, the concentration of glucose detected in synthetic urine samples was down to 1 mmol L⁻¹.

2.2.4. Other types of boronic acid sensors for D-glucose. Liu *et al.* fabricated a novel diboronic acid fluorescent sensor **23** based on tetraphenylethene (TPE), which limits the intramolecular rotation of the TPE aryl rotor by forming oligomers to respond toward glucose.⁵⁷ Interestingly, the sensor **23** was mixed with D-fructose, D-galactose or D-mannose, but the light emission hardly changed. When the glucose concentration reached to 0.2 mmol L⁻¹, two glucose units bound to the TPE, resulting in a decrease in the activity of the adduct formation, thereby releasing the fluorescence. When the concentration of glucose increased to 5 mmol L⁻¹, the adduct further aggregated and the fluorescence intensity reached the maximum. Due to the oligomerization was a reversible equilibrium process, the adduct began to dissolve and the fluorescence intensity began to decrease when the concentration was further increased.

In another intriguing example, Li *et al.* recently reported a similar glucose fluorescent sensor **24** (TPEA + BAP) with the same response mechanism but a different method to induce aggregation, as depicted in Fig. 3.⁷² Negatively charged

phenylboronic acid-containing polymer (BAP) induced positively charged tetraphenylethylene (TPEA) aggregation by electrostatic interaction, thus aryl rotor intramolecular rotation was limited, and the excited state released fluorescence through the radiation decay. Subsequently, after adding glucose and glucose oxidase, there was the formation of H₂O₂ that would react with PBA and then formed a weak acid phenol, thereby reducing the negatively charge on the BAP, resulting in disaggregation of TPEA. The limited internal rotation was liberated, and radiation decay transferred to non-radiation decay, resulting in fluorescence intensity weakening. Simultaneously, the team found that sensor **24** has small fluorescence changes when added D-fructose, D-galactose, and D-mannose, and then they successfully used sensor **24** to detect glucose in human serum. This is the first fluorescent sensor based on the difference in acidity between PBA and phenol, which brings a new concept for the study of glucose fluorescent sensors.

2.3. Ribose boronic acid sensors (Table 4)

Ribose can be used for the treatment of hepatitis B virus (HBV) and other diseases, the detection of ribose concentration in the body is very important.⁷³ Zhang *et al.* synthesized a set of differently substituted diboronic acid sensor arrays (**25**), which achieved a discrimination of all tested five disaccharides and six monosaccharides by linear discriminant analysis (LDA).⁷⁴ Fructose and ribose are the most selective in the binding selectivity of tested monosaccharides. The occurrence of different selectivity may be ascribed to the rigid and coplanar furanose form containing a pair of adjacent hydroxyl groups, which prefer to combine with boronic acid in order to minimize the angular strain. Moreover, the spatial orientation of the diol moiety largely regulates the combined process. This is the first time the IDA protocol involving diboronic acid sensors, providing new ideas for the development of sensors.

Lopez *et al.* described a new long-wavelength fluorescent sensor **26** containing a tricarbocyanine and boronic acid

Fig. 3 Cartoon illustrating sensor **24** detecting glucose.⁷²

Table 4 Key information of ribose boronic acid sensors

Sensor	Structure	Spectroscopic properties (λ_{ex} ; λ_{em})	C (LOD; range)	Functions and applications
25 ⁷⁴		440 nm; 528 nm	—; 1 $\mu\text{mol L}^{-1}$	Ribose: $K_{\text{ortho}} (213 \pm 15 \text{ L mol}^{-1})$, $K_{\text{meta}} (122 \pm 4 \text{ L mol}^{-1})$, $K_{\text{para}} (93 \pm 4 \text{ L mol}^{-1})$; providing IDA protocol for diboronic acid sensors
26 ⁷⁵		637, 720 nm; 820 nm	300 nmol L^{-1} ; —	Displaying selectivity toward ribose in the pH range of 7.8 to 8.3; well-suited for detecting glycan abundance in cells or tissues

structure.⁷⁵ By adjusting the pH of the medium, this sensor can selectively recognize different kinds of carbohydrates. In one typical example, sensor 26 can selectively recognize ribose and fructose in the pH range of 7.8 to 8.3. Interestingly, this sensor has the longest fluorescent emission reported upon carbohydrates interaction. After excited at 720 nm or 637 nm, it has a maximum at 820 nm. Due to a sensitive signal in aqueous media and avoiding the use of co-solvents, sensor 26 can yield a true fluorescent response. Therefore, this sensor is well-suited for detecting glycan abundance in cells or tissues as well as other bioanalytical applications.

2.4. Sialic acid boronic acid sensors (Table 5)

Cell surface glycoprotein is composed of sugar and protein, such as sialyl Lewis X, sialyl Lewis A, etc. closely correlated with the development of tumor cells. These cell surface carbohydrates are normally regarded as markers of tumor cells.²⁴ Borate compounds can bind to tumor cells and visualize them *via* fluorescence. A sensor (such as anthracene boronic acid sensors) prepared by linking two boronic acid groups with a peptide has highly selective to sialyl Lewis X and can be used to selectively label the surface of human hepatoma cells.⁷⁶ Sialyl Lewis X is a kind of carbohydrates, which is not only considered a tumor cell marker but also as an antigen associated with the malignant behavior of tumor cells.⁷⁷

In early 2002, Wang *et al.* reported the synthesis of an anthracene diboronic acid sensor 27 for sialyl Lewis X detection by an exquisite fabrication between diboronic acid groups.⁷⁸ The sensor 27 has a strong affinity with sialyl Lewis X and is capable of selectively labeling sialyl Lewis X of HepG2 cells. Encouraged by the positive result, Wang *et al.* recently fabricated a novel fluorescent sensor 28 which is capable of selectively labeling the HEPG2 and HEP3B cell lines at low concentration (1 $\mu\text{mol L}^{-1}$).⁷⁹

Chu *et al.* developed boronolectin with high affinity and selectivity to recognize sialyl Lewis X, and fabricated sensor 29 by conjugated boronolectin with known fluorescent group BODIPY. In a further study, sensor 29 was successfully applied

to fluorescence imaging of implanted tumor in mice.²⁵ This work indicates that boronolectin can be used for selective imaging tumor *in vivo*.

Wang *et al.* synthesized four anthracene-based fluorescent diboronic acid sensors (30a-d) and examined the selectivity of different length linkers for sialyl Lewis.⁸⁰ It was found that the fluorescence of 30a increased after binding to sialyl Lewis Y. The result indicates that 30a has a high sensitivity and selectivity for sialyl Lewis Y. Although all the diboronic acids 30a-d have very similar molecular structures, the different length linkers may affect the difference in the relative positions of the boronic acid groups, thereby causing different selectivity. Subsequently, Wang and co-worker evaluated the ability of 30a to selectively label sialyl Lewis Y-expressing cells and found that sensor 30a selectively stained HEP3B cells. To date, there are no sensitive and selective boronic acid-based sensors for sialyl Lewis Y, therefore sensor 30a is a very valuable research tool and potential diagnostic agent.

Chang *et al.* synthesized three potential diboronic acid fluorescent sensors 31-33 to detect sialyl Lewis X, which bind to sialyl Lewis X antigens by PET mechanism.²⁴ Wherein the sensor 33 exhibits the strongest fluorescence enhancement when combined with sialyl Lewis X. Moreover, it was confirmed non-toxic to the cells and well selective to detect sialyl Lewis X. This sensor holds great potential for the diagnosis of tumor cells.

Sialic acids are unusual carbohydrates that are widely expressed at the termini of glycan chains on the cell surface. In particular, compared to normal cells, it has a much higher expression level on the cancer cells surface.^{81,82} Zhang *et al.* reported a novel method to analyze sialic acids on cancer cells surface *via* inductively coupled plasma mass spectrometry (ICP-MS).⁴¹ Under physiological conditions (pH 7.4), biotinylated 3-aminophenylboronic acid (biotin-APBA) 34 selectively recognizes sialic acids. Based on this property, gold nanoparticles (AuNPs) can significantly enhance the biotin-APBA signal in ICP-MS when AuNP are used as labeled elements biotin-APBA, as depicted in Fig. 4. The result demonstrated that the

Table 5 Key information of sialic acid boronic acid sensors

Sensor	Structure	Spectroscopic properties (λ_{ex} ; λ_{em})	C (LOD; range)	Functions and applications
27 ⁷⁸		370 nm; 426 nm	—; 60 $\mu\text{mol L}^{-1}$	Fluorescence intensity enhancement (nearly 40%); binding with sialyl Lewis X, labeling sialyl Lewis X of HepG2 cells
28 ⁷⁹		367 nm; 415 nm	—; 60 $\mu\text{mol L}^{-1}$	Fluorescence intensity↑; binding with sialyl Lewis X, staining HepG2 and HEP3B liver carcinoma cells
29 ²⁵		651 nm; 660 nm	—; —	The intensity of tumor (95 ± 12); binding with sialyl Lewis X, imaging of implanted tumor in mice
30 ⁸⁰		375 nm; 424 nm 30a: n=1 30b: n=2 30c: n=3 30d: n=4	—; 60 $\mu\text{mol L}^{-1}$	Fluorescence intensity enhancement (over 70%); 30a and 30d recognize sialyl Lewis Y with selectivity over other Lewis sugars
31 ²⁴		400 nm; 617 nm	—; 0.1 to 20 $\mu\text{mol L}^{-1}$	94% yield, \uparrow 2-fold ($1 \mu\text{mol L}^{-1}$); binding with sialyl Lewis X, showed close integration with hepatocellular carcinoma cell-line HepG2 and with colon cancer cell-line Colo 205, and with Cos-7
32 ²⁴		400 nm; 614 nm	—; 0.1 to 20 $\mu\text{mol L}^{-1}$	89% yield, \uparrow 2-fold ($1 \mu\text{mol L}^{-1}$); binding with sialyl Lewis X, showed close integration with hepatoma B cell-line PLC/PRF/5, with HepG2
33 ²⁴		400 nm; 607 nm	—; 0.1 to 20 $\mu\text{mol L}^{-1}$	82% yield, \uparrow 3-fold ($0.10 \mu\text{mol L}^{-1}$); binding with sialyl Lewis X, showed specific integration with PLC/PRF/5 and with HepG2

proposed method is highly selective to tumor cells. HepG2 cells and MCF-7 cells were used as two tumor models to evaluate the expression level of sialic acid on the cancer cells surface. The mean numbers of sialic acid expression on MCF-7 cells and HepG2 cells were 7.0×10^9 and 5.4×10^9 , respectively. For systematic extension of the research, the numbers of HepG2 and MCF-7 cells were 120 and 64, respectively under the limits of detection. The relative standard deviations were 9.6% and 8.9%, respectively. And the linear ranges for HepG2 cell and MCF-7 cell were 300–1000 and 170–11 000, respectively. This method can be applied to analyze sialic acid on the tumor cells surface, which is favorable to diagnose cancer according to tumor markers.⁸³

2.5. Glucosamine boronic acid sensors

Although pharmacokinetics and pharmacodynamics of glucosamine are unclear, glucosamine is one of the most popular non-prescription nutritional products on the market that is used to treat osteoarthritis. However, reports related glucosamine on the treatment of diseases are various, such as rheumatoid arthritis, gastric ulcer and hepatitis.⁸⁴ The concentration of glucosamine in normal living cells is between 1 and 2 mmol L⁻¹, but it can reach 10 mmol L⁻¹ if oral administration. High concentrations of glucosamine or its derivatives can inhibit certain tumor cells.⁸⁵ Those findings are favorable in developing new drugs for the treatment of cancer, thus the detection of glucosamine is particularly important. Tam Minh Tran *et al.* reported a novel sensor 35 for glucosamine.⁴² Based on a boronic acid-containing coumarin aldehyde, the sensor 35 has a smaller binding chamber. Due to form a boronic ester and an iminium ion, it exhibits an excellent selectivity for glucosamine. The aldehyde group of the sensor 35 can be reversibly bound to the primary amine to form an ammonium ion, and the ammonium ion enhances the ICT of the coumarin, resulting in a large red shift of the excitation spectrum. When added glucosamine at therapeutic concentration and excited at 488 nm, sensor emission increased and moved from 520 nm to 568 nm. The sensor has a higher fluorescence intensity and binding affinity towards glucosamine than other similar biomolecules. Compared to simple amino acids, the binding constant ($K_a = 4100$ L mol⁻¹) was nearly two orders of magnitude higher. The study offered a new concept for the fabrication

of a highly selective open optical sensor that selectively detects multifunctional biomolecules.

2.6. α -hydroxy carboxylate boronic acid sensors

Lactate is a biologically important α -hydroxy carboxylate formed by the red blood cells, and its abnormally high content (>6.5 mM) is associated with sepsis, trauma and other severe diseases. Therefore, monitoring lactate content is an important significance for intensive care unit diagnosis and prevention of diseases. Hansen *et al.* reported that BODIPY-based boronic acid pinacolate derivatives sensors **36a** and **36b** act as high lactate selectivity detectors at physiological pH (7.4).⁴³ Interestingly, some biologically important monosaccharides (D-glucose, D-fructose, and D-mannose) were found to have no response to sensors **36a** and **36b**. The potentially interfering substances (L-malate, vitamin C) are often overlooked because their concentrations are constant and low in the body. Sensors **36a** and **36b** have absorption maxima at 612 nm and 613 nm respectively, and their respective absorption spectra are the same as their excitation spectra. As the DL-lactate concentration is increased, sensors **36a** and **36b** exhibit a significant increase in excitation and emission intensity. This phenomenon may be ascribed to the fact that the electrons are less likely to be accepted by the arylboronate unit, resulting in the oxidative quenching of the BODIPY core upon arylboronate formation decreasing.

Fig. 4 Cartoon illustrating sensor 34 combining with AuNPs.⁴¹

the *ee* of the analytes. In a further study, they combined sensor **37** with an aldehyde-functionalised PBI sensor **39** for sensing of L-DOPA.⁸⁷ As a result, owing to aggregation made the boronic acid and aldehyde groups form two dynamic covalent bonds, the two sensor components showed to be efficient binding to L-DOPA.

2.7. ATP boronic acid sensors

Adenosine triphosphate (ATP) mainly provides energy for cells and plays an important role in the activation of neuronal transmission,⁸⁸ ion channel.⁸⁹ The development of sensors that effectively detect intracellular ATP concentrations is important for the study of human metabolic activity and the monitoring of health levels.⁹⁰ Wang *et al.* reported sensor **40** that has good biocompatibility and membrane permeation can rapidly detect intracellular ATP.⁴⁴ There were three aspects facilitating the formation of ring-opening structure and produce strong fluorescence. First, the boronic acid group combined with the ribose moiety of ATP *via* the reversible covalent bond and forms boronic acid esters. Second, the π - π stack was formed by xanthane and adenine. Third, there was the electrostatic interaction between the amino group and the phosphoric acid ester group. Sensor **40** is effective in response to ATP at a concentration of $10 \mu\text{mol L}^{-1}$, while has no significant fluorescence changes with other biomolecules such as carbohydrates, metal ions, *etc.* The team cultured cells with high levels of ATP by using camptothecin-induced apoptosis, and then sensed them with fluorescent sensor **40**. The results showed that camptothecin-treated cells were clearly stained, while the untreated control group was not stained. The sensor can effectively monitor intracellular ATP levels in real time and provides an effective strategy for the development of such sensors.

Jiang *et al.* reported that gold nanoparticles (AuNPs) coated with 4-mercaptophenylboronic acid (MPBA) can be used for the determination of ATP, as depicted in Fig. 5.⁴⁵ Interestingly, the treated AuNPs are easily polymerized to form a boroxine ring, and its color changes from red to blue. However, in the presence of ATP, a stable borate ester is formed by the boronic acid group of the MPBA preferentially binding the 2,3-hydroxyl group of ATP. At the same time, the polymer dissolves and its color is reversed. In addition, AuNPs-based colorimetric assays successfully detected ATP levels in human breast cancer and in samples treated with antineoplastic drugs. Due to their low cost, easy preparation and the ability to perform bare eyes observation, colorimetric assays offer a potential new strategy for the early diagnosis of cancer.

2.8. Amyloid- β plaques boronic acid sensors

Amyloid- β (A β) plaques are mainly composed of the amyloid- β peptide, which is a key pathological feature of AD.⁹¹ Thus, the detection of A β plaques can be used to monitor the potential for AD progression *in vitro* and *in vivo*.⁹² Recently, the interest in the research of the A β plaque dye has increased, such as Thioflavin T,⁹³ DAPI,⁹⁴ Congo red⁹⁵ and so on. Jung *et al.* found that boronic acid has a good selectivity to A β aggregation and fabricated a boronic acid fluorescent sensor **41c**, which significantly increased the fluorescence intensity in response to A β aggregation (64.37 fold, $F_{A\beta}/F_0$), and the wavelength had a blue shift (105 nm).⁴⁶ They found that boronic acid as a functional group improved the binding affinity with the A β aggregates (K_D value = $0.79 \pm 0.05 \mu\text{mol L}^{-1}$ for **41c**) and confirmed that **41c** selectively stained A β plaques in brain slices of APP/PS1 mice. Using mice (normal and APP/PS1) for fluorescence imaging *in vitro* also showed that **41c** is able to penetrate the blood-brain barrier (BBB) and stains the A β -plaque in the brain. From these results, it showed that **41c** will be useful as a fluorescent sensor in AD-related preclinical studies and provides valuable information for the development of A β -plaque sensors.

Fig. 5 Cartoon illustration of ATP detection via the AuNPs-based colorimetric assay.⁴⁵

3. Catecholamines boronic acid sensors

Catecholamines are benzene derivatives with two neighboring (*ortho*-) hydroxyl groups, including adrenaline, norepinephrine and dopamine and their derivatives.⁹⁶ Adrenaline and norepinephrine are not only hormones secreted by the adrenal medulla, but also the neurotransmitters of the norepinephrine fibers in the central nervous system and the sympathetic nervous system. Adrenaline has low content in the central nervous system, while norepinephrine is widely present in the central nervous system and its content is more abundant. Dopamine is present in the vertebral body as a nerve medium. Catecholamines that contain a strong biological activity of endogenous substances in the brain are important adrenergic receptor agonists and play an important role in various nerve signal transmissions. The content of catecholamines in the organism is closely related to the physiological and pathological phenomena of the human body. Catecholamines not only regulate the metabolism in the body, but also affect the kidney, cardiovascular system, nervous system, endocrine system and other normal physiological activities.⁹⁷ The detection of catecholamines in the human body contributes to the diagnosis of renal insufficiency, thyroid dysfunction, diabetes mellitus, congestive heart failure and other diseases, and some tumor cells can lead to metabolic abnormalities of catecholamines in the body, such as some pheochromocytoma, neuroblastoma, paraganglioma.

In a further study of catecholamines, the analytical methods are increasingly diversified. It is important to choose a high selectivity and sensitivity method for catecholamines. Up until now, the main analytical methods are based on high-performance liquid chromatography (HPLC). It is less application *via* combining capillary electrophoresis with fluorescence spectrophotometry or combining electrochemical analysis with liquid chromatography as analytical methods.⁹⁸ Catecholamines are chemically characterized by a dihydroxybenzene nucleus and a side chain with amino groups. In the biological sample, the content of catecholamines is very low. Furthermore, catecholamines have extremely poor stability and are easily oxidized. In addition, it is difficult to accurately determine the concentration of catecholamines in the biological sample by adding various endogenous chemical disruptors. High selectivity and sensitivity in the determination of catecholamines in biological samples such as the precise determination of serum norepinephrine or adrenaline are currently required to achieve the clinical goal, thus the development of a simple operation,

Fig. 6 Catecholamine detection diagram.²³

cheap and highly sensitive detection methods is imperative. In recent years, the use of fluorescent methods to detect catecholamines is various, wherein boronic acid fluorescent sensors have been widely concerned.^{99,100} Aromatic *cis*-diols or catechol derivatives interact with boronic acid and form reversible cyclic esters. In one typical example, Chaicham *et al.* reported a FRET-based detection system contained two different fluorescent sensors and an appropriate catecholamine acting as a guest linker, as depicted in Fig. 6. Catecholamine can interact with boronic acid and aldehyde, inducing the FRET mechanism to recognize the effectively structural similarity of catecholamines.²³

In another intriguing example, Jun *et al.* fabricated a fluorescent sensor **42** which is used to detect catecholamines, such as dopamine, dopa, and 3,4-dihydroxyphenylacetic acid (DOPAC).¹⁰¹ They found that DOPAC shows the largest association constant with sensor **42** and displays fluorescence quenching effects, while D-fructose, D-glucose, and phenylalanine have no remarkable fluorescence change. In addition, they carefully explained the unique intermolecular excimer formation and fluorescence quenching effects with DOPAC and catechols based on the theoretical calculations. Ptak *et al.* investigated the interaction of PBA with noradrenaline, dopamine, L-DOPA, DOPA-P and catechol *via* potentiometry and NMR spectroscopy, respectively. For comparison, they fabricated sensor **43** and did the same test. They found that PBA has a high affinity to noradrenaline, while sensor **43** shows promising ability to bind dopamine.¹⁰²

Devi *et al.* reported a fluorescent sensor **44** (Au-BSA-APBA) that amino phenyl boronic acid (APBA) conjugated to gold nanocluster (Au-BSA NCs) can apply to detect dopamine,¹⁰³ as depicted in Fig. 7. It took advantage of the combination of lactose and fluorescent sensors resulting in fluorescence quenching, and then dopamine was competitively substituted for lactose resulting fluorescence opening. Compared to glucose and galactose, the lactose molecule has two sets of *cis*-diols groups, showing the highest sensitivity to the Au-BSA-APBA sensor with a detection limit as low as $0.02 \mu\text{mol L}^{-1}$. Due to the sensor has a greater affinity to dopamine, it is easier to form

Fig. 7 Formation of boronic acid conjugated gold nanoclusters (sensor 44).¹⁰³

a stable complex. With the increase of dopamine concentration, lactose was gradually replaced, aggregates ruptured and restored fluorescence with a detection limit of $0.7 \mu\text{mol L}^{-1}$. The team found that the Au-BSA-APBA-lactose conjugate has a specific fluorescence response in the presence of catecholamines such as adrenaline and norepinephrine. They also carried out the effects of interfering analytes including ascorbic acid, uric acid, arginine, histidine, and lysine. It was gratifying that the Au-BSA-APBA-lactose conjugate maintains the specificity and sensitivity to dopamine. Due to the green dual mode turn-off – turn-on nano-sensor and the simple method and low consumption time, the Au-BSA-APBA sensor has a great prospect in the future medical diagnosis and treatment.

4. Reactive species boronic acid sensors

Reactive oxygen species (ROS) are generally referred to a class of substances that contain active oxygen atoms in the body. It mainly includes superoxide anion radical (O_2^-), H_2O_2 , hydroxyl radical (HO^-), hypochlorite (ClO^-), etc. It has been found that peroxides on the regulation of a variety of physiological activities in the cell are indispensable, such as activation of immune cells, immune response, signal transduction, and so on.¹⁰⁴ In addition, ROS are also associated with a number of diseases, such as cancer and Alzheimer's disease, neurodegenerative Parkinson's disease.¹⁰⁵ Therefore, the timely and accurate detection of the concentration of ROS in the body is very valuable in the prevention of disease, diagnosis, and treatment. However, due to the strong reactivity of active oxygen and poor stability, it is extremely important to develop sensors with high selectivity for ROS.

4.1. Hydrogen peroxide boronic acid sensors (Table 6)

As one of the most important biological ROS, H_2O_2 is associated with immune system function and considered as the function of healthy physiological signaling pathways such as cell proliferation, differentiation and migration. Therefore, it is important

to detect H_2O_2 *in vivo*.²¹ The use of fluorescent sensors can be achieved “real-time, visible, quantitative” detection of H_2O_2 in living cells and tissues by means of laser confocal imaging technology. This provides an important approach for demonstrating the role of H_2O_2 in the physiological and pathological process.

4.1.1. Hydrogen peroxide boronic acid sensors directly connected to a fluorophore. Borate or boronic acid groups can quench the fluorescence of fluorophore, thus the sensor itself does not emit fluorescence or emits weak fluorescence. When the borate reacts with H_2O_2 , the sensor can be hydrolyzed to hydroxy and releases fluorescence, as depicted in Fig. 8. There are many compounds that act as fluorophores, such as coumarins, fluoresceins, tricyclics, and merocyanine. Among them, Wang *et al.* reported a water-soluble coumarin-based borate fluorescent sensor 45 with high selectivity to H_2O_2 .²² The sensor excitation wavelength was shorter (332 nm), but it could easily cause damage to the body in the cell or biological imaging. Subsequently, the team had been modified the sensor by introduced triazole to extend its conjugated system and fabricated sensor 46.¹⁰⁶ Interestingly, its excitation wavelength was red shifted 70 nm, and was more suitable for imaging in cells and organisms.

Merocyanine is a heterocyclic compound consisting of an electron withdrawing group and an electron donating group such as a phenol group. When the electron donor group is converted from phenol to phenol salts, ICT mechanism will be significantly improved. Zhan *et al.* reported a boron-based merocyanine sensor 47.¹⁰⁷ When H_2O_2 was present, the borate of sensor 47 was oxidized and hydrolyzed to hydroxyl, and the merocyanine dye was released. The process remarkably changed from colorless ($\lambda_{\text{max}} = 391 \text{ nm}$) to dark red ($\lambda_{\text{max}} = 522 \text{ nm}$). The absorption peak of the merocyanine dye in its acidic form was at 420 nm, while the absorption peak in its alkaline form was at 522 nm. The sensor absorption was linear with the concentration of H_2O_2 in the range of $1.0 \times 10^{-7} \text{ mol L}^{-1}$ to $2.5 \times 10^{-5} \text{ mol L}^{-1}$ with the detection limit of $6.8 \times 10^{-8} \text{ mol L}^{-1}$ under optimum conditions. Subsequently, they found that foreign substances had litter influence on the sensor. In summary, the sensor is successfully applied to detect hydrogen peroxide in rainwater in a buffer solution of pH 9. The unique performance of merocyanine dye makes it possible to be a promising structural scaffold for fabricating sensors.

Lampard *et al.* reported on a series of H_2O_2 boronate fluorescent sensors.¹⁰⁸ 48a and 48b showed fluorescent responses towards H_2O_2 , which may be ascribed to the loss of ICT excited state. Whereas, due to the introduction of ICT excited state, the fluorescence intensity of 48c and 48d decreased in the presence of H_2O_2 . This shows the importance of electron-withdrawing or electron-donating groups in these systems. Based on the above principles, the research team synthesized two H_2O_2 sensors (49 and 50) by using the same steps. Unfortunately, the extended conjugation between boronic acid and dimethylamino in 49 resulted in a fluorescence response similar to that of 48c, whereas the fluorescence of 50, although increased 3.6-fold, could not be applied to detection of H_2O_2 with cell imaging experiments because of poor sensitivity. Nonetheless, these

Table 6 Key information of hydrogen peroxide boronic acid sensors

Sensor	Structure	Spectroscopic properties (λ_{ex} ; λ_{em})	C (LOD; range)	Functions and applications
45 ²²		332 nm; 454 nm	—; 0–100 $\mu\text{mol L}^{-1}$	↑100-fold, high quantum yield and emission in the visible region; useful for the <i>in vitro</i> and <i>in vivo</i> detection of H_2O_2
46 ¹⁰⁶		400 nm; 475 nm	—; 0–250 $\mu\text{mol L}^{-1}$	↑5-fold; good selectivity for H_2O_2 over other ROS
47 ¹⁰⁷		391 nm; 522 nm	6.8×10^{-8} mol L^{-1} ; 1.0 $\times 10^{-7}$ to 2.5 $\times 10^{-5}$ mol L^{-1}	Absorption band reached its maximum over a pH range from 9.0 to 12.0; applied to detect H_2O_2 in rain water
48 ¹⁰⁸		R=N(Me) ₂ 48a =OMe 48b =H 48c =CN 48d 330 nm; 488 nm	3 mmol L^{-1} ; —	Fluorescence intensity ↑, a blue shift; demonstrating the biggest “off-on” response upon reaction with H_2O_2
49 ¹⁰⁸		350 nm; 500 nm	3 mmol L^{-1} ; —	Fluorescence intensity ↓; visualizing a bright signal against a dark background and providing easier analysis of H_2O_2 in a biological sample
50 ¹⁰⁸		350 nm; 455 nm	3 mmol L^{-1} ; 0 to 21 mmol L^{-1}	↑3.6-fold; offering a new strategy to optimize the acidity of the boronic acid groups to enhance the reaction with nucleophilic ROS, whilst maximizing the amount of free sp^2 boron available for the reaction
51 ¹¹⁰		410 nm; 540 nm	—; 200 $\mu\text{mol L}^{-1}$	Emission intensities (F_{540}/F_{475}) ↓ 12-fold; visualize H_2O_2 produced in living cells by ratiometric imaging
52 ²⁰		370 nm; 450, 500 nm	—; 1 mmol L^{-1}	Emission intensities ($F_{\text{green}}/F_{\text{blue}}$) ↑ 17-fold; a marked blue-to-green emission color change in response to H_2O_2 , visualizing H_2O_2 levels in live cells
53 ¹¹¹		365 nm; 525 nm	—; 100 $\mu\text{mol L}^{-1}$	↑20-fold (1 h), two photon imaging of H_2O_2 in live RAW264.7 cells; superior signal to noise and higher spatial resolution compared to other commonly used sensors for ROS, DCF and DHR
54 ¹¹²		400 nm; 650 nm	5 $\mu\text{mol L}^{-1}$; 5×10^{-3} to 100 mmol L^{-1}	16-Fold lower LOD and higher absorption, ↑1.6–1.8-fold (100 mmol L^{-1}); a promising tool for the detection of H_2O_2 in modern medicine and environmental monitoring
55 ¹¹⁴		280 nm	—; 200 $\mu\text{mol L}^{-1}$	↑6-fold, time-gated; capable of detecting changes in H_2O_2 levels in living cells by time-gated emission spectroscopy

Table 6 (Contd.)

Sensor	Structure	Spectroscopic properties ($\lambda_{\text{ex}}; \lambda_{\text{em}}$)	C (LOD; range)	Functions and applications
56 ¹¹⁴		280 nm 545 nm	—; 200 $\mu\text{mol L}^{-1}$	↑ 6-fold, time-gated; capable of detecting changes in H_2O_2 levels in living cells by time-gated emission spectroscopy
57 ¹¹⁵		600 nm; 682, 724 nm	—; 0.2 to 500 mmol L^{-1}	Fluorescence intensity increase (F_{730}/F_{680}), ↑ 0.47-fold; near-infrared imaging and dual-wavelength detection of intracellular H_2O_2

studies are very useful for the development of a series of ICT fluorescent sensors that enhance sensitivity to H_2O_2 .

4.1.2. Hydrogen peroxide boronic acid sensors with broken linker. The researchers connected the borate with the benzylloxycarbonyl group and formed a novel fluorescent sensor. When it encounters H_2O_2 , the borate is converted to a hydroxyl group, causing the cleavage of the benzylloxycarbonyl group and releasing the fluorophore.¹⁰⁹ Based on a similar mechanism, Chang *et al.* fabricated two-photon fluorescent sensor 51¹¹⁰ and 52,²⁰ which have good selectivity for H_2O_2 while imaging H_2O_2 produced in living cells. Two-photon confocal microscopy showed that sensor 51 is able to detect H_2O_2 produced during the cellular immune response. Sensor 52 has good light stability and negligible toxicity, which can observe the distribution of H_2O_2 in cells and tissues.

Lindberg *et al.* reported H_2O_2 sensor 53 using a quinazolone precipitating dye (QPD) connected to a boronic acid-based immovable linker.¹¹¹ QPD is highly photostable and capable of highly localizable fluorescent signals in cells. Synthetic $\text{B}(\text{OH})_2$ -QPD, in the presence of H_2O_2 , yields the *para*-benzyl hydroxyl and QPD, causing a strong fluorescence precipitate. In addition, in the live cell experiments performed, bright fluorescence precipitates were observed, demonstrating a selective response to hydrogen peroxide in a cellular context and enabling the visualization of endogenous hydrogen peroxide in phagosomes.

Jia *et al.* reported a new optical sensing method for detecting H_2O_2 , which introduced phenylboronic acid groups can effectively enhance the response of polydiacetylene vesicles to H_2O_2 .¹¹² Sensor 54 has maximum absorption at 650 nm. It has a good linear relationship in the concentration range from 5×10^{-3} to 100 mmol L^{-1} , and R^2 reaches 0.991. The detection limit is 5 $\mu\text{mol L}^{-1}$.

4.1.3. Other types of hydrogen peroxide boronic acid sensors. Rare earth luminescence sensors have the advantages of large stokes shift and narrow emission range, thus they can reduce the interference of background fluorescence and can be applied to the field of biological detection.¹¹³ However, the molar extinction coefficient of the rare earth compound is relatively low, and the organic ligand needs to be sensitized by energy transfer. Based on this mechanism, Chang *et al.* fabricated two lanthanide-based luminescent sensors 55 and 56.¹¹⁴ The electron-withdrawing boronic acid group on the aromatic ring sensitized the rare earth compound by hydrolyzed to a phenolic hydroxyl group or an amino group in the presence of H_2O_2 , and then the sensors generated fluorescence.

Xu *et al.* reported that borate-functionalized azoborine-methylene dyes 57 showed changes in intracellular H_2O_2 during biological processes, as depicted in Fig. 9.¹¹⁵ This is a designed sensor for near-infrared imaging and dual-wavelength detection. Due to proper cell permeability and long excitation and emission wavelengths, it can avoid autofluorescence from natural cell interference. Moreover, the selectivity of the boronic acid group to react with hydrogen peroxide is higher than other ROS.

Fig. 8 H_2O_2 detection diagram.

4.2. Peroxynitrite boronic acid sensors

Peroxynitrite (ONOO^-) is a highly active oxidant and an effective nitrating agent in physiological and pathological processes, which is formed by nitric oxide (NO) and O_2^- .¹¹⁶ The use of simple and rapid methods for the effective and applicable detection of ONOO^- is increasingly significant. Han *et al.* synthesized a fluorescent borate-based sensor 58 for rapid

Fig. 9 Cartoon illustration of intracellular hydrogen peroxide using sensor 56.¹¹⁵

detection of ONOO^- by a reaction-based indicator displacement assay (RIA).¹¹⁷ The fluorescent sensor KB7 was based on the effective coupling between DCM and the boronic acid moiety. DCM dye had a long excitation and emission wavelength¹¹⁸ and the boronic acid moiety was acted as a saccharide receptor.¹¹⁹ The boronic acid moiety interacted rapidly with lactulose in an aqueous media and formed a fluorescent KB7-lactose complex (sensor 58) that exhibits higher sensitivity and better selectivity for ONOO^- than other tested substances. The introduction of the glycosyl group not only improved the water solubility and biocompatibility of KB7-lactose complex, but also protected the boronic acid from oxidation by other oxidants. This might be ascribed to the mechanism that ONOO^- attacked aromatic carbon adjacent to the boron atom, resulting in partial cracking of the boronic acid. The sensor of KB7 ($20 \mu\text{mol L}^{-1}$)-lactulose ($100 \mu\text{mol L}^{-1}$) can penetrate into viable cells and show strong fluorescence throughout the cytoplasm. Sensor 58 can be used for visualization of ONOO^- . Subsequently, cytotoxicity tests conducted by the team showed non-toxic. Compared to other competitive ROS or nitrogen species (RNS), the sensor exhibits better selectivity for ONOO^- and is more useful for measuring trace amounts of ONOO^- in live cells and real water samples. This study offers insight into the development of displacement test based on fluorescent sensors with enhanced water solubility and biocompatibility.

5. Ions boronic acid sensors (Table 7)

Owing to the simplicity and the low detection limit of the fluorescence, sensors based on the ion-induced changes in fluorescence have attracted numerous researchers devoting their time and energies to the investigation. Recently, an abundance of boronic acid sensors is fabricated to detect all kinds of ionic compounds, including fluoride sensors,¹⁷ copper ions,^{120,121} mercury ion,¹²² etc.

5.1. Fluoride ion boronic acid sensors

Low concentrations of fluoride anions have been shown to be effective in preventing dental caries, and their levels in water are above 4 ppm, which can seriously affect human health, such as fluorosis. It is becoming extremely important to monitor the concentration of fluoride in real time by the simple and efficient method.¹²³ Mohammadpour *et al.* reported that carbon nanodots (CDs) can be used as a fluorescence platform for recognition of fluoride ions by the inner filter effect (IFE) of simple aryl boronic acid, and conducted the comprehensive experiments and theoretical studies of water-soluble fluoride sensors.¹⁷ The comparison of the UV spectra of NPBA and PBA has reflected that the acidic power of the NPBA's acid surpassed that of the PBA when adding the fluoride. It indicated a significant effect on the acidic power of the aromatic acid by the resonance overlap when the electron withdrawing groups was on the *para*-position of the benzene ring. In this experimental condition, it was determined to achieve maximum fluorescence change when the NPBA concentration was adjusted to 0.5 mmol L^{-1} under buffer conditions (phosphate acetate 0.05 mol L^{-1} , pH 4) and after incubated for 5 minutes. The signal of the CDs/NPBA solution was gradually increasing and then suppressed when the concentration of fluoride ions was continuously increased. Furthermore, fluorescence signal changed with fluoride concentration manifesting a linear range of 0 to 15 mmol L^{-1} , and the LOD value of $1.46 \times 10^{-4} \text{ (L)}$ was still meeting EPA's safety requirements for water. Selective experiments indicated that the boron center of NPBA is highly selective for fluoride and has no significant affinity for chlorides, bromides, acetates, phosphates, and nitrates. Subsequently, DFT calculations indicated that the introduction of electron-withdrawing groups on the benzene ring of NPBA may increase the Lewis acids properties and facilitates to fabricate a more sensitive fluoride sensor.

Sensor 16 was reported by Huang *et al.* for recognizing D-glucose. Interestingly, it can detect fluoride ions in another sensing system. Wu *et al.* reported a sensing system based on sensor 16 capable of directly detecting fluoride ions.¹²⁴ This is a combination of fluoride ions that triggers the aggregation of sensor 16 with catechol in an acidic aqueous solution, resulting in intense fluorescence changes. The fluoride binding constant is higher than 10^3 L mol^{-1} . This may be ascribed to the presence of the catechol increasing the Lewis acidity, thereby enhancing the fluoride affinity of the boronic acid. In addition, the boronate fluoride complex is mixed with bulk water to enhance the apparent fluoride affinity.

Table 7 Key information of ionic compounds boronic acid sensors

Sensor	Structure	Spectroscopic properties (λ_{ex} ; λ_{em})	C (LOD; range)	Functions and applications
59 ¹²⁰		450 nm; 525 nm	—; 0–10 $\mu\text{mol L}^{-1}$	Red-shift, fluorescence intensity ↓ 75%; displaying high selectivity for Cu^{2+} in living cells, 59– Cu^{2+} displayed fluorescence enhancement with fructose, and the system could be described as a fluorescence INHIBIT logic gate
59a ¹²⁰		450 nm; 525 nm	—; —	No fluorescence intensity changes; suggesting the importance of the boronic acid moiety in 59 for the binding of Cu^{2+}
59b ¹²⁰		450 nm; 525 nm	—; —	No fluorescence intensity changes; suggesting the imine group plays a role in the coordination of Cu^{2+}
60 ¹²¹		270 nm; 435 nm	—; 5 $\times 10^{-3}$ mol L^{-1}	Huge chemical shift, colourimetric and “turn on” fluorescence sensor of F^- ; distinct visual color changes (colorless to yellow), a colorimetric sensor for Cu^{2+} in aqueous medium; acting as colorimetric sensor for Cu^{2+} and colorimetric as well as fluorimetric sensor for F^- among the studied ions
61 ¹²²		510 nm; 580 nm	—; 3 $\times 10^{-3}$ to 1.5 mol L^{-1}	The colorimetric change, fluorescence intensity ↑; “Off-On”-type fluorescent and colorimetric changes for Hg^{2+}
62 ¹²²		510 nm; 580 nm	—; 3 $\times 10^{-3}$ to 0.6 mol L^{-1}	The colorimetric change, ↑9-fold; “Off-On”-type fluorescent and colorimetric changes for Hg^{2+}
63 ¹²⁶	—	<400 nm; 520, 690 nm	8 nmol L^{-1} ; 0.01 to 5 $\mu\text{mol L}^{-1}$	Fluorescence intensity ↓, colorimetric sensor, changed from blue to red; meeting the requirement of the WHO standard for the detection of the maximum allowable level of Hg^{2+} in drinking water
64 ¹²⁹		319 nm; 540 nm	645 ppm; 500 $\mu\text{mol L}^{-1}$	Blue shift, color change from yellow to colorless, fluorescence quenching; selective fluorescent sensor toward CN^- in the presence of most competing anions
65 ¹³²	—	490 nm; 540 nm	0.28 $\mu\text{mol L}^{-1}$; 1.39 to 260 $\mu\text{mol L}^{-1}$	Fluorescence intensity ↓; detecting Cr(vi)

5.2. Copper ion boronic acid sensors

Copper ions (Cu^{2+}) play a key role in the catalysis of cytochrome C oxidase, tyrosinase, *etc.* And excessive copper ions are highly toxic to organisms and can induce neurodegenerative diseases.¹²⁵ Based on these biological implications, fluorescent

sensors for Cu^{2+} have been extensively explored. Li *et al.* reported three fluorescent sensors (59, 59a and 59b). Wherein borate fluorescent sensor 59 showing high selectivity for Cu^{2+} in living cells, which uses naphthalimide as a mother nucleus and boronic acid group as a binding site.¹²⁰ This is few examples of boronic acid-based fluorescent chemosensors for Cu^{2+} . The

sensor **59** has a maximum absorbance at 450 nm. With the increase of Cu^{2+} concentration (0–300 $\mu\text{mol L}^{-1}$), significant enhancement of absorption can be observed, and red shift to 465 nm occurs at the absorption maximum. Interestingly, the addition of Cu^{2+} significantly decreased the fluorescence intensity by 75% with a binding constant of $3.39 \times 10^5 \text{ mol L}^{-1}$, while the other ions did not cause significant fluorescence changes. In addition, fructose can increase the fluorescence of the chelates (sensor **59**– Cu^{2+}) after Cu^{2+} induces a significant decrease in sensor **59** fluorescence intensity. Subsequently, they studied the ability of sensor **59** to detect Cu^{2+} in HeLa cells. Confocal microscopy showed that sensor **59** entered the cells and showed strong fluorescence in the absence of external copper ions. On the contrary, it was observed a very weak fluorescence response when 5 equivalents of Cu^{2+} (250 $\mu\text{mol L}^{-1}$) were added, illustrating quenching. These encouraging results have great guiding significance for the development of ion sensor systems.

Maity *et al.* reported on new boronic ester sensor **60** that can be used for the detection of both Cu^{2+} and F^- ions.¹²¹ The addition of F^- results in a change in the absorption spectral distribution, which may be ascribed to the coordination of F atoms on the electron-poor boron atoms, resulting in a small blue shift of the lowest energy absorption band, and excessive F^- induce the deprotonation of the phenolic O–H protons, resulting in a bright yellow color. The addition of Cu^{2+} may result in the charge transfer transition of phenoxide-O to Cu^{2+} in the resulting 2 : 1 complex to form a strong and beautiful yellow color. This sensor is capable of detecting both Cu^{2+} and F^- ions as a very rare example.

5.3. Mercury ion boronic acid sensors

Inorganic mercury is one of the most common toxic metals in nature, and it may cause great damage to the brain, kidneys and endocrine systems.¹⁴ Therefore, the detection of mercury ions and mercury salts is of great significance. Kim *et al.* designed two new rhodamine fluorescent sensors with monoboronic acid and diboronic acid groups, respectively. The perchlorate salts of Hg^{2+} , Ag^+ , Ca^{2+} , Cd^{2+} , Co^{2+} , etc. were detected by both sensor **61** and sensor **62** (3 $\mu\text{mol L}^{-1}$) in $\text{CH}_3\text{CN}\cdot\text{H}_2\text{O}$ (9 : 1) solution, respectively. The excitation and emission wavelengths were 510 nm and 580 nm, respectively, and only the Hg^{2+} shows large fluorescence enhancement.¹²² Fluorescence intensity increasing and colorimetric changes are ascribed to open lactam rings. Hg^{2+} complexation results in the conversion of caprolactam (non-fluorescent) to ring-opening amide (fluorescence), thus a switch type of fluorescent sensor was found. In this process, the boronic acid group and Hg^{2+} are combined into one unit. A library of rhodamine derivatives and other fluorophores can apply to a new switched-mode fluorescent sensor through similar transduction.

Zhou *et al.* have designed a simple and rapid colorimetric sensor **63** for detecting Hg^{2+} that induced AuNP aggregation by MPBA in an aqueous medium.¹²⁶ Hg^{2+} inhibited this aggregation, resulting in a visible color change of the AuNP solution from red to blue, while no significant color change was observed

when other competing metal ions were added. It may be ascribed that the thiol group of MPBA preferentially binds to Hg^{2+} and MPBA loses the ability to induce AuNP aggregation. It has a good linear relationship in the concentration range from 0.01 to 5 $\mu\text{mol L}^{-1}$, and R^2 reaches 0.998. The detection limit is 8 nmol L^{-1} . Interestingly, Kong *et al.* developed a similar method and found Hg^{2+} inhibited AuNP aggregation, which can apply to detect Hg^{2+} in aqueous solutions.¹²⁷

5.4. Other ions boronic acid sensors

The use of cyanide is widespread in chemical and related industries, which eventually accidental releases into the environment. Cyanide can inhibit cytochrome oxidase activity and is considered as one of the most toxic compounds. Normally, oral administration of a small amount of CN^- solution is sufficient to cause death in a few minutes. Consequently, it is important to develop a highly sensitive sensor for CN^- detection.^{16,128} Wang *et al.* fabricated boronic acid sensor **64** with 2-aminophenol and (2-formylphenyl)boronic acid as raw materials.¹²⁹ The sensor has a strong fluorescence efficiency at 540 nm, which may be ascribed to the B–N interaction of the rigid five-membered ring framework. Interestingly, the fluorescence disappeared when added CN^- . While the addition of F^- , Cl^- , Br^- , I^- , NO_3^- , HSO_4^- , H_2PO_4^- , AcO^- and N_3^- did not cause much fluorescence change. The detection limit of the boron-based receptor for CN^- was determined to 645 ppm by fluorescence titration experiments. In the past, most of the CN^- sensors relied on the interaction of hydrogen bonds to improve the selectivity. Furthermore, sensors were interfered by F^- , AcO^- .¹³⁰ Boronic acid sensor **64** removes of those defects, and its own structure is simple and easy to fabricate.

Owing to mining, electroplating, dyes and other industries discharge a large amount of waste water containing Cr, it brings great harm to the environment. The development of sensors capable of efficiently monitoring Cr in real time can undoubtedly control the random discharge of Cr and reduce the pollution of heavy metals to the environment.¹³¹ Tian *et al.* used 3-aminophenylboronic acid as a starting material to prepare nitrogen and boron co-doped carbon dots sensor **65** that has a high quantum yield.¹³² It has a good linear relationship in the concentration range from 1.39 to 260 $\mu\text{mol L}^{-1}$, and R^2 reaches 0.997. The detection limit is 0.28 $\mu\text{mol L}^{-1}$. The synthesized N/B-CD exhibited strong green fluorescence, which is applied to real sample detection. The moreover, the sensor was utilized for the analysis of dopamine in biological samples.

6. Electrochemical boronic acid sensors

Electrochemical sensors detect compounds by converting biological events to an electronic signal through the special combination or catalytic reaction on the electrode surface.^{133,134} The electrochemical biosensor is typically fabricated by modifying the surface of the metal and carbon electrode with special materials, such as polymers, self-assembled monolayers, organic oils, biomaterials (enzymes, antibodies), and so on.¹³⁵

One of the most widely studied electrochemical biosensors is based on ferrocene boronic acid (FcBA).¹³⁶ Due to FcBA containing the unique properties of binding sites (boronic acid moieties) and electrochemically active moieties (Fc residues),¹³⁷ it is normally used for electrochemical sensing of ribose,¹³⁸ glycosylated hemoglobin (HbA1c),¹³⁵ fluoride ion,¹³⁹ etc. The basis of the electrochemical determination of carbohydrates mainly consists of two aspects. First, it is the cyclic borate formed by FcBA residues with 1,2- or 1,3-diols. Second, the redox properties of FcB-carbohydrates adducts are different from those of free FcBA.¹⁴⁰

It is generally accepted that microRNAs (miRNAs) play a key role in cancer diagnosis and prognosis serving as reliable molecular biomarkers. Xia *et al.* used FcBA as a redox marker and fabricated a label-free electrochemical sensor which is sensitive to miRNAs.¹³⁸ The surface of the Au electrode was modified with a single molecular layer of single-stranded deoxyribonucleic acid (DNA). After incubation of the electrodes in the sample solution, FcBA was anchored to the ribose sugar in miRNAs *via* the formation of the boronic acid ester covalent bond. Consequently, miRNAs could be captured by the pre-immobilized DNA sensor and recognized by voltammetric measurement of FcBA. Due to the 1,2-diols function can't be used for DNA, FcBA can selectively recognize miRNAs in the concentration range of 5 nmol L^{-1} to $1 \mu\text{mol L}^{-1}$.

Thakur *et al.* fabricated a new ferrocene-modified boronic acid sensor **66** and found the electrochemical and spectral properties in acetonitrile.¹³⁹ The sensor exhibits large cathodic displacements of the redox potential of Fe (II/III) pairs when combined with fluoride ions ($K = 10^6 \text{ L mol}^{-1}$), whereas it displays a negligible affinity towards other effective competitors, such as Cl^- , Br^- , I^- , AcO^- . It indicated that the sensor has good selectivity for fluoride ion in organic solvents. Consequently, it can induce a strong color change from yellow to deep green associated with aerobic oxidation of the Fc moiety, and the fluorescence emission is quenched drastically. Due to the transformation of boronic esters to anionic borates, there is a strong effect on the redox potential and color adjacent to ferrocene. Therefore, it holds the potential to "naked eye" detection of fluoride ions.

Zhou *et al.* developed a potentiometric method for the detection of sialic acid.¹⁴¹ Glassy carbon (GC) electrodes were modified with poly(anilineboronic acid) (PABA) and electrodeposition of reduced graphene oxide (ERGO). The principle of sialic acid detection is ascribed to the reversible covalent bonds of PABA/ERGO/GC electrode. Boronic acid and diols formed a cyclic ester, as depicted in Fig. 10. Due to the introduction of the graphene layer on the electrode surface, the prepared electrochemical sensor significantly improved the sensitivity of the sensor response. Under the optimum conditions, the detection limit of the sensor is $0.8 \mu\text{mol L}^{-1}$ and the linear range is

Fig. 10 Schematic illustration of modification progress of the GC electrode and the sensing mechanism of sialic acid.¹⁴¹

$2 \mu\text{mol L}^{-1}$ to 1.38 mmol L^{-1} . Furthermore, the electrochemical sensor has the advantages of good stability and high selectivity. It is able to accurately analyze sialic acid in human serum. The use of boronic acid electrochemistry as a new method of sensing carbohydrates and other substances holds the great potential in the practical applications.

7. Smart polymeric materials boronic acid sensors (Table 8)

Incorporation of boronic acid groups into the polymer matrix can significantly enhance the binding. This boronic acid functional polymer dates back to the pioneering work of Wulff *et al.*¹⁴² Smart polymers can convert the variation in external stimuli, such as temperature, pH, or glucose level. Due to the stability, handling and biocompatibility of polymers, scientists tend to consider this smart polymer when fabricating sensors, including Asher *et al.*¹⁴³ Boronic acid functional polymers are extensively used, such as the modification of quantum dots (QDs) with PBA,^{11,144} the use of molecularly imprinted polymers,¹⁴⁵ the construction of multifunctional hybrid nanogels,¹⁰ including the fluorescent beads mentioned above.^{61,62} Those molecular sensors that combined with smart polymers to detect D-glucose are receiving increasing attention.

7.1. Quantum dot boronic acid sensors

With the application of fluorescent sensors to protein labeling in living cells, it is more clearly understood dynamics of intracellular structures, signal transduction and interactions of cells, but more complex environmental requirements are encountered, such as the need for long observation times, masked signals from labeled molecules by cells autofluorescence, and so on.¹⁴⁶ This requires new methods and tools. The size and shape of QDs can be precisely controlled by time, temperature, etc. Their energy levels are quantized with values directly related to the size (hence the name quantum dots).¹⁴⁷ Compared with traditional fluorophores, QDs with a diameter of several nanometers have broader band absorption spectrum and long fluorescence lifetime, which meet the needs of fluorescent sensors.¹⁴⁸

Zhou *et al.* reported that the CdS QDs were immobilized in a microgel containing boronic acid groups and have a good

Table 8 Key information of smart polymeric materials boronic acid sensors

Sensor	Structure	Spectroscopic properties (λ_{ex} ; λ_{em})	C (LOD; range)	Functions and applications
67 ¹⁵⁰	—	620 nm; 736 nm	0.2 $\mu\text{mol L}^{-1}$; 0–400 $\mu\text{mol L}^{-1}$	Fluorescence intensity↓; applied to the detection of dopamine in human serum sample
68 ¹⁵¹	—	—; 653 nm	23.1, 118.7 $\mu\text{mol L}^{-1}$; 0–30 mmol L^{-1}	Fluorescence intensity↑; serving as “turn-on” detection of glucose in blood serum
70 ¹⁶⁰	—	360 nm; 500 nm	2 mg mL^{-1} ; 2 to 75 mg mL^{-1}	Fluorescence intensity↑; easily synthesized and can be stored for a period of long time for the detection based application
72 ¹⁶¹	—	260 nm; 340 nm	0.12 $\mu\text{mol L}^{-1}$; 1–100 mmol L^{-1}	Fluorescence intensity↑; fast and ultrasensitive determination of carbohydrates in biofluids and semi-solid biotissues carbohydrate
73 ¹⁷⁰	—	302 nm; 388 nm	—; 0–200 mmol L^{-1}	Fluorescence intensity↓, higher binding constant of sialic acid compared to other carbohydrates ($K_{\text{pH}7.4} = 12.3$, $K_{\text{pH}6.5} = 12.7$); offering a highly translational approach for clinical diagnosis and therapy of solid tumors
74 ¹⁷¹	—	281 nm; 418 nm	0.167 nmol L^{-1} ; 0–100 nmol L^{-1}	Fluorescence intensity↑; determining the 5hmC content of genomic DNA in tissue samples, serving as a useful diagnostic and prognostic tool for disease

selectivity to glucose.¹⁴⁴ For the expanded research, they modified CdTe/ZnTe/ZnS core–shell (CS) QDs with PBA, and incorporated them into mouse melanoma cells, as depicted in Fig. 11. As a result, they could successfully image mouse melanoma cells.¹¹

Zhang *et al.* reported firstly the method of boron-doped graphene quantum dots (BGQD), which selectively recognize glucose on the surface of BGQD,¹⁴⁹ as depicted in Fig. 12. This may be ascribed to the reaction of two *cis*-diols units in glucose with two boronic acid groups on the surface of BGQD. They produced a structurally rigid BGQD-glucose aggregation that limited intramolecular rotation, blocked nonradiative relaxation channels, and filled the radiation attenuation, resulting in a substantial increase in the strength of PL. Due to the absence of two *cis*-diols units, fructose, galactose or mannose were simply combined with BGQDs containing exposed boronic acid groups, but couldn't be further combined to form an aggregation. They found that the signal intensity increases with increasing glucose concentration in the range of 0.1 to 10 mmol L^{-1} , the detection limit is about 0.06 mmol L^{-1} . This study brought a new scientific understanding of glucose detection.

Due to boronic acids formed stable boronate complexes with vicinal diols, Liu *et al.* functionalized water-soluble sensor 67 (CuInS₂ QDs) with 3-aminophenyl boronic acid by the one-step hydrothermal method.¹⁵⁰ The CuInS₂ QDs were covalently bound to the 3-aminophenyl boronic acid and formed 3-aminophenyl boronic acid functionalized CuInS₂

Fig. 11 Schematic illustration of modification progress of CdTe/ZnTe/ZnS core–shell (CS) QDs with PBA.¹¹

quantum dots (F-CuInS₂-QDs). This sensor contained boronic acid groups, which were capable of reacting with *ortho*-diols to form a five- or six-membered cyclic ester in an aqueous alkaline solution. This combination caused F-CuInS₂-QDs fluorescence quenching. Consequently, the sensor could be applied to detect dopamine based on this property, as depicted in Fig. 13. Under the optimum conditions, the linear range of dopamine detection is 0.5 to 40 mol L^{-1} , and the detection limit is 0.2 mol L^{-1} .

Fig. 12 Schematic illustration of the BGQD.¹⁴⁹Fig. 13 Boronic acid QDs synthesis and dopamine detection diagram.¹⁵⁰

7.2. Smart polymer gels boronic acid sensors

The microgels react with 1,2- or 5,6-*cis*-diols of glucose and form glucose bisboronate complexes, resulting in gel network shrinkage. Based on this nature, Zhou *et al.* prepared a highly selective glucose sensor **68**, which had two boronic acid microgels (GS@(4-VPBA) and GS@pPBAs) with covalently immobilized graphene sheet (GS),¹⁵¹ as depicted in Fig. 14. The monolayer carbon atoms of graphene have a huge electron mobility, can induce the PBA ionization around graphene, making the microbial gel into a negatively charged at physiological pH 7.4. Glucose crosslinked with two boronic acid groups of microgels, causing microgel volume shrinkage and further leading to an increase in photoluminescence of graphene. However, the fructose and borate formed a monodentate complex, causing microgel volume expansion. The team had successfully applied this material to the detection of glucose in serum samples, which may open up new possibilities for the synthesis of potentially selective glucose-reactive microgels.

The hydrogel is a polymer network that can swell and retain aqueous solutions, meeting the need of functional and tunable biomaterials.¹⁵² Cai *et al.* synthesized a glucose-reactive hydrogel **69** that 3-acrylamidophenyl boronic acid copolymerized with ethylaminoethyl methacrylic (p(APBA-b-LAMA)).²⁷ When glucose was added, the insulin release was significantly increased, indicating that glucose was triggered by the molecular exchange process. Subsequently, cytotoxicity analysis *in vitro* showed that the presence of carbohydrates polymers did not adversely affect cell proliferation. Due to the introduction of the carbohydrates moiety, cell compatibility of the carbohydrates-polymer hydrogel with PBA is significantly improved, which makes it potentially useful in the biomedical field. Consequently, the development of intelligent glucose response insulin delivery system in the treatment of diabetes has an important practical application.

The molecularly imprinted polymer (MIP) is selectively detected the target compound by binding the binding cavity. Target compound polymerizes with the crosslinking agent and functional acceptor, and then binding cavity forms by removing the target compound under appropriate conditions, which is similar to target compound on size, shape and surface chemical properties. Owing to the prepared binding cavity is suitable for the target compound, selective recognition can be performed.¹⁵³ Zhao *et al.* developed the biologically significant sensor for glucose, mannose, and galactose through the borate affinity MIP method,¹⁴⁵ as depicted in Fig. 15. They converted glucose into diborate and then implanted it into the micelle by copolymerization with the methacrylate group in the micellar nucleus, followed by washing with different polar solutions to remove the glucose and obtained a binding cavity. The K_a value between MINP (glucose) and glucose is $1.18 \times 10^3 \text{ L mol}^{-1}$, and the K_a value of the other monosaccharides is negligible, which is in good agreement with the expected selective binding of the target compound. Molecular imprinting creates complementary objects that are increasingly popular,¹⁵⁴ and the number of binding sites of per nanoparticle can be controlled by the ratio of surfactant to the target compound. It is completely water-soluble and can be used to precisely position and orient the binding groups on a cross-linked micelle, which distinguishes different carbohydrates.

7.3. Nanosensors

For small molecule sensors, there are some constraints to improving the selectivity by changing their structure, such as increasing the amount of boronic acid groups as recognition sites. Owing to the comfortable spatial position between boronic acids also plays an important role in the selectivity of the sensor, increasing the molecular structure undoubtedly increases the difficulty of synthesis. Thus, designing higher selective sensors requires the assistance of other fields of technology. Nanosensors have the high surface area, strong adsorption capacity and good electrical conductivity, which endows special properties to some small molecule sensors. Nanomaterials are very sensitive to changes in the external environment, such as temperature, light, humidity, *etc.*, which can cause rapid changes in surface or interface ion valence and electron output.¹⁵⁵ Therefore, the small molecule sensors connected to the nanomaterial interact with detection object causing a small change, which is amplified by the nanomaterial, making easily captured by the detector, thereby improving the selectivity and sensitivity of the sensor to a certain extent. Carbon nanometer is an ideal building material. For instance,

Fig. 14 Schematic illustration for the synthesis of GS@poly(4-VPBA) and GS@pPBAs microgels.¹⁵¹

Fig. 15 Schematic illustration the progress of boronic acid-functionalized MIP for glucose.¹⁴⁵

boronic acid modified carbon nanotubes (CNTs) can be prepared by a variety of sensors, one of which is near infrared reflection (NIR) optics glucose sensor for *in vivo* glucose monitoring prepared by combining boronic acid with single-walled CNTs (SWNT).¹⁵⁶ There are transistors composed of CNTs and pyrene boronic acid, which are used to detect D-glucose concentration.¹⁵⁷ The content of D-glucose, D-fructose, and D-mannose in fruit juice can be determined by the glass carbon electrode modified with graphene oxide and 4-amino-phenylboronic acid.¹⁵⁸

7.3.1. Nanosensors for carbohydrates. Tatiana V. Shishkina *et al.* had developed functional gold nanoparticles as sensing elements for electrochemical sensors to analyze neutral materials such as carbohydrates.¹⁵⁹ They bound 4-mercaptophenylboronic acid to the surface of AuNPs through its thiol and introduced MPBA-AuNPs into the polymer matrix to prepare electrochemical sensors to detect neutral carbohydrates. Although carbohydrates are a neutral molecule, the interaction between PBA and carbohydrates leads to the release of protons, altering the proton concentration in the pH sensitive matrix of polyaniline (PANI) and resulting in generating an electric potential. The sensor has the following advantages. First, the sensor can analyze the neutral analyte. Second, it solves the compatibility issues between the ion carrier and the polymer matrix.

Basiruddin *et al.* reported on a fluorescent nanosensor **70** that can be applied to detect glucose.¹⁶⁰ It consists of phenylboronic acid functionalized reduced graphene oxide (rGO PBA) and diol-modified fluorescent sensor. Diol modified fluorescent sensor and rGO PBA form cyclic ester bonds, leading to fluorescence quenching. However, after addition of glucose, glucose replaces the diol-modified fluorescent sensor on the GO and forms a new cyclic boronate **71** with rGO PBA, thereby starting fluorescence. Glucose concentrations in the range of 2 mg mL^{-1} to 75 mg mL^{-1} can be tracked by this fluorescent nanosensor.

Due to their ease of synthesis and long-term storage, nanosensors can be designed as drug delivery drug carriers for the detection of various cancer cells.

Ouyang *et al.* reported an ultra-sensitive solid phase micro-extraction (SPME) sensor **72**. It was fabricated by PBA functionalizing CNTs and successfully applied to direct recognition of carbohydrates in biological fluids and semi-solid biological tissue *in vitro* or *in vivo*.¹⁶¹ First, PBA functionalized CNTs acted as carbohydrates nanoreceptors. Nano-receptors hybridized with acid resisting polyacrylonitrile (PAN) groups in an appropriate ratio and then linked to a pretreated quartz fiber *via* the dip-coating method. In this progress, 3D interconnected architecture was formed, which facilitated the sensor binding to carbohydrates, and its enrichment factor was up to 151. The proposed sensor is able to couple with GC-MS after changing the pH, which is remarkably increasing the sensitivity of carbohydrates recognition, as depicted in Fig. 16. The sensor offered a specific scaffold of the diols unit, in particular, *cis*-diols. Thus carbohydrates that have various 1,3 or 1,2 *cis*-diols units can be easily captured by the scaffolds. Up until now, the

Fig. 16 Schematic illustration of saccharides sensing by means of the PBA-functionalized CNTs.¹⁶¹

sensor was far superior to other sensors that were widely used for bioanalysis, including polydimethylsiloxane (PDMS)^{162,163} and C18,¹⁶⁴ and they were ideally suited for the identification and differentiation of carbohydrates in multi-carbohydrates systems. Compared to most carbohydrates sensors, the sensor has higher sensitivity, wider linear range and excellent qualitative ability in multi-carbohydrates systems. Consequently, this approach holds the unique potential of new avenues for the facile and efficient recognition of carbohydrates.

Based on the principle that boronic acid forms a reversible five- or six-membered cyclic boronic esters with *cis*-1,2- or 1,3-diols, Ramsay *et al.* reported the identification and discrimination of mixtures containing different components of carbohydrates by single molecule analysis.¹⁶⁵ According to the fluctuation of the ion current generated by the binding of the boronic acid-modified engineering protein nanopore to different sugars, this method can determine the binding mode, thereby realizing the differentiation of different carbohydrates. In the disaccharide (D-maltose) and monosaccharide (D-glucose) mixture components, it is easy to discriminate by visually checking the current recording. In the monosaccharide mixed components, the characteristics of D-glucose and D-fructose can be distinguished by dwell-time analysis. Owing to distinguishing multi-component carbohydrates, this single-molecule

analysis method is beneficial to improve the accuracy of blood glucose monitoring and will have a great impact on the design of continuous blood glucose monitoring devices for medical diagnosis. Similarly, Nishino *et al.* reported a supramolecular strategy for carbohydrates detection by single molecule junction.¹⁶⁶ Owing to only glucose forms a single molecule junction composed of 1 : 2 monosaccharide 4MPBA supramolecular complex, this strategy can contribute toward the achievement of minimally invasive glucose sensing.

7.3.2. Nanosensors for glycoproteins. Zhang *et al.* firstly reported a novel fluorescent nanosensor for selective monitoring of glycoproteins.¹⁶⁷ This nanosensor, which regulated the recognition of glycoproteins by controlling pH and temperature, was based on molecularly imprinted spatial structures and borate affinity. The team obtained the glycoprotein template by copolymerizing OVDAC-coated CdTe nanocrystals (NCs) with NIPAAm of the temperature-sensitive element and VPBA of the recognition element, and successfully applied to detection of horseradish peroxidase (HRP) in human urine samples, as depicted in Fig. 17. This study provides a simple and effective fluorescent tool for the diagnosis of clinical glycoproteins.

7.3.3. Nanosensors for sialic acid. Targeting recognition of tumors by nanoparticles is an effective method of improving the efficiency of chemotherapy.¹⁶⁸ The expression of sialoglycans in tumor cells provides a favorable target.⁷⁷ Owing to PBA can selectively recognize sialic acid,¹⁶⁹ Deshayes *et al.* had developed PBA-conjugated micellar nanoparticles 73 combining the maternal complex of anticancer drug oxaliplatin. The micellar nanoparticles can target cancer cells containing overexpression of sialic acid epitopes.¹⁷⁰ After assembly of the PBA, the micelles show high affinity for sialic acid and are confirmed by fluorescence spectroscopy in tumor cells. At pH 6.5, micelles could improve the capacity of recognition and uptake of tumor cells, thereby enhancing the cytotoxicity of drugs on B16F10 murine melanoma cells *in vitro*. The incorporation of PBA complex micelles could effectively reduce the growth rate of melanoma *in situ* and lung metastatic models. Those studies indicated that nanoparticles in combination with PBA can achieve tumor-targeted therapy and provide a method for clinical diagnosis and therapy of solid tumors, as depicted in Fig. 18.

Fig. 17 Schematic illustration of NCs self-assembly and sensing progress.¹⁶⁷

Fig. 18 PBA moieties on the surface of the nanocarriers can identify sialic acid.¹⁷⁰

7.3.4. Nanosensors for DNA. Chen *et al.* developed a spectroscopic method based on the boronic acid functional nanospheres fluorescent sensor 74 to determine the 5-hydroxymethylcytosine (5hmC) content of genomic DNA in tissue samples,¹⁷¹ as depicted in Fig. 19. Firstly, PBAQAPGMA nano-microsphere were prepared by emulsion polymerization. And then T4- β -glucosyl-transferase (β -GT) transferred glucose from uridine diphosphate glucose (UDP-Glu) to 5hmC and glucosylated 5 hmC DNA (G-5 hmC-DNA) was obtained.¹⁷²

Fig. 19 Schematic illustration of the quantification of 5hmC content in genomic DNA using the PBAQAPGMA sensor.¹⁷¹

Finally, the boronic acid groups of the PBAQAPGMA sensor interacted with the glucose moiety of the G-5hmC-DNA and formed a boronic acid ester, enhancing the fluorescence signal. The fluorescence signal of the DNA sample solution was proportional to the content of 5hmC. Furthermore, the PBAQAPGMA sensor could gather G-5hmC-DNA from complex raw materials containing a low content of 5hmC, which facilitated to increase its sensitivity. They found that the fluorescence intensity increased with increasing 5hmC concentration in the range of 0 to 100 nmol L⁻¹, the detection limit was about 0.167 nmol L⁻¹. The sensor displays good detection sensitivity and selectivity and holds great potential to be an effective diagnostic and prognostic tool for the disease in the term of the physiological significance of 5hmC.

8. Conclusions and perspective

Boronic acids have been successively developed as fluorescent sensors for carbohydrates since the phenomenon that boronic acids and 1,2-dihydroxy or 1,3-dihydroxy group can reversibly bind in an aqueous solution was reported in 1959. These sensors are based on different fluorescence mechanisms such as PET, FRET and so on, which can combine with carbohydrates to achieve off-on or on-off fluorescence changes. Owing to the carbohydrates have multiple binding sites, the diboronic acid having a specific structure can significantly increase the affinity and selectivity for certain carbohydrates. The selective recognition of carbohydrates, especially those with physiological and pathological functions, is of great significance for the in-depth study of related diseases. For example, glucose selective fluorescent sensors provide great help for the diagnosis and treatment of diabetes. Fluorescent sensors targeting tumor cell surface-specific sialyl Lewis oligosaccharide lay a foundation for tumor cell imaging and *in vivo* imaging. Early effective diagnosis and screening of cancer have always been the direction of scientists' constant efforts. In this regard, boronic acid fluorescent sensors may provide an effective strategy. In addition, there are many reports on the identification of boronic acid sensors such as catecholamines, various ions, and reactive oxygen species. They are expected to be utilized in several analytical tasks in the future, including on-site diagnosis of disease,¹⁷³ detections of ionic compounds,¹⁴⁻¹⁷ protein modifications,¹⁷⁴ or cancer cells imaging.^{24,77}

In recent years, the design of boronic acid sensors has become more sophisticated, and the more fields involved. As mentioned in the review above, the selectivity can be increased by adding a boronic acid groups to the molecular structure and maintaining a comfortable spatial position, or by connecting a new material such as a quantum dots to increase the fluorescence intensity. Some new material fields endow unique properties to boronic acid sensors. For example, a smart gel that forms a multifunctional hybrid nanogel with boronic acids can respond to the release of insulin regulation by a glucose sensor detecting the blood glucose concentration. Owing to smart gels can remain in patients for long periods of time, hydrogels with highly selective glucose sensors have enormous potential for clinical treatment of diabetes.¹⁷⁵ Simultaneously, some research

has focused on exploiting next-generation functional materials for other uncharted regions, such as PBA-modified QDs,¹⁵⁰ PBA functionalized CNTs,¹⁵⁶ boronic acid functionalized gold nanoparticles as electrochemical sensing elements,¹⁵⁹ etc.

Although there are many fluorescent sensors reported so far, most of the discovery strategies are based on blind screening, and the hit rate is not high. A truly effective borate screening model for a target carbohydrates, especially related models based on computer-aided design, is rarely reported. The main reason is the compatibility of boronic acids in some calculation software, and some parameters combined in aqueous solution are difficult to simulate with calculation software. With the increasing number of boronic acid sensors reported so far, if we can summarize the relevant binding rules and structure-activity relationships, and establish an effective screening model to achieve a “rational design” of boronic acid sensors, it will greatly save development time and cost. Sensors targeting tumor cell surface-specific oligosaccharides have been reported now. However, due to the complexity of the physiological environment in the body and many interference factors, there is still a long way to go before they can be applied to human body. In the future, if breakthroughs can be made in terms of selectivity and fluorescence properties, achieving early diagnosis of diseases, tumor treatment and prognosis will be the gospel of cancer patients and all human beings. From a personal perspective, the research of boronic acid sensors is as hot now as it has ever been. We anticipate that this review will inspire others to explore more practical boronic acid sensors.
