## Bone regeneration in critically sized rat mandible defects through the endochondral pathway using hydroxyapatite-coated 3D-printed $Ti_6Al_4V$ scaffolds

Yan Wang, <sup>†</sup><sup>a</sup> Xinjie Cai, <sup>†</sup><sup>ab</sup> Jing Huang, <sup>a</sup> Yi Zhou, <sup>ab</sup> Tao Jiang, <sup>ab</sup> and Yining Wang <sup>ab</sup>

The endochondral approach has been proved to be a promising pathway in bone tissue engineering. However, whether it is suitable for repairing critically sized mandible defects is unknown. We designed  $Ti_6Al_4V$  scaffolds with a suitable shape and pore size by a 3D-printing selective-laser-melting technique to implement this approach. In order to improve the surface bioactivity of the scaffolds, hydroxyapatite (HA) coatings (HA/L group and HA/H group) of different crystallite size were prepared on the scaffolds via electrochemical deposition. Rat bone mesenchymal stem cells (BMSCs) were seeded onto the scaffolds and chondrogenically differentiated *in vitro* for 4 weeks and then the scaffolds were implanted into critically sized rat mandible defects for 8 weeks. The bare scaffold and HA coatings were characterized with field emission scanning electron microscopy, water contact angle measurements and X-ray diffractometry. Cell proliferation results showed that the bioactivity of the HA coatings could better improve the growth rate of BMSCs compared with the bare surface. Additionally, safranin O staining showed abundant cartilage matrix and chondrocytes in the HA coated scaffold. Analyses using qPCR detected higher expression of chondrogenic-related gene *Col2a1* and *vegfα* in the HA coated groups, especially in the HA/H group. Together these data demonstrate that the HA coating could improve the chondrogenic differentiation of BMSCs. *In vivo*, methylene blue staining of histological sections and micro-computed tomography revealed that the HA-coated groups, especially the HA/H group, increased new bone formation via endochondral ossification compared with the control group. Therefore, this strategy provides an alternative method to improve bone formation in mandible defects via the endochondral pathway and the scaffold with larger HA crystals was superior to those with smaller HA crystals.

### 1. Introduction

Oral and maxillofacial critically sized defects (CSDs) caused by congenital abnormalities, trauma or cancer surgery do not self-heal without external intervention. A widely used strategy involves autologous bone graft and allogeneic bone tissue transplantation.<sup>1</sup> However, these strategies are usually associated with complications, such as pain and risk of infection, as well as a lack of sources,<sup>2</sup> which limited their application in clinics. In contrast to traditional approaches, the field of bone

tissue engineering (BTE) focuses on biological substitutes to induce new functional tissues. BTE that addresses the previously described issues in current clinical treatments has attracted the attention of scientists as a promising strategy for bone repair and regeneration.<sup>3</sup>

Mesenchymal stem cells (MSCs) can differentiate into several types of cells, including osteoblasts<sup>4</sup> and chondrocytes,<sup>5</sup> and therefore, may be an alternative resource for regenerative therapy using BTE.<sup>6,7</sup> During the development of the skeletal system, MSCs differentiate to form bone *via* two different pathways. The first is intramembranous ossification and the second is endochondral ossification.<sup>8</sup> In the current field of BTE, using undifferentiated MSCs incorporated into a degradable scaffold as a bone tissue substitute to elicit bone regeneration has attracted wide attention.<sup>9</sup> This direct ossification process is analogous to intramembranous ossification. However, the vascular supply and degradation of the tissue-engineered constructs when implanted *in vivo* have been

<sup>†</sup> Both authors contributed equally.

a challenge in BTE.<sup>10–12</sup> In addition, there are few studies that support the effectiveness of this strategy in bone repair of large defects, including CSDs of the mandible.<sup>13,14</sup>

Endochondral ossification occurs in the development of long bones and fracture healing.<sup>8</sup> The chondrocytes can survive with poor nutrition and hypoxia.<sup>15</sup> In addition, they secrete vascular endothelial growth factor (VEGF) in the hypertrophic stage, which enable the blood vessel in-growth.<sup>16</sup> Several recent studies have achieved vascularized bone formation by subcutaneously implanting chondrogenically differentiated cell pellets.<sup>17–20</sup> Our previous study showed regeneration of alveolar bone and ligament tissues *via* the chondrogenic differentiation approach.<sup>21</sup> Although there are a few reports on the long-bone regeneration in CSDs through this pathway,<sup>22,23</sup> there are no reports on the regeneration in maxillofacial CSDs *via* this pathway. In addition, these two types of bones develop *via* two different pathways. A previous study showed that the best chondrogenic priming time *in vitro* was 4 weeks,<sup>24</sup> and so this time is also applied in our research. In this study, we explored repair of the mandible CSDs *via* the endochondral ossification pathway.

In this pathway, MSCs were firstly pre-differentiated into chondrocytes *in vitro*. A crucial process prior to the chondrogenic priming is the initial 3D expansion of the MSCs. Cells grow in a 2D manner *in vitro*,<sup>25</sup> and so a 3D scaffold mimicking bone structure should be used to help the cells grow in a 3D manner. Selective-laser-melting (SLM) can melt metal powders to produce 3D structures layer by layer with high precision.<sup>26</sup> It can produce a scaffold with a designed shape and interconnected pores that provide enough space for nutrient diffusion and blood vessel invasion and thus is promising for BTE.<sup>27</sup> Ti<sub>6</sub>Al<sub>4</sub>V is a widely used material in clinical applications for bone substitution and fixation but insufficient bioactivity limits its application. Therefore, biochemical surface modification has been applied. A hydroxyapatite (HA) coating improves biocompatibility and osteoconductivity of titanium alloy scaffolds and has a similar chemical composition to the native bone mineral.<sup>28,29</sup> In this study, we prepared HA coatings onto porous 3D scaffold using electrochemical deposition (ECD), which is widely used to produce HA coating.<sup>30–32</sup> ECD is a versatile technique with the advantages of short processing time, and simple production apparatus compared with other methods of preparing HA coatings on porous substrates.<sup>33</sup> Here we produced the HA coatings of different crystal size by increasing the concentration of ECD solution to evaluate and compare the effects of HA coatings on the differentiation of MSCs into chondrocytes.

We hypothesised that the 3D scaffolds with HA coatings would increase the cartilage formation and then achieve bone regeneration in mandible CSDs *via* endochondral ossification.

## 2. Materials and methods

### 2.1 Producing of the 3D titanium alloy scaffold

Porous Ti<sub>6</sub>Al<sub>4</sub>V scaffolds (porosity: 85 ± 6.2%, Ø: 5 mm, thickness: 1 mm, pores size: 600 ± 35 µm, stiffness: 0.46 ± 0.04 GPa, compressive strength: 6.28 ± 0.83 GPa) were fabricated using

a BLT-S300 Metal Additive Manufacturing Machine (Bright Laser Technologies Co., Ltd, China) through SLM techniques. The 3D models were designed with Materialise/Magics™ software (Materialize, Leuven, Belgium), by which a 3D CAD file was designed then converted into a 2D STL file of each layer. Medical-grade Ti<sub>6</sub>Al<sub>4</sub>V powder (Ø: 35 µm) was preheated to 30 °C. The fine metal powder was fused by high-power laser beam (IPG Photonics, Burbach, Germany) layer by layer repeatedly to build the final structure. The process was performed in argon gas. Disk-shaped samples (Ø: 15 mm, thickness: 1 mm) were used in water contact angle test.

### 2.2 Surface modification of porous Ti<sub>6</sub>Al<sub>4</sub>V scaffolds

**2.2.1 The preparation of the 3D scaffold.** The 3D Ti<sub>6</sub>Al<sub>4</sub>V scaffolds were acid etched in hydrochloric acid and sulfuric acid (1 : 1) at 65 °C for 30 min. After etching, the specimens were ultrasonically cleaned with acetone, ethanol, and distilled water for 15 min per treatment and then rinsed with ultrapure water.

**2.2.2 Deposition of HA coatings.** Deposition of HA coatings was performed according to previous studies.<sup>30–32</sup> The Ca/P molar ratio was 1.67. The pH values were adjusted with ammonia. There were two ECD solutions: low concentration (2.4 mM Ca(NO<sub>3</sub>)<sub>2</sub>, 1.4 mM NH<sub>4</sub>H<sub>2</sub>PO<sub>4</sub>, pH 6.0; HA/L group) and high concentration (4.2 mM Ca(NO<sub>3</sub>)<sub>2</sub>, 2.5 mM NH<sub>4</sub>H<sub>2</sub>PO<sub>4</sub>, pH 6.0; HA/H group). One piece of the samples (3D samples and disc-shaped samples) and a platinum plate were connected to the cathode and anode electrodes respectively. The distance between the electrodes was 4 cm. The voltage was maintained at 3.0 V by a direct current power supply (Model 6614C, Agilent Technologies, Santa Clara, CA, USA) at 85 °C for 1.5 h. After deposition, the scaffolds were rinsed with ultrapure water, and dried in air overnight. Before use, the 3D scaffolds were sterilized in a steam autoclaving machine at 121 °C for 2 h.

### 2.3 Characterization of titanium meshes and coatings

The microstructure of the scaffold and the HA coatings were visualized by field-emission scanning electron microscopy (FE-SEM, Zeiss, Germany). The specimens were coated with an ultra-thin layer of gold by sputtering to increase surface conductivity.

The water contact angle was determined using a contact angle meter (SL200KS, KINO Industry Co., Ltd., USA). Briefly, water droplets of about 10 µl were dropped onto the surface of each disc-shaped samples at a flow rate of 0.25 µl s<sup>-1</sup>. Each sample was tested for three times. The shapes of the water droplet were captured and measured using drop shape analysis system CAST®3.0 (Cast, Toronto, Canada) (*n* = 3).

The powder of the HA coatings was collected and the crystalline state of the composition was measured using an X-ray diffractometer (Panalytical X'Pert Pro, Holland) at a voltage of 40 kV and a current of 30 mA with Cu K<sub>α</sub> radiation. The diffraction angle ranged from 10° to 80° in the 2θ angle. The data was analysed by the jade 6.0 software and refers to Joint Committee on Powder Diffraction Standards (JCPDS) card number 09-0432.

## 2.4 Isolation and culture of cells

The MSCs were derived from 4 week-old male SD rats after approval from the School and Hospital of Stomatology, Wuhan University Animal Ethics Committee (approval number: 00140830). Briefly, both femora were dissected, the ends of the bones were cut-off and the bone marrow was flushed out using the basic cell culture medium ( $\alpha$ -MEM supplemented with 10% foetal bovine serum) through a 10 ml needle. The flush-out from four rats was collected and cultured in  $\alpha$ -MEM medium for 24 h in a humidified incubator (37 °C, 5% CO<sub>2</sub>), after which the medium was refreshed. Cells expanded for two passages were used for cell seeding. In order to ensure a high cell-loading efficiency, MSCs were seeded onto the 3D scaffolds by gently dropping 20  $\mu$ l of the cell suspension containing  $2 \times 10^6$  cells into none treated 24-well culture plates. Cells were cultured for 30 min and then the proliferation medium ( $\alpha$ -MEM medium supplemented with 10% foetal bovine serum, 100 U ml<sup>-1</sup> penicillin, 100  $\mu$ g ml<sup>-1</sup> streptomycin, 50  $\mu$ g ml<sup>-1</sup> L-ascorbic acid and 10 nM dexamethasone) was gently added (1 ml per well). The cell-seeded scaffolds were cultured in proliferation medium for 7 days. Thereafter, the medium was replaced with chondrogenic medium (RASMX-90041, Cyagen Biosciences, Santa Clara, CA, USA), which was refreshed twice a week and cells were cultured for another four weeks. All animal procedures were approved by the School and Hospital of Stomatology, Wuhan University Animal Ethics Committee (approval number: 00140830), and relevant guidelines and regulations were applied.

## 2.5 In vitro tests

**2.5.1 BMSCs proliferation analysis and morphology.** Four scaffolds of each group ( $n = 5$ ) were seeded with MSCs of passage 2 at a density of  $2 \times 10^4$  cells per scaffold in none treated 24-well plates and were measured on day 3 and day 7 using the cell count kit-8 (CCK-8, Dojindo, Japan). At each time point, the specimens were moved to new 24-well plates. Cell count reagent was mixed with the basic cell culture medium at a concentration of 10%, then incubated for 2.5 h at 37 °C in 5% CO<sub>2</sub>. 100  $\mu$ l of the reaction solution was transferred into a new 96-well plate, the absorbance of the solution was then measured by an Elisa reader (Bio-Tek Instruments Inc., USA) at 450 nm.

The MSCs were seeded onto the 3D scaffolds at a density of  $2 \times 10^4$  cells per scaffold in none treated 24-well culture plates. After incubation for 36 h, samples were fixed in 4% paraformaldehyde (PFA) in phosphate buffer saline (PBS) for 15 min and then permeabilized with 0.1% Triton-X 100 in 1× PBS for 5 min. Subsequently, the samples were rinsed with PBS for three times and then stained with rhodamine–phalloidin (RP (1 : 200; Cytoskeleton, Inc. Germany)), at room temperature (RT) for 30 min. The nuclei were counterstained with 4',6 diamidino-2-phenylindole (DAPI, Invitrogen, Basel, Switzerland). Images were captured using a fluorescence microscopy (Leica dm4000b, Germany) equipped with a digital camera (Olympus dp71, Japan).

**2.5.2 Glycosaminoglycan (GAG) content.** After 4 weeks of chondrogenic culture, in order to quantify the GAG production

in each digested sample, a dimethylmethylen blue (DMMB, Sigma Aldrich, USA) dye-binding assay was used.<sup>34</sup> First, all samples were washed twice in PBS, then digested in proteinase K enzymatic reagent solution (1 mg ml<sup>-1</sup> proteinase K with 1 mM iodoacetamide, 10  $\mu$ g ml<sup>-1</sup> pepstatin A and 1 mM EDTA in 50 mM Tris at pH 7.8; all reagents from Sigma) for 20 h at 56 °C.<sup>24</sup> The amount of GAG was measured with DMMB using chondroitin sulfate (Sigma) as a standard. The absorption of the solution was measured at 530 nm and 590 nm using an Elisa reader (Bio-Tek Instruments Inc.). The results were calculated according to a previous study.<sup>35</sup> For each group ( $n = 4$ ), the GAG value was normalized by the DNA content as described below.

**2.5.3 DNA content.** DNA content ( $n = 4$ ) was determined according to the manufacturer's protocols (Aidlab Biotech, Beijing, China). This assay shared the same cell extract solution that was used in GAG assay. The concentration of DNA was measured using a spectrophotometer (NanoDrop 2000, Thermal Scientific, Wilmington, USA).

**2.5.4 Histological staining.** After 4 weeks of chondrogenic induction, the cell-scaffold samples ( $n = 4$ ) were fixed in 4% PFA in PBS for 2 h, transferred to graded ethanol from 70% to 100% for dehydration, then embedded in methyl methacrylate (MMA) with 3% benzoyl peroxide (BPO). The embedded species were sliced into 15  $\mu$ m thickness using a diamond saw (Leica Microtome XP-1600, Germany) and stained with safranin O (Sigma). Images were captured using a light microscopy (Olympus dp51, Japan). The panoramic images were made by photoshop (Adobe Systems, San Jose, CA, USA).

**2.5.5 Analysis of expression by quantitative polymerase chain reaction (qPCR).** After 4 weeks of chondrogenic priming, the total RNA was extracted from the cells on the scaffolds ( $n = 5$ ) using TRIzol reagent according to the manufacturer's protocol (Takara, Japan). The precipitated RNA pellet was dispersed in RNase-free water. The amount of RNA was measured using a spectrophotometer (NanoDrop 2000). Subsequently, the RNA was reverse transcribed into complementary DNA (cDNA) using a PrimeScriptTMT reagent Kit with gDNA Eraser (Takara). The cDNA was then further amplified and the real-time two-step PCR was performed using an SYBR® Premix Ex TaqII kit (Takara) to quantify the expression level of specific genes (collagen type II (*Col2a1*), collagen type X (*Col10a1*), vascular endothelial growth factor (*Vegfa*) and *Sox9*). Primer specificity was tested before the real-time PCR reaction.  $\beta$ -Actin was used as a reference gene to evaluate the expression levels, which were calculated *via* the  $2^{-\Delta\Delta C_t}$  method. The primers are shown in Table 1.

Table 1 Primer sequences used for qPCR

Primers	Forward (5' → 3')	Reverse (5' → 3')
$\beta$ -Actin	GCAGGACTACGATGACTCCG	ACCGAGCTCAGTAACAGTC
Sox9	TCCCCGCAACAGATCTCTA	AGCTGTGTAGACGGGTTG
<i>Col2a1</i>	GACGCCAGGCTCAAGTCGCT	CGCTGGGTTGGGGTAGACGCC
<i>Col10a1</i>	GGGCCCTATTGGACCCAGG	CCGGCATGCCTGTTACCCCC
<i>Vegfa</i>	ACTCATCAGGCCAGGGAGTCT	GGGAGTGAAGGAGCAACCTC

## 2.6 *In vivo* implantation

The cell-scaffold structures and the bare scaffolds as a control were implanted into the mandible CSDs in 10 week-old male SD rats ( $n = 6$ ). The rats were first anesthetized with 2% pentobarbital sodium (0.3 ml/100 g) *via* intraperitoneal injection. The hair on the lower faces of the rats was depilated and sterilized with povidone-iodine. Under aseptic conditions, an incision was made through the masseter muscle. A full thickness circular CSD ( $\varnothing$ : 5 mm) was created with a core drill with intermittent rinses of PBS. The cell-scaffolds and the bare scaffolds were implanted directly into the prepared defects. The skin and muscle incisions were sutured and sterilized. To avoid wound infection, each animal was given an intramuscular injection of 20 000 U of penicillin per day for 3 days after the operation.

## 2.7 Micro-computed tomography ( $\mu$ CT) imaging

Eight weeks after implantation, rats ( $n = 5$ ) were sacrificed under anesthesia by intravenous injection with pentobarbital. The mandibular bone samples were harvested and fixed immediately in 4% PFA in PBS for 2 days. All samples were scanned using  $\mu$ CT (Y. Cheetah, YXLON, Hamburg, Germany) to determine the new bone formation at a voltage of 90 kV, the beam current of 44 mA. The resolution is about 9.0  $\mu$ m. The area of the 3D scaffold was selected as the region of interest (ROI). For the 3D analysis, image reconstruction and visualizations were made with VGStudio Max2.2 software (Volume Graphics, Germany). Percent bone regeneration was calculated by normalizing the bone volume by the ROI (BV/TV) using the threshold of 100–1500 for bone and 1500–3085 for scaffold *via* this software.

## 2.8 Histological evaluation

After the  $\mu$ CT analysis, the same species ( $n = 5$ ) then experienced the same histological preparation as previously described. The slices were stained with methylene blue and basic fuchsin (Sinopharm, Shanghai, China). Images were captured using a light microscopy (Olympus dp51). The panoramic images were made by photoshop (Adobe).

## 2.9 Statistical analysis

Statistical data was analyzed with SPSS19.0 (SPSS, Chicago, USA) by one-way analysis of variance (ANOVA) with Tukey's post hoc test. Data are presented as the mean  $\pm$  standard deviation. A  $P$ -value  $< 0.05$  was defined as statistically significant.

# 3. Results

## 3.1 Characterization of the bare scaffold and the HA coatings

Fig. 1A shows the macro-morphology of three groups: the bare scaffold, the HA/L coated group and the HA/H coated group. Highly porous scaffolds composed of thin grids were produced. The HA coating was evenly distributed on the surface of the

scaffold (Fig. 1A(b) and (c)). The HA coatings appeared gray/white in HA/L group and white in the HA/H group.

SEM images of low magnification show that the 3D scaffolds had lots of granular balls on the rough surface (Fig. 1B(a)) while at high magnification, laminated structures could be seen on the surface (Fig. 1B(d) and (g)). The homogeneous HA coatings were distributed across the entire surface (Fig. 1B(b) and (c)) and rod-like crystals formed a petal-shaped structure (Fig. 1B(h) and (i)). We also observed that the size of the crystals grew larger and there were more flower-like structures as the ECD concentration increased (Fig. 1B(f)) and the rod-like crystals in the HA/L group showed a more uniform morphology (Fig. 1B(e)). The average length of the crystals in the HA/L group and in the HA/H group was  $650 \pm 62$  nm and  $500 \pm 55$  nm, respectively ( $p < 0.05$ ).

For all the specimens, the values of contact angle were smaller than  $90^\circ$ , which indicates hydrophilic behaviour. The average water contact angle decreased from  $33.18 \pm 1.32^\circ$  for the bare samples to  $4.86 \pm 0.21^\circ$  in the HA/L coated group and to  $6.48 \pm 0.32^\circ$  in the HA/H coated group ( $p < 0.05$ , Fig. 1C(d)), which indicates that the scaffolds after HA depositions had greater surface hydrophilicity. We assumed that the HA coating significantly increased the surface roughness of the scaffolds, which resulted in better hydrophilicity. The hydrophilicity is related to the biocompatibility; the smaller the contact angle the better biocompatibility.<sup>36</sup> Therefore, the results reveal that the HA/H coated group gained better biocompatibility.

The diffraction peaks of the HA powder produced by ECD from the two different groups are displayed in Fig. 1D ( $2\theta = 25.9^\circ$  and  $31^\circ$  to  $33^\circ$ ), which matched well with those of the characteristic HA pattern. The highest peaks of HA powder indicated that the preferable growth face of the HA crystals was 211 planes. Few peaks corresponding to other impurities were found in the traces. The XRD patterns suggest that a highly purified HA crystalline structure was successfully made in these two groups.

## 3.2 *In vitro* assays

### 3.2.1 Cell proliferation assay and morphology.

After a 7 day culture, the number of cells attached to the substrates was observed using a CCK-8 kit. Regardless of the HA coating, the cells grew well on the bare scaffold. However, the HA-coated groups showed increased cell proliferation compared with the control group even at day 3 and kept the advantage till day 7 (Fig. 2A). These results indicate that the HA coating effectively increased the MSCs growth rate on the 3D  $Ti_6Al_4V$  scaffolds.

After being cultured for 36 h, MSCs were fluorescently stained with RP and DAPI to investigate cell growth and morphology. The abundant blue-stained nuclei indicate that ample cells were evenly seeded on the entire surface in all three groups (Fig. 2B(a)–(c)). Larger extensions area and more lamellipodia extensions and filopodia in the HA-coated groups (Fig. 2B(e) and (f)) which indicates that the HA coating is favorable for cell proliferation. However, in the control group most of the cells displayed a slender fusiform structure (Fig. 2B(d)).

### 3.2.2 GAG production and DNA content.

The total amount of GAG deposition, representing the cartilage matrix, in the

Fig. 1 (A) The macro morphology of (a) bare scaffold, (b) HA/L coated scaffold, (c) HA/H coated scaffold. (B) SEM images of (a, d and g) bare surface, (b, e and h) HA/L coated surfaces, (c, f and i) HA/H coated surfaces. (C) Contact angle between the water drop and the disk-shaped samples: (a) bare scaffold; (b) HA/L coated surface; (c) HA/H coated surface. (d) Water contact angle analysis; asterisks (\*) indicate statistical significance,  $p < 0.05$ ; error bars represent SD ( $n = 3$ ). (D) The XRD patterns of ha powder in HA/L group and HA/H group; asterisks (\*) indicate the peaks of the HA crystal.

three groups is showed in Fig. 3A. The greatest amount was found in the HA/H coated scaffolds. Moreover, the amount of GAG formed in the HA/H coated scaffolds, after normalization

by the DNA amount (Fig. 3B), was two times greater than that of the bare scaffolds, but there was no difference between the two HA-coated groups.

Fig. 2 (A) Measurement of MSCs proliferation by CCK-8 assay after 3 and 7 days incubation. For each group,  $n = 5$ ; asterisks (\*) indicate statistical significance compared to the control group,  $p < 0.05$ . (B) Fluorescence images of MSCs after 36 h of culture. (a and d) Control group; (b and e) HA/L coated group; (c and f) HA/H coated group. White arrows indicate the lamellipodia extensions.

**3.2.3 Histological staining.** To visualize the cartilage matrix deposition in the scaffolds, hard tissue sections were made and stained with safranin O. After 4 weeks of chondrogenic differentiation, the cell-scaffold constructs displayed GAG content throughout the scaffolds in (Fig. 3C(a)–(c)), which was stained purple-red and represents the cartilage matrix. An abundant GAG content could be clearly observed throughout the scaffolds in the HA coated scaffolds (Fig. 3C(b) and (c)). There was a thick layer of GAG deposition on the top-side in the HA/L coated group (Fig. 3C(b)). The GAG surrounded the periphery of the scaffolds in the HA/H coated scaffold (Fig. 3C(c)). In contrast, little GAG was formed in the control group and the GAG was mainly located on the top (Fig. 3C(a)). However, there were few GAG depositions in the pore center, leaving large blank areas. The cells present in the scaffolds mainly consisted of chondrocytes with a typical spherical shape embedded in large lacunae (Fig. 3C(d)–(f)). The cell morphology was uniform, which indicated that most of the chondrocytes were at the same stages of cell differentiation.

**3.2.4 Expression of chondrogenic related gene markers.** Cell differentiation was assessed at 28 days with chondrogenic markers. There were higher expression levels of *Col2α1* and *Vegfα* in HA-coated groups compared with the control group (Fig. 4), especially in the HA/H group. However, the expression levels of *Sox9* and *Col10α1* showed no differences.

### 3.3 μCT and histological analysis

The newly formed bone (yellow color) *in vivo* was characterized by μ-CT. The average value of bone volume/total volume (BV/TV) was significantly higher in the HA/H group ( $0.205 \pm 0.006$ ) compared with the control group ( $0.115 \pm 0.003$ ) and the HA/L

group ( $0.153 \pm 0.003$ ). The difference was statistically significant between the control group and the HA-coated groups (Fig. 5d). These results show that the bioactive HA coating on the 3D scaffolds played an important role in bone regeneration.

Histological analysis based on the methylene blue and basic fuchsin staining was used to assess osteogenesis. There was integration between the newly formed bone and the scaffolds in the HA-coated groups. Furthermore, the newly formed bone (the dark red bone) was larger in the HA/H group (Fig. 6c) compared with the other two groups (Fig. 6a and b). In the control group, there was very little new bone formation and the gaps were obvious throughout the scaffold.

## 4. Discussion

To repair the clinically large maxillofacial bone defect, it is imperative to establish critically sized bone defect models *in vivo*. In this study, we demonstrated the successful bone regeneration in mandible CSDs *via* the endochondral pathway. For this purpose, electrochemically deposited HA was coated onto porous 3D scaffolds seeded with chondrogenically differentiated MSCs in rat mandible CSDs.

The 3D-structure is essential in BTE. The SLM technique could provide a porous 3D scaffold with a controllable pore size, geometry and porosity. Such 3D scaffolds are superior to the traditional 2D scaffold for bone defect regeneration.<sup>37</sup> Previous studies showed that high porosity and a macropore size above 400 μm were beneficial for the growth of bone tissues<sup>38,39</sup> and allowed higher production of GAGs.<sup>40</sup> In this study, we designed a scaffold with 85% porosity and a pore size of about 600 μm which achieved bone regeneration in mandible CSD. However, during cell seeding, the large pore size led to less cell adhesion.

Fig. 3 (A) GAG and (B) DNA content of three groups after chondrogenic priming for 4 weeks *in vitro*; asterisks (\*) indicate statistical significance,  $p < 0.05$ ; error bars represent SD ( $n = 4$ ). (C) Safranin O staining of GAG and the chondrocytes after 4 weeks of chondrogenic priming *in vitro* ( $10\times$ ), GAG was stained red throughout the scaffolds, (a–c), especially in the HA coated groups (b and c). (d, e, f) are the high magnification of (a, b, c) respectively. Black arrows indicate chondrocyte-like cells which were embedded in lacunae. Ti: titanium alloy scaffold.

Fig. 4 levels of transcripts for *Sox9*, *Col2α1*, *Col10α1* and *Vegfα* in three groups after chondrogenic priming for 4 weeks *in vitro*, \* $p < 0.05$ ; error bars represent SD ( $n = 5$ ).

In the future experiments, we will explore the optimal pore size of 3D scaffold for bone regeneration *via* the endochondral pathway.

The biological milieu can influence the extracellular matrix by host tissue-biomaterial interactions.<sup>41</sup> Previous studies showed that surface wettability and roughness were crucially important for cellular responses to the substrates.<sup>42–44</sup> In the present study, we show that the water contact angle was

significantly decreased by the HA coating on the  $\text{Ti}_6\text{Al}_4\text{V}$  scaffold (Fig. 1C(d)), indicating that the surface wettability and hydrophilicity was substantially enhanced. It is well-known that the hydrophilic surfaces could promote cell adhesion and proliferation.<sup>45</sup> Moreover, surface roughness increased after HA immobilization on the scaffolds, which could also enhance cell adhesion and proliferation.<sup>46,47</sup> In this study, the CCK-8 results and the immunofluorescent staining indicate that the HA coating showed good bioactivity, which could improve the proliferation of BMCs.

Chondrocytes are characterized by a characteristic rounded morphology and excretion of extracellular matrix, such as sulfated GAGs and *Col2α1*.<sup>48</sup> The HA coating is commonly employed to improve bone regeneration of titanium scaffolds.<sup>49</sup> However, there is no clear answer about the relationship between the HA and the formation of cartilage template elicited by MSC chondrogenic differentiation. One study by Isao Shibusawa showed that the CaP-coated hydroxyapatite mineral particles (MPs) promoted the gene expression of chondrogenic and early osteogenic markers.<sup>50</sup> However, another study showed that octacalcium phosphate suppresses chondrogenic

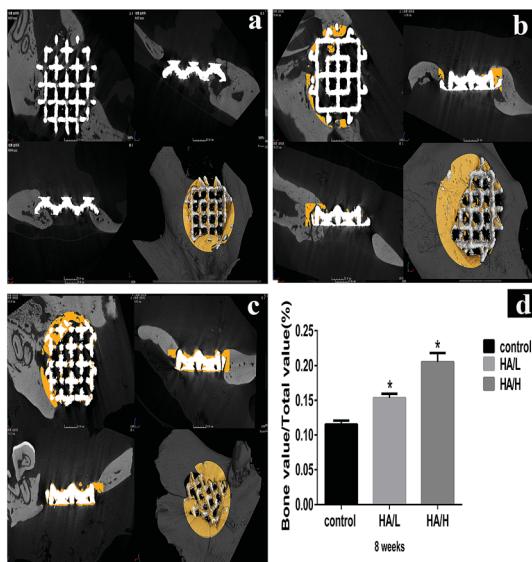

Fig. 5 Micro-CT images of (a) bare scaffold, (b) HAL coated cell-scaffold, and (c) HA/H coated cell-scaffold after being implanted in mandible critically-sized defects for 8 weeks *in vivo*. The yellow color component was newly formed bone in these scaffolds. (d) Percentages of regenerated bone volume/total volume (BV/TV) in these implants. Asterisks (\*) indicate statistical significance compared to the control group,  $p < 0.05$ .

Fig. 6 Histological overview of three groups after 8 weeks of *in vivo* implantation (10 $\times$ ). The tissue stained with dark red color was the newly formed bone marked by purple arrows. (a) Control group, (b) HAL coated group, and (c) HA/H coated group. Ti: titanium alloy scaffold.

differentiation of ATDC5 cells.<sup>51</sup> In order to mimic the endochondral ossification process, we firstly produced a cartilage template by seeding the BMSCs onto the scaffolds for chondrogenic priming *in vitro*. The RT-PCR results demonstrated the high expression of *Col2 $\alpha$ 1* and *Vegf $\alpha$*  in the HA coated group, but there was low expression of *Col10 $\alpha$ 1* and *Sox9* among the three

groups. As previous study showed, after 4 weeks of priming *in vitro*, the chondrocytes were at the late stage of hypertrophy, the expression level of *Col10 $\alpha$ 1* (ref. 52) and *Sox9* decreased.<sup>53</sup> This result was consistent with our study. The results of GAG content, expression of *Col2 $\alpha$ 1* and histological staining of safranin O in this study proved that the BMSCs successfully differentiated into chondrocytes. Moreover, the HA-coated scaffold induced higher expression of *Col2 $\alpha$ 1* and increased GAG content, especially in the HA/H coated scaffold. We conclude that the HA coating is good for the chondrogenic differentiation of the BMSCs, and larger HA crystals had a better effect than smaller crystals. However, safranin O staining showed that the majority of cartilage matrix was located at the periphery of the scaffold. During the cell seeding, we observed that due to the large pore size, the cells in the pore center were lost. In addition, we found a deficiency of cartilage template in the central part of the scaffold. We assume that BMSCs in the central part of the scaffold can't tolerate poor nutritional support and so eventually undergo apoptosis.

Subsequently the cell-scaffold structures were put into the defect site, and this *in vivo* experiment showed that the new bone formation was also located at the periphery of the scaffolds, which is in line with the cartilage deposition. The HA/H group, which had highest expression level of *Col2 $\alpha$ 1* and GAG deposition, induced the highest bone volume. It's assumed that the hypertrophic chondrocytes play important roles in bone formation. First, the hypertrophic chondrocytes release several factors, *e.g.* VEGF,<sup>54</sup> matrix metalloproteinase 13 (MMP-13), bone morphogenetic protein-2 (BMP-2), osteopontin (OPN) and osteocalcin.<sup>55</sup> The invasion of blood vessels triggers the breakdown of the cartilage matrix and new bone formation.<sup>53,56,57</sup> Secondly, the hypertrophic chondrocytes recruit osteoblast and osteoclast precursors directly promote bone formation. Thirdly, the surrounding MSCs are attracted by the hypertrophic chondrocytes and then differentiated into osteoblasts, which lead to the mineralization of the matrix.

In terms of the results mentioned above, the close relationship between the cartilage and bone formation, we assume that more cartilage formation induces more new bone formation. However, the value of BV/TV in all the groups was not encouraging. In the next step, we will make attempt to improve the cartilage production. However, we still do not know what factors played a major role in this process, and these factors may include the pore size, porosity, the coating, or the source of stem cells.

## 5. Conclusions

Based on our findings, it can be concluded that HA coatings fabricated onto porous  $Ti_6Al_4V$  scaffolds *via* ECD are favor for cell proliferation and can promote the chondrogenic differentiation of MSCs. Moreover, more bone regeneration occurred in the HA-coated group. Therefore, HA coatings of 3D porous  $Ti_6Al_4V$  scaffolds are attractive for bone defect applications *via* the endochondral pathway. In particular, larger HA crystals showed a better ability to induce cartilage matrix formation and bone regeneration.

## Conflicts of interest

There are no conflicts to declare.

## Acknowledgements

We thank Chao Cheng who helped us manufacture the 3D scaffolds and Dong Chen who assisted in making hard tissue slices.
