# Nanostructured WO<sub>3</sub>/graphene composites for sensing NO<sub>x</sub> at room temperature

 Parag V. Adhyapak,<sup>a</sup> Amruta D. Bang,<sup>a</sup> Pooja More<sup>b</sup> and N. R. Munirathnam<sup>a</sup>

WO<sub>3</sub> has emerged as an outstanding nanomaterial composite for gas sensing applications. In this paper, we report the synthesis of WO<sub>3</sub> using two different capping agents, namely, oxalic acid and citric acid, along with cetyltrimethyl ammonium bromide (CTAB). The effect of capping agent on the morphology of WO<sub>3</sub> material was investigated and presented. The WO<sub>3</sub> materials were characterized using X-ray diffraction analysis (XRD), field emission transmission electron microscopy (FETEM), field emission scanning electron microscopy (FESEM), particle size distribution (PSD) analysis, and UV-visible spectroscopic analysis. WO<sub>3</sub> synthesized using oxalic acid exhibited orthorhombic phase with crystallite size of 10 nm, while WO<sub>3</sub> obtained using citric acid shows monoclinic phase with crystallite size of 20 nm. WO<sub>3</sub> obtained using both capping agents were used to study their gas sensing characteristics, particularly for NO<sub>x</sub> gas. The cross sensitivity towards interfering gases and organic vapors such as acetone, ethanol, methanol and triethylamine (TEA) was monitored and explained. Furthermore, the composites of WO<sub>3</sub> were prepared with graphene by physical mixing to improve the sensitivity, response and recovery time. The composites were tested for gas sensing at room temperature as well as at 50 °C and 100 °C. The results indicated that the citric acid-assisted WO<sub>3</sub> material exhibits better response towards NO<sub>x</sub> sensing when compared with oxalic acid-assisted WO<sub>3</sub>. Moreover, the sensitivity of the WO<sub>3</sub>/graphene nanocomposite was better than that of the pristine WO<sub>3</sub> material towards NO<sub>x</sub> gas. The WO<sub>3</sub> composite prepared using citric acid as capping agent and graphene exhibits sensing response and recovery time of 29 and 24 s, respectively.

## 1 Introduction

In power stations, the main component of the released exhaust gases is a mixture comprising 90% NO and NO<sub>2</sub> at different ranges of ppm levels. NO<sub>x</sub> has been the cause for calamities such as acid rain, smog and ozone depletion. The Threshold Limit Value (TLV) for NO and NO<sub>2</sub> estimated by environmental monitoring organizations is 3 and 25 ppm, respectively. Looking at these facts, many researchers tried to fabricate gas sensors using different sensing materials such as ZnO, SnO<sub>2</sub>, WO<sub>3</sub>, TiO<sub>2</sub>, and Fe<sub>2</sub>O<sub>3</sub>.<sup>1,2</sup> All these compounds have a non-stoichiometric structure and therefore, electrical conductivity is observed due to the presence of free electrons resulting from oxygen vacancies. When an oxidizing or reducing gas comes in contact with the semiconducting nanocompounds, their resistivity changes accordingly; hence, they can act as a sensor for the gas. Even though the same working mechanism exists for adsorption and desorption in all the above mentioned compounds such as ZnO, SnO<sub>2</sub>, and WO<sub>3</sub>, the operating

temperature and voltage required by WO<sub>3</sub> for gas sensing is lower than that of the other compounds.<sup>3</sup>

The nanostructured<sup>4,5</sup> WO<sub>3</sub> powder with different morphologies have been synthesized by various methods such as hydrothermal method, acidification, atmospheric plasma spray method, solvothermal method, sol spin coating, template-directed wet chemical synthesis, thermal evaporation, and reactive DC magnetron sputtering.<sup>4–8</sup> Meng *et al.* synthesized flower-like WO<sub>3</sub> nanostructure using citric acid as a capping agent, which exhibited sensing response towards ethanol at 250 °C.<sup>9</sup> Su *et al.* also reported WO<sub>3</sub> nanoplates with square morphology using citric as well as tartaric acid.<sup>10</sup> Wang *et al.* synthesized WO<sub>3</sub> nanorods with high crystallinity by hydrothermal method from ammonium meta-tungstate and citric acid. It was also reported that citric acid plays a major role in determining the morphology. With the increase in concentration of citric acid, there was growth observed along [202] and [220] crystallographic directions, resulting in the formation of nanorods.<sup>11</sup> Patil *et al.* synthesized WO<sub>3</sub> nanorods using oxalic acid by the hydrothermal method, and the role of oxalic acid in synthesis was explained.<sup>12</sup> Similarly You *et al.* synthesized oxalic acid-assisted WO<sub>3</sub> nanoparticles, which showed good response to NO<sub>x</sub> at 125 °C.<sup>13</sup>

<sup>b</sup>Savitribai Phule Pune University, Pune, 411007, India

Considering the variations in morphologies yielded by two dicarboxylic acids, namely, citric and oxalic acid, with different experimental conditions, we selected these dicarboxylates for the synthesis of  $\text{WO}_3$ . Furthermore, the as-synthesized  $\text{WO}_3$  was blended with graphene to increase its effective sensitivity. Thus, we achieved maximum sensitivity for  $\text{WO}_3$  with lesser response and recovery time at room temperature for  $\text{NO}_x$  when compared with  $\text{WO}_3$  synthesized with earlier published literature.

## 2 Experimental

All the chemicals used in the experiment are of AR grade.

### 2.1 Synthesis of nanostructured $\text{WO}_3$

Sodium tungstate dihydrate was dissolved in water to form 20 mL 3 mM solution. To this solution, 2 M HCl was added dropwise to form a pale yellow precipitate. The precipitate was centrifuged and dissolved in 1 M citric acid solution. To the above solution, 4.5 mM CTAB was added and the resultant mixture was diluted to 40 mL. The reaction mixture was further transferred to a Teflon-lined stainless steel autoclave and heated at 180 °C for 12 h in an oven. The autoclave was naturally cooled to room temperature. The intermediate products were collected after centrifugation (5000 rpm) and dried at 80 °C for 4 h. The as-prepared precursors were sintered at 600 °C for 2 h to obtain the final oxides.  $\text{WO}_3$  obtained using citric acid is labelled as PA1. Similar experiment was conducted to synthesize  $\text{WO}_3$  by using oxalic acid instead of citric acid.  $\text{WO}_3$  obtained using oxalic acid is labelled as PA2.

### 2.2 Synthesis of $\text{WO}_3$ /graphene nanocomposite

The nanocomposite of  $\text{WO}_3$  and graphene was prepared using a physical mixture method. Initially, 1% graphene was taken in 10 mL ethanol and sonicated for 20 min. To this solution, the as-synthesized  $\text{WO}_3$  powder was added and further sonicated for 1 h. The resultant  $\text{WO}_3$ /graphene nanocomposite solution was allowed to evaporate at room temperature to form a paste, which was then applied on the substrate.

### 2.3 Physicochemical characterization

The crystalline structures of the resultant powders were characterized by XRD on a Rigaku Miniflex diffractometer using  $\text{CuK}\alpha$  radiation ( $\lambda = 1.5405 \text{ \AA}$ ; nickel filter). The crystallite size was estimated using the Scherrer's formula. Optical absorption spectrum was recorded on a Hitachi UV-Visible Spectrophotometer (model U-3210). Morphological studies were conducted using FE-SEM (Hitachi Model 5890). FETEM analysis was performed using an FETEM analyzer (JEOL JEM 220Ks model). PSD analysis was conducted *via* a dynamic light scattering method using a submicron particle size analyzer, PSS-Nicom-380 (Santa Barbara, California, USA).

### 2.4 Gas sensing characterization

The gas sensing measurements were performed for  $\text{WO}_3$  and  $\text{WO}_3$ /graphene nanocomposite products. Planar interdigitated

Fig. 1 (a) Photograph of an interdigitated electrode. (b) Photograph of the material drop-casted on the electrode. (c) Schematic of the gas sensing set up.

electrode<sup>14</sup> arrays are a commonly used electrode configuration for conductimetric sensing applications. The electrodes were fabricated in-house using a thick film paste. The design of the interdigitated electrode structure is illustrated in Fig. 1a. At one end of the structure, there is a set of interdigitated electrodes that occupy an area of  $8 \times 8 \text{ mm}$ . The width of the digits is 1 mm and the space between them is 0.5 mm. Alumina substrate (0.6 mm thick and  $10 \times 10 \text{ mm}$  area) was used for the fabrication of interdigitated electrodes. Screen-printing technique was used for the printing of the electrode pattern on the substrate. Silver paste was screen-printed on the substrate. The thickness of the silver pattern was 8  $\mu\text{m}$ . The gas sensing measurements were performed using a set-up (shown in Fig. 1c) as reported earlier.<sup>15,16</sup> It essentially consists of a circular platform with a place for mounting the substrate and sensing material. The platform was covered with a glass dome to house it in inert atmosphere and to protect it from other gaseous disturbances. The process conducted was as follows. Initially, 25 mg each of the  $\text{WO}_3$  ( $\text{WO}_3$  prepared using oxalic acid and citric acid) were taken in a mortar and pestle. Then, 0.5 mL ethanol was added to form a paste. The semi-liquid paste was then drop casted on an alumina substrate with silver electrodes patterned on it. The substrate was then dried at 60 °C for 1 h.

The  $\text{WO}_3$ -coated substrate was kept inside the dome and a provision was made to inject the gas in the dome. For measuring the change in resistance, a Digital Multimeter (Keithley model 7510) was used.

Fig. 2 X-ray diffraction pattern of the as-synthesized  $\text{WO}_3$  samples prepared using (a) citric acid (PA1) and (b) oxalic acid (PA2).

### 3 Results and discussion

The particulate properties of the nanostructured  $\text{WO}_3$  were studied *via* XRD, FESEM, FETEM, UV-visible spectroscopy and PSD. The diffraction patterns of the  $\text{WO}_3$  products obtained using citric acid and oxalic acid as capping agents exhibited sharp crystalline peaks. The diffraction pattern of  $\text{WO}_3$  obtained using citric acid perfectly matches with the JCPDS card no. 05-0363, confirming the formation of the monoclinic phase (Fig. 2a). The prominent peaks were observed at  $2\theta$  values of 23.4, 23.86, 24.64, 26.85, 28.93, 33.54, 34.45, 35.88, 42.12, 47.52, 48.49, 50.18, 53.69, 54.41, 54.99, 56.16, and 62.47 corresponding to (001), (020), (200), ( $-120$ ), ( $-111$ ), (021), (220), (121), (221), (003), (040), (140), (022), (041), ( $-240$ ), ( $-420$ ), and ( $-340$ ) diffraction planes, respectively.<sup>17</sup> All the observed XRD peaks were found to be shifted to higher  $2\theta$  values ( $\sim 0.2^\circ$ ) than those in the reported JCPDS data with lattice parameter values  $a = 7.2850$ ,  $b = 7.5170$ , and  $c = 3.8350$ . The mean crystallite size calculated using Scherrer's equation ( $0.9\lambda/\beta \cos \theta$ ) was found to be 20 nm.

Similarly, XRD pattern of the  $\text{WO}_3$  product obtained using oxalic acid (Fig. 2b) matches with the JCPDS card no. 01-071-0131, depicting the orthorhombic phase. The major diffraction peaks are observed at  $2\theta$  values of 23.37, 23.90, 26.35, 28.44, 33.88, 41.48, 44.68, 45.61, 49.75, 51.65, 54.76, 55.70, and 62.12 corresponding to (020), (200), (120), (112), (220), (222), (132), (312), (140), (303), (214), (420), and (314) diffraction planes, respectively. The lattice parameters match with the standard values, with  $a = 7.3410$ ,  $b = 7.5700$ , and  $c = 7.7541$ , and are in accordance with the literature.<sup>17,18</sup> The mean crystalline size calculated is around 10 nm. No other impurity peaks were observed in both the XRD patterns.

The optical absorption spectra of  $\text{WO}_3$  obtained using citric acid and oxalic acid as capping agents are displayed in Fig. 3a and b. The inset shows the plot of absorbance *vs.* energy. The band gap energy was calculated by extrapolating the straight line portion of the curve on the energy axis. The band gap for both the products obtained using citric acid and oxalic acid was recorded as 2.1 eV and 1.9 eV, respectively. The particle sizes

Fig. 3 Optical absorption spectrum of  $\text{WO}_3$  obtained using (a) citric acid (PA1) and (b) oxalic acid (PA2). (c) Optical absorption spectrum of PA1/graphene composite.

were also calculated from optical absorption spectra<sup>19</sup> and were found to be 4.52 nm and 4.18 nm for PA-1 and PA-2, respectively.

The optical absorption spectra of  $\text{WO}_3$ /graphene composite are as shown in Fig. 3c. It could be observed that there is a change in the optical absorption spectrum after addition of graphene. The band located at 250 nm is due to the  $\pi$ - $\pi^*$  transition of graphene.<sup>20</sup>

The SEM and FESEM photomicrographs obtained using citric acid and oxalic acid-assisted  $\text{WO}_3$  are presented in Fig. 4. It can be observed that the citric acid-assisted  $\text{WO}_3$  product consists of a mixture of nanoparticles as well as rod-like structures (Fig. 4a). The rod-like structures were presumably formed by the agglomeration of nanoparticles and can be evidenced by FETEM analysis. The diameter of the nanorods is 90 nm and length is a few microns.

Fig. 4 SEM photograph of  $\text{WO}_3$  obtained using (a) citric acid (PA1) and (b) oxalic acid (PA2). (c) SEM photograph of PA1/graphene composite.

Fig. 5 TEM images of  $\text{WO}_3$  obtained using (a) citric acid (b) oxalic acid (inset: electron diffraction patterns).

In case of  $\text{WO}_3$  obtained using oxalic acid, clusters of nanoparticles are observed (Fig. 4b). The size of the nanoparticles is around 20–30 nm. The nanoparticles are intact and form an island of clusters all over.

The FESEM photomicrographs of  $\text{WO}_3$  (obtained using citric acid) and graphene composite are presented in Fig. 4c. It can be observed that the composite consists of  $\text{WO}_3$  nanoparticles well-wrapped with graphene sheets. The interface of  $\text{WO}_3$  and graphene can also be clearly seen.

Closer observations on morphological characterization were performed using FETEM analysis. The corresponding FETEM images are displayed in Fig. 5. The  $\text{WO}_3$  product obtained using citric acid shows spherical nanoparticles with size of around 60–70 nm, and were agglomerated to form rod-like structures (Fig. 5a). Fig. 5b illustrates the clusters of 10 to 20 nanoparticles with size varying from 20–50 nm. All these results are in accordance with the SEM observations. The inset shown in Fig. 5 is a clear crystallite diffraction pattern for both the products.

The chemical reaction mechanism for the formation of  $\text{WO}_3$  using citric acid and oxalic acid is explained below. In the initial stage, sodium tungstate reacts with HCl to form tungstic acid and sodium chloride.

In case of citric acid-assisted  $\text{WO}_3$ , the initially obtained precipitate was redissolved in 1 M citric acid solution. The probable reaction is given below:

Thus,  $\text{WO}_3$  formation takes place, and the growth of  $\text{WO}_3$  is controlled by citric acid. Citric acid acts as a shape modifier. The growth of the particles is controlled in citric acid by the coating of citric ions on the particles of  $\text{WO}_3$ . However, after heating at 600 °C, the one directional growth accelerated, resulting in formation of the nanorods of  $\text{WO}_3$ .<sup>21</sup>

The reaction with oxalic acid can be presented as follows:

Oxalic acid is a well-known chelating agent that can combine with  $\text{WO}_4^{2-}$  ions and form  $\text{WO}_3 \cdot \text{OC}_2\text{H}_4$ . Subsequent chelating

Fig. 6 Room temperature sensitivity of  $\text{WO}_3$  obtained using (a) citric acid and (b) oxalic acid with different gases at 1000 ppm.

forms  $\text{WO}_3$  after calcination at 600 °C. Thus,  $\text{WO}_3$  formed after calcinations at 600 °C exhibit distinct crystal growth. The  $\text{WO}_3$  nanocrystals formed are unidirectional and in the form of clusters.

### 3.1 Sensing characterization

Gas sensing measurements were performed to check the sensitivities using various gases such as  $\text{NO}_x$ , acetone, ethanol, methanol, and TEA.

The sensitivity was calculated using the formula:

$$\text{Sensitivity} = (R_g/R_a) - 1, \text{ for oxidizing gases;}$$

$$\text{Sensitivity} = (R_a/R_g) - 1, \text{ for reducing gases;}$$

where  $R_a$  is resistance in air and  $R_g$  is resistance in gas.

The effect of morphologies of two different samples and the effect of graphene on the sensitivity of the gas sensing was studied. Due to its small band gap,  $\text{WO}_3$  shows a sensing response even at room temperature, and is the most desirable property of  $\text{WO}_3$ . The sensitivity of both the  $\text{WO}_3$  samples was studied at room temperature for different gases such as  $\text{NO}_x$ , acetone, ethanol, methanol, and TEA. As shown in the Fig. 6, the  $\text{WO}_3$  product sensitivity obtained using citric and oxalic acid is the highest towards  $\text{NO}_x$  as compared with other gases.

$\text{WO}_3$  obtained using citric acid has higher sensitivity than  $\text{WO}_3$  obtained using oxalic acid. In case of the product obtained using oxalic acid, even though the sensitivity for  $\text{NO}_x$  is more, there is hardly any difference between the sensitivities of the five gases studied, as shown in Fig. 6.

To compare the sensitivity towards  $\text{NO}_x$ , both the products were exposed to different concentrations of  $\text{NO}_x$ , and the results

Fig. 7 Response towards different concentration of  $\text{NO}_x$  for  $\text{WO}_3$  obtained using (a) citric acid and (b) oxalic acid at room temperature.

Fig. 8  $\text{NO}_x$  sensing response of  $\text{WO}_3$  obtained using citric acid at different temperatures (RT, 50 °C and 100 °C) as a function of increase in concentration of  $\text{NO}_x$ .

are presented in Fig. 7. The concentration of  $\text{NO}_x$  was varied from 200 ppm to 1000 ppm in steps of 200 ppm. At 200 ppm the response of both the products towards  $\text{NO}_x$  is comparatively similar. However, as the concentration changes from 200 ppm to 500 ppm, the response of citric acid-assisted  $\text{WO}_3$  increases linearly up to 1000 ppm compared with oxalic acid-assisted  $\text{WO}_3$ , which increases linearly up to 400 ppm and drops thereafter. Thus, the overall response of  $\text{WO}_3$  obtained using citric acid towards  $\text{NO}_x$  was found to be better and higher when compared with oxalic acid-assisted  $\text{WO}_3$ .

We can depict from the above study that the morphology of the material and band gap affects the sensing response considerably. It is further opined that smaller the band gap, higher would be the response at room temperature. Particle size also plays an important role. As shown in Fig. 7(a & b), it could be observed that oxalic acid-assisted  $\text{WO}_3$  has slightly greater response at lower concentration of  $\text{NO}_x$  than the citric acid-assisted  $\text{WO}_3$ , which can be attributed to the smaller particle size of oxalic acid-assisted  $\text{WO}_3$ . As the overall sensitivity and response of  $\text{WO}_3$  obtained using citric acid is higher than that of the other product, the citric acid-assisted  $\text{WO}_3$  was selected for further studies.

The  $\text{NO}_x$  gas sensing experiment was performed with the citric acid-assisted  $\text{WO}_3$  at different temperatures namely, at room temperature, 50 °C and 100 °C (Fig. 8). For these three temperatures, the sensitivity towards  $\text{NO}_x$  was found to increase with the increase in concentration of  $\text{NO}_x$ .

As the temperature increases, the resistance of the material decreases and therefore, the change in resistance ( $\Delta R$ ) decreases, resulting in reduction in the sensitivity at higher temperature. Thus, the maximum sensitivity was observed at room temperature. Furthermore, to increase the sensitivity, graphene was introduced.

A gas sensing experiment in the concentration range of 10–200 ppm of  $\text{NO}_x$  was performed for citric acid-assisted  $\text{WO}_3$  and graphene nanocomposite at room temperature and compared with pristine  $\text{WO}_3$  obtained using citric and oxalic acid (depicted in Fig. 9). As the concentration of gas increases in the range between 10 and 200 ppm, the sensitivity of  $\text{WO}_3$ /graphene composite was found to be linearly increasing. However, in case

Fig. 9 Comparison of sensitivity of pristine  $\text{WO}_3$  (obtained using citric acid and oxalic acid) and  $\text{WO}_3$ /graphene composite at room temperature.

of pristine  $\text{WO}_3$ , the increase in sensitivity with respect to concentration is not clearly linear.

The response time and recovery time of the sensing material is also a crucial aspect. The composite was found to have a minimum response time of 29 s and recovery time of 24 s, as depicted from the graph (Fig. 10). The response and recovery time of the composite was compared with the reported literature. Qin *et al.*<sup>21</sup> reported the  $\text{NO}_x$  sensing response of solvothermally prepared  $\text{WO}_3$  nanowire and nanosheets. Their sensor worked at 200 °C and the response time and recovery time achieved were 19 s and 112 s, respectively. You *et al.*<sup>22</sup> reported more sensitive square-like geometrical  $\text{WO}_3$  sheets, exhibiting  $\text{NO}_x$  response at 150 °C with a response time of 300 s and recovery time of 30 s. You *et al.*<sup>13</sup> tested the sensing response and recovery time for spherical  $\text{WO}_3$  nanoparticles at 125 °C. The response time observed was 180 s, while the recovery time was 90 s. Xia *et al.*<sup>23</sup> synthesized ultrathin ZnO nanorods/reduced graphene oxide mesoporous nanocomposites for high-performance room-temperature  $\text{NO}_2$  sensors, showing response time of 75 s and recovery time of 132 s. Bai *et al.*<sup>24</sup> doped  $\text{WO}_3$  nanoparticles with Sb, Cd and Ce to enhance the room temperature sensitivity of the material. They have also concluded that lowering the band gap of the material may result in an increase in its response towards  $\text{NO}_x$  at room temperature. Hence, compared with the above

Fig. 10  $\text{NO}_x$  gas sensing response of  $\text{WO}_3$  and  $\text{WO}_3$ /graphene nanocomposite at room temperature, 50 °C, and 100 °C.

mentioned reports, the composite of  $\text{WO}_3$  and graphene prepared in the present study shows a very good response and recovery time at room temperature.  $\text{WO}_3$  is generally immobilized on graphene, and the electrons generated are quickly transported to the surface due to graphene. Hence, graphene works as an electron transporter and shows good response. This can be attributed to its efficient functioning at room temperature. The mechanism of sensing is as follows.  $\text{WO}_3$  is an n-type semiconductor in which electrons are majority charge carriers responsible for sensing the gas molecules.  $\text{NO}_2$  is an oxidizing gas. When  $\text{NO}_2$  is adsorbed on the active sites of  $\text{WO}_3$ , it captures the electrons from  $\text{WO}_3$ , which in turn increases the resistance of  $\text{WO}_3$ . In case of the  $\text{WO}_3$  graphene composite, graphene contributes to enhancement of sensitivity by (i) increasing the conductivity of the composite, (ii) facilitating the adsorption and diffusion of the gas molecule (due to the higher surface area), and (iii) specific capturing and migration of electrons from  $\text{WO}_3$  to graphene due to the Schottky barrier at the interface of graphene and  $\text{WO}_3$ .<sup>20</sup> The gas sensing experiments of the composite were also performed at specific time intervals to check its stability and reproducibility and the results were found to be consistent.

## 4 Conclusions

$\text{WO}_3$  nanocomposites for sensing at room temperature were successfully synthesized by citric acid and oxalic acid. Nanorod structures caused by agglomeration of spherical particles were observed in citric acid-assisted  $\text{WO}_3$ , whereas a uniformly distributed spherical particle structure was observed in oxalic acid-assisted  $\text{WO}_3$ . The sensitivity of citric acid-assisted  $\text{WO}_3$  was higher at room temperature and it increases drastically when mixed with graphene. The composite of graphene and  $\text{WO}_3$  nanorods prepared by the physical mixture method showed a 29 s response time and 24 s recovery time at room temperature for 10 ppm. The increase in concentration of  $\text{NO}_x$  resulted in a linear increase in sensitivity for 10, 25, 50, 100 and 200 ppm of  $\text{NO}_x$  compared with the published study on  $\text{WO}_3$  sensors, indicating that both the response time and recovery time were better. We can also depict from this study that the morphology of the material and band gap affects the sensitivity response considerably. The overall results indicate that a room temperature  $\text{NO}_x$  sensor could be fabricated using graphene and  $\text{WO}_3$  nanocomposite with better response and recovery time. Further studies to use the findings of this research to fabricate a  $\text{NO}_x$  sensing device based on citric acid-assisted  $\text{WO}_3$  are in progress.
