Visible-light-driven H₂ production and decomposition of 4-nitrophenol over nickel phosphides

Xing Liu, ab Lanhua Zhao,*c Haixia Wang,a Hua Lai,a Gang Peng,*a Junhua Li,a Zhengji Yi*a and Kang Chen a

Photocatalytic H₂ production and photocatalytic decomposition are efficient and economical methods to obtain hydrogen fuel and dispose of organic pollutants. In this paper, amorphous nickel phosphide (Ni₂P) is synthesized by an extremely simple precipitation method under low temperature. The prepared nickel phosphide was not only used to produce H₂ in the presence of Eosin Y as sensitizer and triethanolamine (TEOA) as a sacrificial electron donor but also to degrade 4-nitrophenol under visible light illumination. The rate of hydrogen evolution is 34.0 mmol h⁻¹ g⁻¹ and the degradation efficiency is 25.5% within 4 h at initial 5.0 mg L⁻¹ 4-nitrophenol. Probable photocatalytic mechanisms were discussed. The present work is expected to contribute toward the hydrogen evolution and disposal of highly toxic pollutants by cost-effective photocatalytic means.

1. Introduction

Energy and the environment are two major topics in today's society. Molecular hydrogen (H₂) is an ideal candidate as a carbon free fuel for the replacement of fossil fuels in the future. The photocatalytic approach is considered as one of the most promising ways to produce H₂ from water splitting.1–4

4-Nitrophenol, used as a raw material or intermediate for the manufacture of agrochemicals, dyes, drugs etc., is one of the most difficult organic contaminants to dispose of, with high toxicity, stability and bioaccumulation.5–6 Photocatalytic degradation of organic compounds, including 4-nitrophenol, is one of the most popular approaches of pollution control and disposal.7–12

For photocatalytic hydrogen evolution and degradation of organic compounds, many semiconductor photocatalysts, like TiO₂, can be only activated by UV light due to their high-energy band gaps. The UV light accounts for only ca. 4% to 6% of the solar spectrum, while visible light is about 43%. Thus, the development of visible-light-driven photocatalysts is needed.13–16

Transition metal phosphides have attracted considerable attention in the fields of electrochemical catalysis due to many advantages such as earth-abundance, high catalytic activity, good stability and facile synthesis.17–20 Nickel phosphide is one of the most promising candidates among transition metal phosphides because it is the most active mono-metallic phosphide.21–23 Inspired by the high activity of phosphides in electrochemical H₂ evolution, they were subsequently used as cocatalysts in photocatalytic H₂ evolution.24–26 For example, Cao et al. employed Ni₂P as cocatalysts to modify CdS, and the composite photocatalysts exhibited remarkably improved activity and excellent stability in lactic acid aqueous solution.27 However, it is a new attempt for using nickel phosphide to photocatalytically degrade organic contaminants 4-nitrophenol and photosensitized hydrogen evolution from water splitting.

In this work, nickel phosphide (Ni₂P) material was prepared by a simply precipitation method. The prepared nickel phosphide was used to degrade 4-nitrophenol under visible light illumination and produce H₂ in the presence of Eosin Y (EY) as sensitizer and triethanolamine (TEOA) as a sacrificial electron donor.

2. Experimental

Synthesis of nickel phosphide

The nickel phosphide was synthesized by a simple precipitation method using nickel acetate (Ni(Ac)₂·4H₂O) and sodium hypophosphite (NaH₂PO₂) as the starting materials, and all of the used reagents were of analytical grade and were used without further purification. Typically, 5.0 mmol of Ni(Ac)₂·4H₂O, 100.0 mmol of NaAc·3H₂O and a given NaH₂PO₂ (the mole ratio
of P/Ni = 20/1, 15/1, 10/1 and 5/1) were dissolved into 50.0 mL of distilled water by stirring for 30 min at room temperature, and then the pH of aqueous solution was adjusted to 8.0 with 1.0 M KOH, the reaction system was transferred into a 150 mL three-necked flask and heated at 90 ~ 95 °C for 12 h. The black products were filtered under vacuum, washed carefully with water and anhydrous ethanol for three times in sequence, and finally dried in a vacuum oven at 60 °C for 5 h. The nickel phosphide catalyst for H₂ production and 4-nitrophenol degradation was obtained after grinding in an agate mortar.

**Photocatalytic test**

Photocatalytic reaction was conducted at room temperature, and a high pressure Hg lamp (150 W) was used as the light source, which was equipped with a cutoff filter (λ > 420 nm) to remove the radiation below 420 nm. The IR fraction of the beam was removed by a cool water filter to ensure illumination of visible light only.

In a typical H₂ production experiment, 0.10 g of nickel phosphide catalyst was added into 80.0 mL of aqueous solution containing TEOA (9.5 × 10⁻² mol L⁻¹) and EY (pH was adjusted as 7.0 with hydrochloric acid). Before irradiation, the catalyst was dispersed in an ultrasonic bath for 5 min and N₂ was bubbled through the reaction mixture for 30 min to remove oxygen. The top of the cell was sealed with a silicone rubber septum. Sampling was operated intermittently through the septum during experiments. The amount of hydrogen evolved was determined on a gas chromatograph (TCD, 13X molecular sieve column, N₂ gas carrier).

In a 4-nitrophenol degradation experiment, 0.10 g of nickel phosphide photocatalysts was suspended into 100 mL of 4-nitrophenol aqueous solution and stirred under dark for 30 min to reach adsorption equilibrium. The mixed solution was irradiated under continuous stirring. Samples were taken out every 60 min, and centrifuged at speed of 10 000 rpm for 10 min in order to remove the photocatalysts, the obtained clear solution was analyzed using spectrophotometric method on a 7SS2 spectrophotometer (made in Shanghai, China), and the absorbance was measured at the wavelength of 315 nm.

**Characterization and instruments**

X-ray diffraction (XRD) analysis was carried out using a BRUCKER D8 polycrystalline X-ray diffractometer with Cu Kα radiation as the X-ray source (λ = 0.15406 nm) at a scan rate of 6° min⁻¹. Scanning electron microscopy (SEM) image was taken on a EVO-10 (Carl Zeiss AG, Germany) working at 30 kV, the sample was mounted onto carbon adhesive pad attached to aluminum stub. X-ray photoelectron spectroscopy (XPS) analyses were performed using an ESCALAB250xi photoelectron spectrometer (Thermon Scientific) with a monochromatized Mg Kα X-Ray resource (150 W). The C 1s peak (284.8 eV), was used as an internal reference for absolute binding energy.

**3. Results and discussion**

XPS spectra of Ni₃P were shown in Fig. 1, from the element measurement from XPS, the atom ratio of Ni/P is 2, this confirms that the prepared nickel phosphide is Ni₃P. For Ni 2p region, three peaks at 852.6, 855.5 and 861.2 eV, which is ascribed to Ni²⁺ (0 < δ < 2) in Ni₃P, oxidized Ni species (Ni²⁺) and the satellite of the Ni 2p₁/₂ peak, respectively. And the peaks at 873.1 and 879.7 eV is corresponding to Ni²⁺ in Ni₃P, oxidized Ni species and the satellite of the Ni 2p₃/₂ peak, respectively. For the P 2p, the peak at 129.9 eV is a mark of metal–P bonds in metal phosphides (i.e. NiₓP), while the peak at 133.1 eV can be attributed to the oxidized P species due to air contact.

As shown in Fig. 2, the XRD diffraction pattern of Ni₃P showed no obvious diffraction peaks, which indicates that the Ni₃P has an amorphous structure. The morphology of Ni₃P is revealed using SEM. As shown in Fig. 3A and B, the Ni₃P sample is composed of nanospheres with various sizes, and nanospheres are stacked together. The statistical particle size distributions of Ni₃P were shown in Fig. 3C, the average diameter of Ni₃P nanospheres is 800 ± 30 nm.

A noble-metal-free hydrogen production system was constructed with the as-prepared Ni₃P as a catalyst, EY as a photosensitizer, and TEOA as a sacrificial electron donor. It is observed from Fig. 4 that Ni₃P (without photosensitizer) displays very low photocatalytic H₂ evolution activity, while no
H₂ can be observed in the system containing only EY (without nickel phosphides). And the EY–Ni₂P (EY sensitized Ni₂P) system has a remarkable activity under the same experimental condition, the rate of hydrogen generation is 34.0 μmol h⁻¹ g⁻¹. The result indicates that EY can markedly enhance the hydrogen generation activity.

From the UV-Vis absorption spectra of EY (the inset of Fig. 4), EY can strongly absorb visible light during the range of 450 ~ 560 nm with the absorption centre at 515 nm. When the EY photosensitizer is irradiated by visible light, EY absorbs photons, and electrons in the HOMO (highest occupied molecular orbital) can be excited to the LUMO (lowest unoccupied molecular orbital), and resulting in excited EY*. EY* is prevalingly quenched reductively by electron donor TEOA to form radical EY⁻ anion, the surplus electrons of EY⁻ can be trapped by Ni₂P, and then the electrons react with H⁺ adsorbed on Ni₂P to generate H₂ gas. A possible reaction mechanism of the hydrogen evolution is shown in Fig. 5. However, the produced EY⁻ anion could also undergo self-degradation by debromination, the self-degradation decreases the sensitization activity.³³,³⁵

In Fig. 4, it can be found that the H₂ evolution activity decreased in the last two hours, this phenomenon suggests the above discussion.

Based on the above discussions, the EY plays a critical role in number of photo-induced electrons, which results in the photocatalytic hydrogen evolution. Fig. 6A shows the impact of EY concentration on hydrogen evolution. The photocatalytic activities increases first and then declines with increase of EY concentration, and reached a maximum at 3.1 × 10⁻⁴ mol L⁻¹. If no dye is added, only a little evolved hydrogen is observed, this demonstrates that hydrogen generation is indeed driven by dye sensitization. When concentration of EY increases from 0 to 3.1 × 10⁻⁴ mol L⁻¹, the antenna effect of dye to absorb light is boosted, more and more radical EY⁻ anion generates, thus the hydrogen evolution is improved. Nevertheless, when the concentration of EY is extremely high, numerous free dye molecules in solution absorb the input light but would not contribute to hydrogen evolution reaction. Moreover, greater collisional deactivation of the EY* excited state happens due to

serried dye molecules, so the activity of hydrogen evolution
would not increase. Fig. 6B reveals the effect of mole ratio of
initial P/Ni on hydrogen evolution over EY sensitized Ni₂P, the
highest photo-activity occurs at P/Ni = 10. All Ni₂P samples
prepared with different ratio of initial P/Ni has exactly similar
XRD diffraction patterns, indicating that they are amorphous.
When the ratios of initial P/Ni are 5/1, 10/1, 15/1, 20/1, the BET
specific surface areas of the prepared nickel phosphides
samples are 18.9, 27.7, 23.1, 20.5 m² g⁻¹, respectively. This
suggests that the specific surface areas of nickel phosphide with
ratio of initial P/Ni = 10 is largest. Since the hydrogen evolution
reaction is surface-dependent, a large surface area should
provide more surface active sites for the adsorption of reactants,
making the photocatalytic H₂ production more efficient.

The photocatalytic performance of Ni₂P was also evaluated
by degradation of 4-nitrophenol under visible light illumina-
tion. As shown in Fig. 7A, self-degradation of 4-nitrophenol is
almost negligible when the initial concentrations of 4-nitro-
phenol is 5 mg L⁻¹. In the presence of the Ni₂P, the remarkable
degradation was found, and the degradation efficiency is 25.5%
within 4 h. In 4-nitrophenol degradation, the activity decrease
in second cycle degradation is not obvious (see the inset of

Fig. 4 Time courses of photocatalytic H₂ production of EY–Ni₂P and
Ni₂P. Conditions: 0.10 g Ni₂P, 9.5 × 10⁻² mol L⁻¹ TEOA, light source:

absorption spectra of EY.

Fig. 5 Schematic illustration of probable mechanism of photo-
sensitized hydrogen production. Noted that EY⁺, EY⁻, TEOA represent
the triplet excited state of Eosin Y, the radical anion of Eosin Y and
triethanolamine, respectively.

Fig. 6 Effect of (A) initial EY concentration and (B) mole ratio of initial
P/Ni on hydrogen evolution of EY sensitized Ni₂P.

Fig. 7A), this indicates that nickel phosphides is stable. A
control experiment reveals that the degradation of 4-nitro-
phenol over Ni₂P under dark condition is also negligible, this
result confirms that the degradation is indeed a photochemical
reaction. The degradation efficiency of 4-nitrophenol over Ni₂P
is not high, which can be explained as following: firstly, charge
recombination happens easily in Ni₂P when it is excited by
visible light, thus the generated oxidative species (see the
following discussion) is limited. Secondly, the light source in
our experiments was a 150 W high pressure Hg lamp (equipped
with a cutoff filter (λ > 420 nm)), compared with xenon lamp, its
light intensity was very low, so the photocatalytic activity is low.
In addition, the BET specific surface areas of prepared nickel
phosphides is relatively small (<28 m² g⁻¹), so photocatalytic
active sites are limited.

According to previous study, the kinetic behavior of the
photocatalytic reaction obeys pseudo-first-order kinetics. To
confirm this speculation, the natural logarithm of 4-nitro-
phenol concentration ln(C/C₀) is plotted as a function of irra-
diation time (C and C₀ are the concentrations of 4-nitrophenol
at time t and zero, respectively). The kinetics for the photo-
degradation of 4-nitrophenol was shown in Fig. 7B, the
regression curve is roughly linear, indicating that the kinetics of 4-nitrophenol degradation over the photocatalyst is indeed pseudo-first-order, and the reaction rate constant $k$ was calculated to be 0.16 h$^{-1}$.

As is known, the photocatalyst Ni$_2$P can be directly excited to generate electron (e$^-$)–hole (h$^+$) pairs after visible light illumination. The photoinduced holes react with surface-bound H$_2$O and produce the hydroxyl radical ·OH species that are extremely strong oxidant for the mineralization of organic pollutants, including 4-nitrophenol. Meanwhile, the photoinduced electrons can react with the adsorbed molecular oxygen to yield superoxide radical ·O$_2^-$, which combine with H$^+$ to produce HO$_2^*$. The HO$_2^*$ can further react with the trapped electrons to generate ·OH radicals. To further study the photocatalytic mechanism and identify the main oxidative species (h$^+$, ·OH and ·O$_2^-$) in the photocatalytic process, we studied the effect of active-species scavengers on the degradation of 4-nitrophenol. It is found that ·OH and ·O$_2^-$ radicals are the main reactive species in the photocatalytic degradation. The intermediate products of 4-nitrophenol photodegradation include 4-nitrocatechol, 1,2,4-benzenetriol, hydroquinone, which have been demonstrated by previous works containing ours.$^{34,37,38}$ The ultimate products are carbon dioxide, water, nitrate after complete mineralization.

Fig. 8 illustrates the performance of Ni$_2$P when the initial concentrations of 4-nitrophenol vary from 2.5 to 15.0 mg L$^{-1}$. The dependence of the photodegradation yield of 4-nitrophenol on the initial concentration may be based on the fact that the degradation reaction mainly occurs on Ni$_2$P surface. On the surface of catalyst, the reaction happens between ·OH radicals and 4-nitrophenol molecules. When the initial 4-nitrophenol concentration is low, the transfer rate plays an important role, the adsorption of 4-nitrophenol on the catalyst surface increases as the initial concentration increases, which in favour of the subsequent photocatalytic degradation. However, with further increase of 4-nitrophenol concentration, the rate of photocatalytic degradation decreases due to the reduced ratio of ·OH (or ·O$_2^-$)/4-nitrophenol. Therefore, the highest photocatalytic degradation efficiency is obtained when the initial 4-nitrophenol concentration is 5.0 mg L$^{-1}$. This finding demonstrates that the degradation kinetics of 4-nitrophenol is indeed not of simple first order but pseudo first order within the experimental range, which is consistent with many previous reports.$^{37–40}$

4. Conclusions

In conclusion, nickel phosphide was synthesized by a simple precipitation method, XRD and SEM characterization results demonstrate that the Ni$_2$P is an amorphous nanospheres. Eosin Y sensitized nickel phosphide displays relatively high photocatalytic activity for hydrogen evolution with the rate of 34.0 µmol h$^{-1}$ g$^{-1}$. The Ni$_2$P also exhibits 4-nitrophenol degradation under visible light illumination with degradation efficiency of 25.5% within 4 at initial 5.0 mg L$^{-1}$ 4-nitrophenol.
concentration. Probable mechanisms of photocatalytic hydrogen evolution and photo-degradation of 4-nitrophenol were discussed.
