# High-performance multi-functional graphene/hexagonal boron nitride/poly(ethylene oxide) nanocomposites through enhanced interfacial interaction by coordination

Chen Lin, <sup>a</sup> Xiong-Ying Ye<sup>\*b</sup> and Xu-Ming Xie<sup>\*a</sup>

In this study, multi-functional nanocomposites with excellent mechanical, electrical and thermal properties were prepared through metal-ion coordination. Reduced graphene oxide (rGO) and hexagonal boron nitride (h-BN) interacted through calcium coordination bonding. Poly(ethylene oxide) (PEO) was added to bridge these two nanomaterials, providing more resistance to tensile deformation. The results of UV-Vis and FTIR spectra proved that coordination bonding was successfully formed among the three compounds. SEM images showed homogenous dispersions of the nanocomposite. After calcium-ion coordination, the mechanical, electrical and thermal properties of Ca<sup>2+</sup>-coordinated rGO/BN/PEO composite improved significantly, indicating that metal-ion coordination is a potential method for multi-functional nanocomposite fabrication.

## Introduction

Two-dimensional materials, such as graphene and hexagonal boron nitride (h-BN), have attracted significant attention in recent years because of their unique structures and excellent properties. Graphene is a one-atom-thick nanomaterial composed of sp<sup>2</sup>-hybridized carbons. It is the most well-known representative of two-dimensional material and has outstanding mechanical (Young's modulus, ~1 TPa; ultimate strength, ~130 GPa) and electrical (conductivity, ~6000 S cm<sup>-1</sup>) properties.<sup>1,2</sup> Reduced graphene oxide (rGO) is one of the derivatives of graphene; it can be easily synthesized and shows similar mechanical and electrical performances to those of graphene. Thus, rGO is usually used as a substitute for pristine graphene.<sup>3,4</sup> Hexagonal boron nitride is also a novel two-dimensional material, which is composed of covalently connected nitrogen and boron atoms arranged in an alternating manner;<sup>5,6</sup> it has remarkable properties such as high thermal stability, high thermal conductivity, high oxidation resistance and a low dielectric constant. Because of their outstanding properties, rGO and BN are excellent candidates to synthesize high-performance nanocomposites.

However, in most previous reports, researchers always focused on only one of these nanomaterials.<sup>7-11</sup> Zheng *et al.*<sup>7</sup> prepared an rGO/PA6 nanocomposite with low percolation

threshold and high electrical conductivity, which was due to excellent electrical properties of rGO. Song *et al.*<sup>10</sup> prepared BN/PVA nanocomposites with high thermal diffusivity due to excellent thermal conductivity of BN. Although some studies on graphene/BN composites have been performed,<sup>12-15</sup> the two nanomaterials do not exhibit their respective properties simultaneously. For example, BN/GO and BN/graphene papers with high thermal conductivities were prepared by Yao *et al.*<sup>13</sup> and Liem *et al.*,<sup>14</sup> respectively; however, they only utilized the high thermal property of h-BN. The excellent properties of graphene, such as mechanical property and electrical property, were not utilized. To the best of our knowledge, research on composites with multiple 2D nanomaterials is insufficient because there is no universal method to bond 2D materials and take advantage of their combined properties.

In this article, coordination bonding, as a dynamic covalent bonding, was chosen to enhance the interfacial interaction between rGO and BN. In our previous studies,<sup>16-21</sup> coordination bonding was used to provide strong interactions in many systems. After being reduced, rGO still has residual oxidized functional groups such as carboxyl groups and hydroxyl groups. These groups can be coordinated with B-N bonds through metal-ion coordination. Furthermore, to increase the elongation at break of the nanocomposite, we chose poly(ethylene oxide) (PEO), which could also be coordinated through metal ions, to bridge rigid 2D nanomaterials. With enhanced interaction provided by metal-ion coordination, the rGO/BN/PEO composite showed excellent performances in all mechanical, electrical and thermal aspects.

<sup>a</sup>Laboratory of Advanced Materials (MOE), Department of Chemical Engineering, Tsinghua University, Beijing 100084, China. E-mail: xxm-dce@mail.tsinghua.edu.cn

<sup>b</sup>Department of Precision Instrument, Tsinghua University, Beijing 100084, China. E-mail: xyYe@mail.tsinghua.edu.cn

Herein, we report a novel strategy for bridging different 2D nanomaterials by metal-ion coordination to utilize the excellent properties of each in one system. This simple and cost-effective method is applicable to a variety of nanomaterials (and polymers, if needed) containing coordination atoms. Thus, a new opportunity to prepare high-performance multi-functional nanocomposites can be achieved by this strategy.

## Experimental

### Raw materials

Graphite (325 mesh) powder was purchased from Qingdao Xinghe Graphite Co. Ltd. h-BN (diameter =  $\sim 1 \mu\text{m}$ , purity > 98%) powder and calcium chloride were both purchased from Sigma Aldrich Corporation. PEO ( $M_w = \sim 100\,000$ ) was purchased from Alfa-Aesar Corporation. Also, 98% sulfuric acid, 37% hydrochloric acid, 30% hydrogen peroxide, potassium permanganate, sodium nitrate, and hydrazine hydrate were all purchased from Beijing Chemical Works. All chemicals were used as received.

### Fabrication of $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO nanocomposite

In our experiments, the ratio of  $\text{Ca}^{2+}/(\text{rGO} + \text{BN})$  in the coordinated composites was kept constant at  $0.001 \text{ mol g}^{-1}$ .

Graphene oxide was prepared from natural powder according to our previous reports by a modified Hummers method.<sup>18,19,21–23</sup> The fabrication procedure of  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO nanocomposite films was as follows: GO aqueous solution was diluted to  $2 \text{ mg mL}^{-1}$  after preparation. BN was dispersed into deionized water using an ultrasonic bath (Kunshan Ultrasonic Instrument Co., Ltd, model: KQ100DE, 100 W) for 8 h. The obtained slurry was then centrifuged at 9000 rpm for 40 min. The top 2/3 supernatant was collected. The concentration of this BN aqueous solution was determined by drying a fixed volume and weighing the remaining solid. The result was  $1.2 \text{ mg mL}^{-1}$ . PEO was dissolved in deionized water and stirred under room temperature to obtain  $8 \text{ mg mL}^{-1}$  PEO aqueous solution. The three solutions were mixed and then,  $2 \text{ mg mL}^{-1}$   $\text{CaCl}_2$  aqueous solution was added. The mixed solution was kept at  $50^\circ\text{C}$  for 0.5 h for coordination. Hydrazine hydrate at  $0.8 \text{ L g}^{-1}$  of GO was then added, and the solution was kept at  $80^\circ\text{C}$  for 8 h for reduction. After that, the solution was poured into Teflon Petri dishes for deposition at  $50^\circ\text{C}$  for 24 h. Finally, they were kept in a vacuum oven at  $50^\circ\text{C}$  to remove residual water.

### Characterization

GO and BN aqueous solutions were prepared for AFM observation. Samples were kept at  $50^\circ\text{C}$  for 0.5 h for coordination and then spin-coated on mica at 2000 rpm for 1 min. The AFM observation was obtained using Shimadzu SPM-9700 in the tapping mode. To calculate the number-average thickness of GO and BN, 50 sheets of each nanomaterial were measured. For UV-Vis characterization, rGO/BN/PEO and  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO aqueous solutions were prepared. Samples were kept at  $50^\circ\text{C}$  for 0.5 h for coordination. UV-Vis analysis was

performed by a PERSEE TU-1810 spectrophotometer. The wavelength range was 200–900 nm. For FTIR characterization, rGO/BN/PEO and  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO nanocomposites were scanned by an AVATAR 360 FTIR spectrometer. For Raman spectrum analysis, a RENISHAW RM2000 spectrometer was used with 514 nm laser excitation. The samples were  $\text{Ca}^{2+}$ -coordinated GO/BN/PEO and  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO filtered films. To calculate the intensity ratio of  $I_D/I_G$ , 5 different areas of each sample were measured for averaging. The morphologies and structures of the nanocomposites were characterized by scanning electron microscopy (SEM) with a TESCAN VEGA 3 SBH-EasyProbe. For tensile strength tests, the films were cut into  $10 \text{ mm} \times 3 \text{ mm} \times 50 \mu\text{m}$  strips. The tensile tests were performed under a speed of  $100 \mu\text{m s}^{-1}$ . For electrical conductivity tests, the composites were cut into  $10 \text{ mm} \times 3 \text{ mm} \times 50 \mu\text{m}$  strips and characterized by a KEITHLEY 327 voltage current tester. For thermal conductivity tests, samples were cut into  $10 \text{ mm} \times 3 \text{ mm} \times 20 \mu\text{m}$  strips and then characterized by a LFA427 laser thermal conductance instrument. In the mechanical, electrical and thermal tests, five different samples were tested for average values.

## Results and discussion

Fig. 1a and b show two typical atomic force microscopy (AFM) images of GO and BN sheets that are spin-coated on mica at 2000 rpm for 1 min. The thickness of the GO sheet is 1.03 nm, corresponding to the thickness of a GO monolayer (0.8–1.2 nm).<sup>24</sup> The thickness of the BN sheet is 0.94 nm, corresponding to the thickness of 2–3 layers of BN monolayer (0.33–0.34 nm).<sup>10,25</sup> The diameter of GO is about  $1 \mu\text{m}$ , which is much larger than that of BN (about  $0.5 \mu\text{m}$ ). Both nanomaterials have large aspect ratios. Fig. 1c and d show thickness distributions of GO and BN counted from AFM images. The average thickness of GO is 1.75 nm and that of BN is 1.12 nm. This result shows that majority of these two nanomaterials are few-layers, indicating that both GO and BN have been fully exfoliated.

The mass ratio of  $\text{PEO}/(\text{rGO} + \text{BN})$  is important for the properties of the composite; if it is too low, the film will be fragile and unusable and if it is too high, the electrical and thermal properties of the composite will decrease. Taking these into consideration, in this study, the ratio of  $\text{PEO}/(\text{rGO} + \text{BN})$  is always kept at 4 : 10. The UV-Vis spectra of an rGO/BN/PEO aqueous solution before and after coordination are shown in Fig. 2. Since the UV-Vis spectra of PEO and BN are nearly featureless within the 200–900 nm range,<sup>5,16</sup> the characteristic peaks are derived from rGO. The major peak at 242 nm is due to the  $\pi \rightarrow \pi^*$  transition of C–C bonds; the shoulder peak at 305 nm is due to the  $n \rightarrow \pi^*$  transition of the residual C=O bonds.<sup>26</sup> As seen from Fig. 2b, the shoulder peak at 305 nm becomes much weaker after calcium-ion coordination, which is probably related to the complexation between C=O bonds of rGO sheets and  $\text{Ca}^{2+}$  ions.

FTIR analysis was performed to further prove the successful coordination on rGO, BN and PEO, as shown in Fig. 3. The characteristic peaks at  $\sim 1730$ ,  $\sim 1680$ ,  $\sim 1375$  and  $\sim 1270 \text{ cm}^{-1}$  correspond to the residual C=O bonds on the edge of rGO,

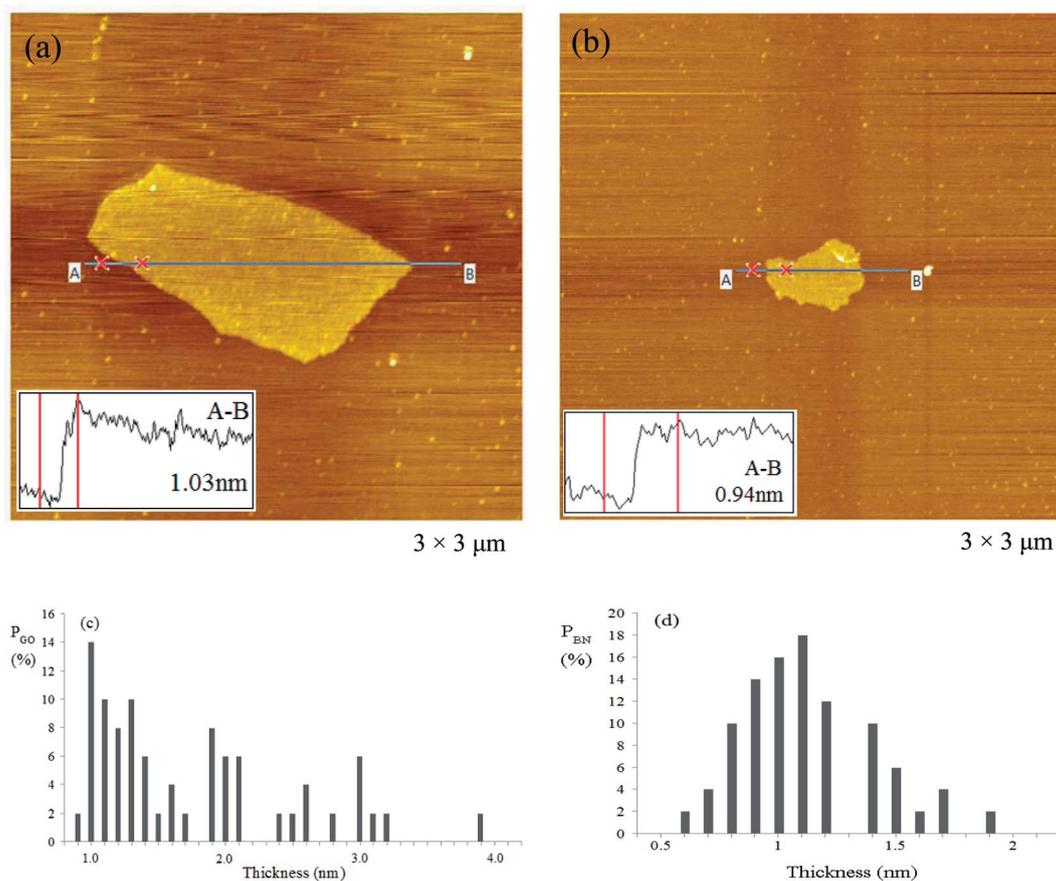

Fig. 1 AFM images of (a) GO and (b) BN aqueous solutions spin-coated on mica at 2000 rpm for 1 min, and thickness distributions of (c) GO and (d) BN sheets counted from their AFM images. The average thickness of GO is 1.75 nm and that of BN is 1.12 nm.

aromatic C=C bonds in the plane of rGO, B–N bonds on BN sheet and C–O–C bonds on the PEO chain.<sup>16,25,27</sup> During the coordination process, Ca<sup>2+</sup> ions have no effect on C=C bonds; thus, the peak at ~1680 cm<sup>-1</sup> is chosen as the standard peak. After Ca<sup>2+</sup> ions are added, coordination bonds are formed on

the C=O bonds of rGO, C–O–C bonds of PEO and B–N bonds of BN. After comparing curve 3d and curve 3e, it can be seen that the C=O peak at 1733 cm<sup>-1</sup> decreases significantly, the C–O–C

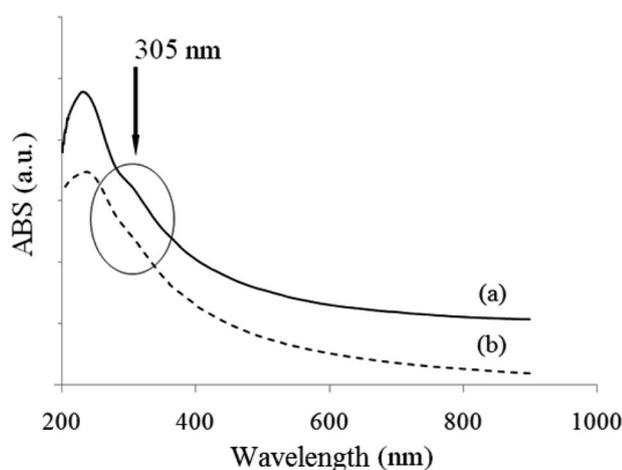

Fig. 2 UV-Vis spectra of (a) rGO/BN/PEO aqueous solution and (b) Ca<sup>2+</sup>-coordinated rGO/BN/PEO aqueous solution. The mass ratio of rGO : BN : PEO is 4 : 6 : 4. Both samples were first kept at 50 °C for 0.5 h for coordination and then at 80 °C for 8 h for reduction.

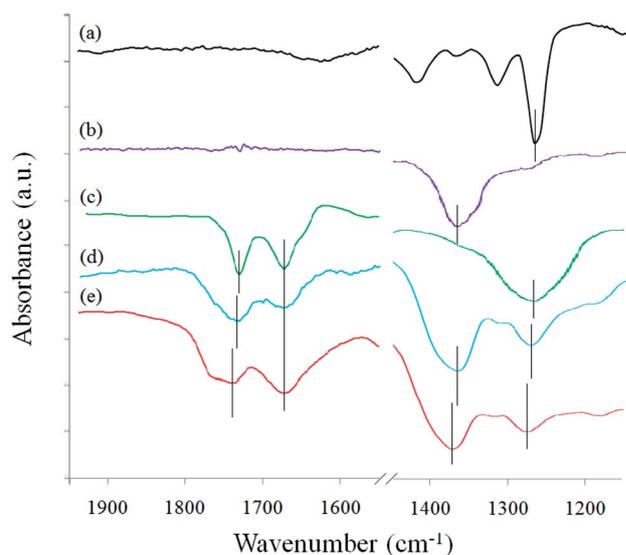

Fig. 3 FTIR spectra of (a) pure PEO, (b) BN, (c) rGO, (d) rGO/BN/PEO and (e) Ca<sup>2+</sup>-coordinated rGO/BN/PEO nanocomposites. The mass ratio of rGO : BN : PEO is 4 : 6 : 4.

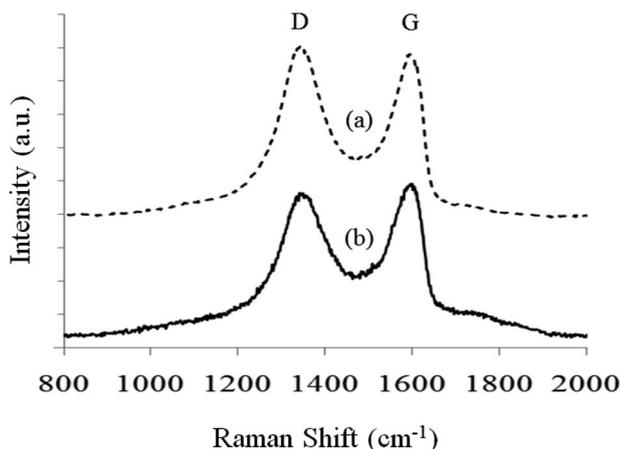

Fig. 4 Raman spectra of (a)  $\text{Ca}^{2+}$ -coordinated GO/BN/PEO and (b)  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO nanocomposites. The mass ratio of both GO : BN : PEO and rGO : BN : PEO is 4 : 6 : 4.

peak shifts from  $1375\text{ cm}^{-1}$  to  $1386\text{ cm}^{-1}$ , and the B-N peak shifts from  $1270\text{ cm}^{-1}$  to  $1282\text{ cm}^{-1}$  after coordination. These results indicate the presence of interactions due to metal-ion coordination. The peak decrease and shift phenomena are similar to the results demonstrated in previous reports.<sup>19,28,29</sup> The FTIR result is in accordance with the UV-Vis observation, confirming successful coordination in  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO nanocomposite.

Fig. 4 shows the Raman spectra of a  $\text{Ca}^{2+}$ -coordinated GO/BN/PEO nanocomposite before and after reduction by hydrazine hydrate. The two major peaks at  $\sim 1580\text{ cm}^{-1}$  and  $\sim 1350\text{ cm}^{-1}$  correspond to the G peak and the D peak of GO (or rGO). The G peak shows the vibration of the  $\text{sp}^2$ -hybridized carbon in GO (or rGO), whereas the D peak shows the structural defects in the graphitic plane.<sup>30</sup> The  $I_{\text{D}}/I_{\text{G}}$  intensity ratio ( $I_{\text{D}}/I_{\text{G}}$ ) is

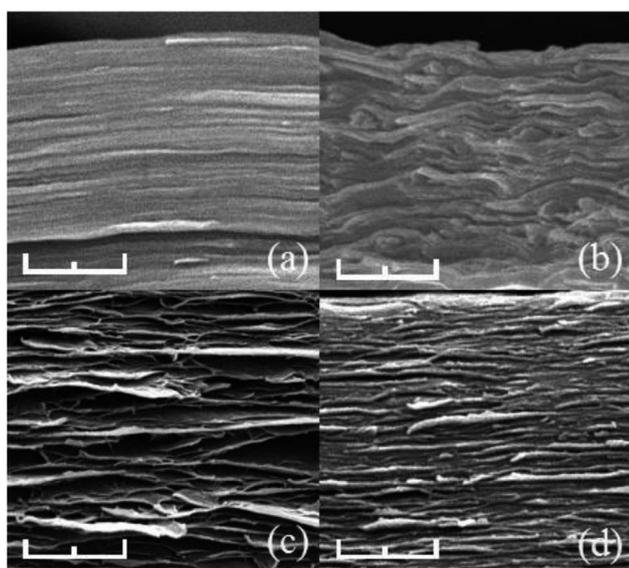

Fig. 5 SEM photographs of (a) rGO, (b) BN, (c) rGO/BN/PEO, (d)  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO samples. The mass ratio of rGO : BN : PEO is 4 : 6 : 4. The scale bar is 500 nm.

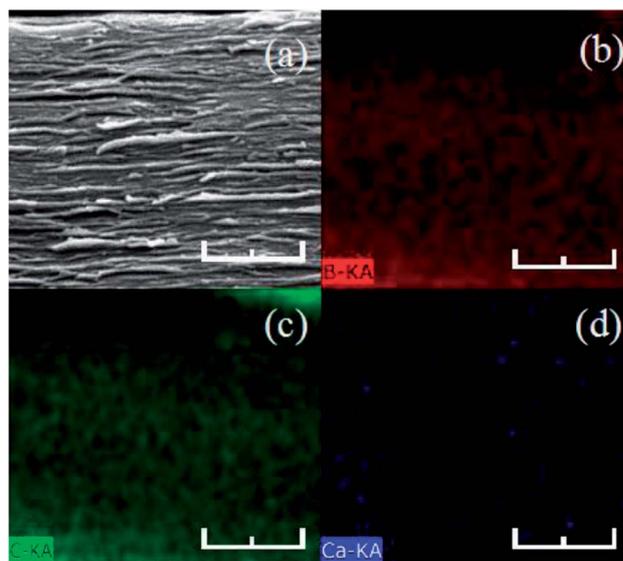

Fig. 6 (a) SEM image and (b) boron, (c) carbon and (d) calcium element energy spectra of  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO. The mass ratio of rGO : BN : PEO is 4 : 6 : 4. The scale bar is 500 nm.

a qualitative measurement of the defects of GO (or rGO). Samples with higher  $I_{\text{D}}/I_{\text{G}}$  are considered to have more defects. In Fig. 4, the  $I_{\text{D}}/I_{\text{G}}$  value changes from 1.06 (before reduction, curve 4a) to 0.91 (after reduction, curve 4b), indicating successful reduction of GO. This result is in accordance with previous results.<sup>30,31</sup>

The morphology and structure of the cross-sections of different samples were observed by SEM. As shown in Fig. 5a and b, both rGO and BN revealed well-packed layers through almost the whole cross-section of the samples. In rGO/BN/PEO (Fig. 5c) and  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO (Fig. 5d), rGO (large sheet, 800–1100 nm) and BN (small sheet, 300–600 nm) stacked with each other were bridged by wire-like PEO polymer chains. These results showed a good dispersion state in the composites before and after coordination, indicating that this metal-ion coordination method causes no precipitation of nanomaterials.

Elemental energy spectra of  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO composite are shown in Fig. 6. Boron (red dots in Fig. 6b) in the h-BN sheet, carbon (green dots in Fig. 6c) in rGO sheets and PEO chain, and calcium (blue dots in Fig. 6d) were uniformly dispersed and filled almost the entire cross-section. This further improves homogeneous dispersion in the sample, showing that metal-ion coordination does not affect homogeneous dispersion of rGO and BN.

Fig. 7 shows the stress-strain curves of rGO/BN/PEO,  $\text{Ca}^{2+}$ -coordinated rGO/BN and  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO nanocomposites. Compared with other samples, the  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO sample (curve 7c) shows the best mechanical properties (Young's modulus is 1.34 GPa, tensile strength is 52 MPa and the elongation at break is 7.9%). The sample that has no PEO (curve 7b) exhibits a good Young's modulus (1.15 GPa) but low tensile strength (22 MPa) and elongation (3.5%) because it has no elastic polymer chain to bridge rigid rGO and BN nanosheets; thus, the composite is

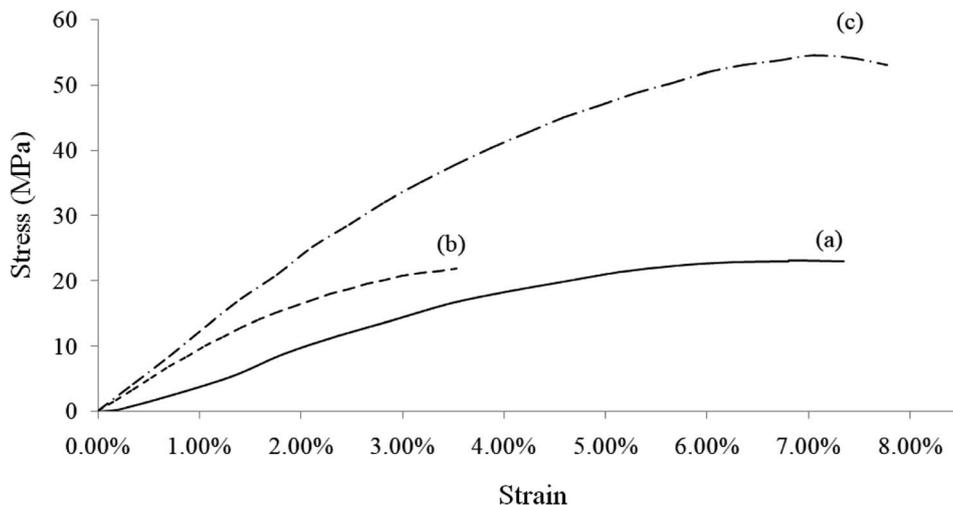

Fig. 7 Stress–strain curves of (a) rGO/BN/PEO, (b)  $\text{Ca}^{2+}$ -coordinated rGO/BN and (c)  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO. The mass ratio of rGO : BN : PEO is constantly 4 : 6 : 4.

hard and brittle. The sample without calcium ions (curve 7a) shows good elongation (7.3%) but low Young's modulus (460 MPa) and tensile strength (23 MPa) because there is no coordination bonding to provide strong interfacial interactions between the nanomaterials and the polymer chain. This fact indicates the important roles of both coordination bonds and elastic polymer chains in these composites. From curve 7a and 7c, it can be seen that after coordination, the mechanical properties of the composite are significantly improved (Young's modulus increases by 191.3% and tensile strength increases by 126.1%). Because coordination bonding can realize dynamic interfacial interactions, efficient transfer from the matrix to the dispersed fillers can be achieved.<sup>16,32</sup>

The stress–strain curves of composites with different ratios of rGO/BN are shown in Fig. 8. The Young's modulus and tensile strength increase with the increase in the ratio of rGO/BN (Young's modulus from 31 MPa to 1.8 GPa; tensile strength from 2 MPa to 89 MPa). This result indicates that samples with a higher ratio of rGO have better mechanical performances because the residual oxidized functional groups on rGO (such as carboxyl group and hydroxyl group) can form coordination bonds with metal ions more easily than B–N groups. Thus, to achieve good mechanical performance, the ratio of rGO/BN should not be low.

The electrical conductivity of different composites is shown in Fig. 9. The curves 9a and 9b correspond to the samples before

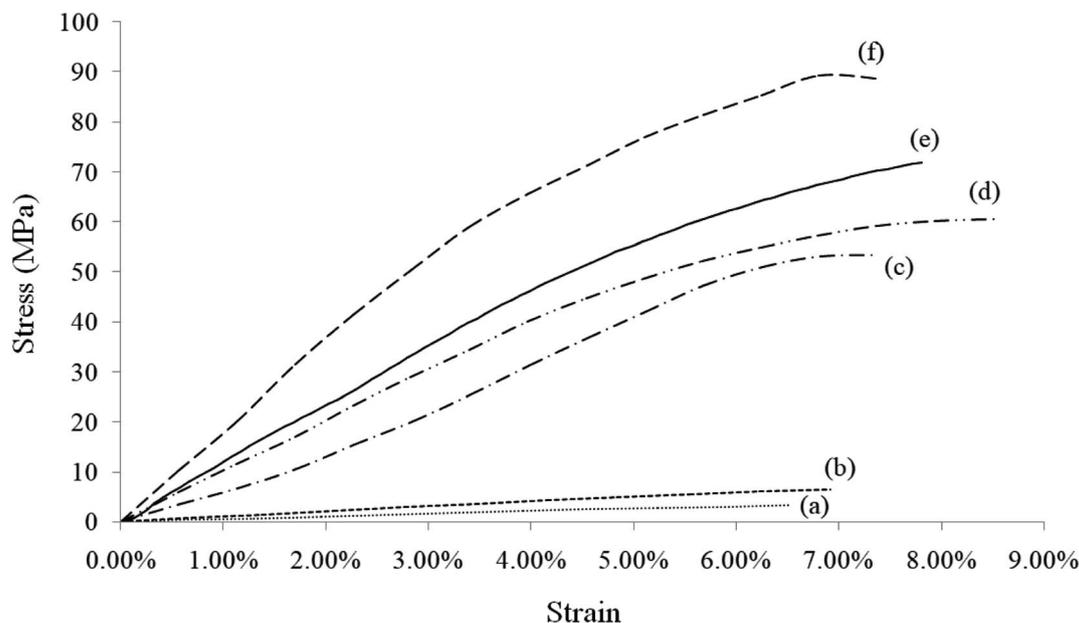

Fig. 8 Stress–strain curves of  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO nanocomposites. The mass ratios of rGO/BN are (a) 0 : 10, (b) 2 : 8, (c) 4 : 6, (d) 6 : 4, (e) 8 : 2, (f) 10 : 0. The ratio of (rGO + BN) : PEO is constantly 10 : 4.

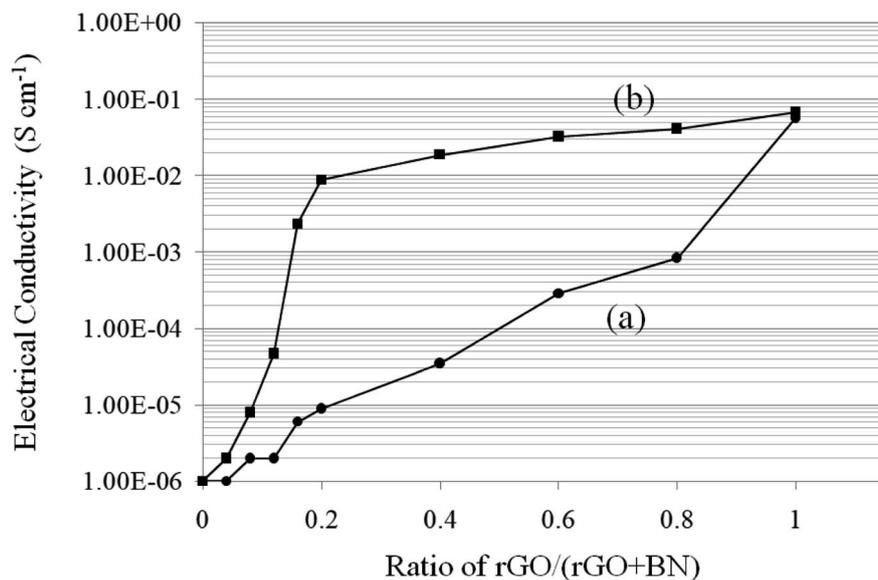

Fig. 9 Electrical conductivity of (a) rGO/BN/PEO and (b)  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO nanocomposites. The ratio of rGO/(rGO + BN) changes from 0 to 1. The ratio of (rGO + BN) : PEO is constantly 10 : 4.

and after coordination, with the mass ratio of rGO/(rGO + BN) changing from 0 (only BN) to 1 (only rGO). In all samples, the ratio of PEO is constant. As shown in the two curves, with the increase in rGO content, the electrical conductivity clearly increases (from  $\sim 10^{-6}$  S  $\text{cm}^{-1}$  to  $\sim 10^{-1}$  S  $\text{cm}^{-1}$ ) since rGO is a conductor, whereas BN is an insulator. When the ratio of rGO is too low, the conductive network cannot form; thus, the sample shows poor electrical conductivity. However, after metal ions are added, the conductivity is improved significantly. The percolation threshold decreases from 0.4 to 0.08 because coordination bonding can dramatically increase the interfacial interaction in the composite. With improvement in interaction, the rGO sheets can form a conductive network more easily (rGO is more likely to be coordinated). As shown in curve 9b, the

electrical conductivity can reach a high value (more than  $0.01$  S  $\text{cm}^{-1}$ ) when the ratio of rGO : BN is 2 : 8.

The thermal conductivity of different composites is shown in Fig. 10. Curve 10a and 10b correspond to the samples before and after coordination. The mass ratio of rGO/(rGO + BN) changes from 0 (only BN) to 1 (only rGO), as described in previous discussions. In all samples, the ratio of PEO is constant. Because rGO has residual oxidized functional groups on its plane, its  $\text{sp}^2$  structure contains defects. Thus, h-BN has higher thermal conductivity than rGO. The composites with a higher ratio of BN have better thermal conductive performance. Before coordination, the thermal conductivity of the sample without BN is  $1.5$  W  $\text{m}^{-1}$   $\text{K}^{-1}$  and that of the sample without rGO is  $3.4$  W  $\text{m}^{-1}$   $\text{K}^{-1}$ . After coordination, the thermal

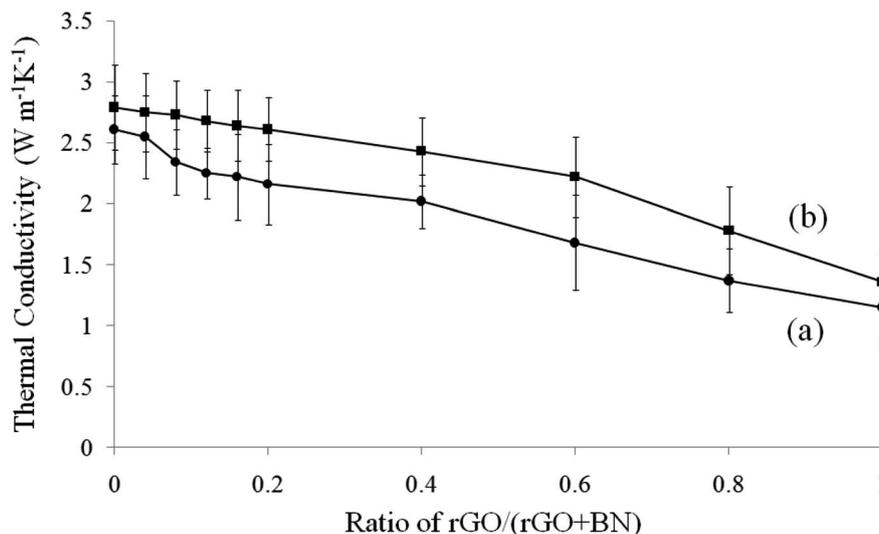

Fig. 10 Thermal conductivity of (a) rGO/BN/PEO and (b)  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO nanocomposites. The ratio of rGO/(rGO + BN) changes from 0 to 1. The ratio of (rGO + BN) : PEO is constantly 10 : 4.

conductivities of all samples increase by 10–30%. This result indicates that due to the strong interfacial interaction provided by metal-ion coordination, BN and rGO can easily form thermal conductive networks.

From the results shown in the previous sections, a multi-functional nanocomposite (for example,  $\text{Ca}^{2+}$ -coordinated rGO/BN/PEO with rGO : BN : PEO = 4 : 6 : 4) with excellent mechanical (Young's modulus = 1.34 GPa, tensile strength = 52 MPa), electrical (electrical conductivity =  $0.02 \text{ S cm}^{-1}$ ) and thermal (thermal conductivity =  $3.2 \text{ W m}^{-1} \text{ K}^{-1}$ ) performances can be prepared through our method. By changing the ratio of rGO : BN, the three properties can be adjusted. Thus, this metal-ion coordination method is a potential route for fabricating multi-functional nanocomposites with desirable properties.

## Conclusions

Here, we demonstrate a simple and cost-effective strategy for preparing multi-functional nanocomposites through strong interfacial interactions of coordination bonds by divalent metal ions. The strong interaction provides efficient load transfer to significantly improve the mechanical property, and it is easier for nanomaterials to form conductive networks to improve electrical and thermal properties. The product shows excellent performance in all three aspects: mechanical, electrical and thermal. This strategy is applicable to a variety of nanomaterials and polymers containing coordination atoms with different properties, opening up a new opportunity for fabricating multi-functional nanocomposites.
