Site-selective bromination of sp$^3$ C–H bonds†

Shyam Sathyamoorthi, a Shibdas Banerjee, b J. Du Bois,*a Noah Z. Burns b,*a and Richard N. Zare b,*a

A method for converting sp$^3$ C–H to C–Br bonds using an N-methyl sulfamate directing group is described. The reaction employs Rh$_2$(oct)$_4$ and a mixture of NaBr and NaOCl and is performed in aqueous solution open to air. For all sulfamates examined, oxidation occurs with high selectivity at the γ-carbon, affording a uniquely predictable method for C–H bond halogenation. Results from a series of mechanistic experiments suggest that substrate oxidation likely proceeds by a radical chain process. Initial formation of an N-halogenated sulfamate followed by Rh-mediated homolysis generates an N-centered radical, which serves as the active oxidant.

Introduction

Oxidation of a specific sp$^3$ C–H bond in a complex molecule remains an outstanding challenge in reaction methods development.1-3 While several protocols for the selective conversion of sp$^3$ C–H centers to C–N and C–O bonds are now available,4-14 fewer methods for the synthesis of C–halogen bonds15-18 have been described despite the fact that molecules bearing halogen functional groups are prevalent in nature. In addition, as alkyl halides are versatile precursors for a variety of synthetic transformations, including cross-coupling, substitution, elimination, and the installation of boron-, silicon-, nitrogen-, and oxygen-based functional groups, methods for accessing these types of materials have value in synthesis.19-23 Here, we describe a reaction protocol for the site-selective bromination of sp$^3$ C–H bonds using an N-methyl sulfamate directing group. This auxiliary is facile to install on 1° and 2° alcohol derivatives and can be removed through nucleophilic displacement. Mechanistic studies suggest that the reaction proceeds through an N-centered radical, reminiscent of the Hoffman–Löffler–Freytag amine synthesis.24-26 With all sulfamates tested, oxidation occurs preferentially at the γ-carbon, offering a predictable and precise method for oxidative C–H bond halogenation under mild reaction conditions.

Results and discussion

Initial optimization of conditions for alkylbromide formation was performed with isopentyl methylsulfamate 1, a simple, unfunctionalized substrate with a single tertiary C–H bond. A variety of transition metal salts were tested in conjunction with 3 equivalents each of NaBr and NaOCl, a reagent combination known to generate hypobromite in situ and used previously for the oxidative cyclization of sulfamate esters.27 While little to no reaction ensued in the presence of catalytic Mn$^{3+}$, Co$^{2+}$, Cu$^{2+}$,

and Ni²⁺ (Table 1, entries 1–4), switching to Rh₂(oct)₄ (Table 1, entry 5) afforded a marked increase in conversion to brominated product 2. The choice of dirhodium complex had a clear influence on reaction performance, as catalysts bearing hydrophobic ligands such as octanoate or triphenylacetate (Table 1, entries 5–7) out-performed others tested (Table 1, entries 8, 9), likely owing to the greater solubility of these complexes in dichloromethane. In the complete absence of transition metal, conversion to product still occurred (Table 1, entry 10) in a process that appears to be promoted by ambient light (Table 1, entry 11).

A 1 : 1 biphasic mixture of CH₂Cl₂/saturated aqueous Na₂HPO₄ was found to be the optimal solvent combination (Table 1, entry 5). In neat CH₂Cl₂, conversion to product was significantly reduced, and in unbuffered water with CH₂Cl₂ a mixture of both brominated and chlorinated products was obtained (Table 1, entries 12 and 13). Using organic co-solvents other than CH₂Cl₂ was similarly deleterious to reaction performance (Table 1, entries 14 and 15).

A range of structurally diverse N-methyl sulfamates has been prepared by condensation of the corresponding 1° and 2° alcohols with ClSO₂NHMe and subjected to the optimized halogenation protocol (Table 2). Oxidation of both tertiary and benzylic C–H bonds is possible in moderate to good yields, even with Rh₂(oct)₄ loadings as low as 0.1 mol% (entry 2). Different functional groups, including alkyl and benzylic esters, epoxides, trichloroethylsulfamate-protected aziridines, and silylated alcohols, are compatible with these conditions (Table 2, entries 3–6). For all substrates examined, C–H bond oxidation occurs nearly exclusively at the γ-carbon. This finding compares favorably with other directed C–H halogenation methods, which afford mixtures of constitutional isomers.¹⁵,²⁰ The directed nature of this process is further highlighted in entries 8, 9, and 10. Each of these substrates furnishes the product of γ-C–H bond bromination despite possessing an activated benzylic C–H center. Positional selectivity is also noted in entries 11 and 12. Experiments with the latter substrate show that oxidation of an optically active 3° C–H bond gives racemic alkylbromide, a result consistent with the formation of a carbon-centered radical intermediate (vide infra). In addition, we have found that the absence of NaBr leads to generation of the corresponding chlorinated product (entry 12), albeit in reduced yield. All told, this new protocol offers an efficient, predictable, operationally simple method for C–H bond functionalization.

Displacement of the N-methyl alkoxy sulfanyl auxiliary can be achieved in a single-flask, two-step protocol that involves initial N-carbamoylation with Boc₂O followed by an S₈2 reaction (Scheme 1). The N-acylated sulfamate undergoes smooth reaction with nucleophiles such as N₃⁻ and I⁻ to give the corresponding alkylazide and alkyl iodide products, respectively. This method for excising the sulfamate directing group should add to the overall utility of the C–H halogenation process.

Previous work exploring the use of NaBr/NaOCl for the synthesis of [1,2,3]-oxathiazinan-2,2-dioxide heterocycles suggested the formation of an N-halogenated species as a first step in the reaction pathway. In accord with this hypothesis, we
have demonstrated that the N,N-dimethyl sulfamate 3 is not a competent substrate for oxidation. Additionally, we have prepared an N-brominated sulfamate 5 and have shown that this compound will react with 5 mol% Rh$_2$(oct)$_4$ to form alkyl-bromide 6 in 40% yield (Scheme 2 and Fig. S3†). Although the efficiency of this process is reduced from that of the catalytic protocol (entry 1, Table 2), these findings establish the N-brominated species as a chemically competent intermediate on the reaction pathway.

The ability to access N-brominated sulfamate 5 has enabled a series of experiments to determine the role of Rh$_2$(oct)$_4$ in the oxidation reaction. UV/Visible spectroscopic monitoring of the reaction of 5 with Rh$_2$(oct)$_4$ in CH$_2$Cl$_2$ reveals a distinct change in the absorption spectrum, evidenced by the disappearance of the feature at $\lambda_{max} = 418$ nm, shifting of the $\lambda_{max}$ at 655 to 595 nm, and the appearance of a new $\lambda_{max}$ at 985 nm (Fig. 1a).

The final absorption spectrum is indicative of a mixed-valent Rh$^{2+}$/Rh$^{3+}$ tetracarboxylate dimer, consistent with a mechanism involving one-electron reduction of the N-Br bond to generate an N-centered radical. Support for this conclusion has been obtained through electrospray ionization mass spectrometric (ESI-MS) analysis, which confirms the presence of both the Rh$^{2+}$/Rh$^{3+}$ complex and free Br$^-$ (Fig. 1b–c) resulting from this reaction.

In a reaction mixture containing 5 and Rh$_2$(oct)$_4$, the red color ascribed to the mixed-valent dirhodium species persists for several hours. Under standard catalytic reaction conditions, however, the deep green color of intact Rh$_2$(oct)$_4$ bleaches to pale yellow within 30 min following NaOCl addition. A UV/vis spectrum of the reaction mixture at this time point shows a featureless spectrum, consistent with decomposition of the rhodium dimer (Fig. S4a†). Interestingly, at 30 min, product conversion is only ~30%, with starting material accounting for the remainder of the mass balance (Fig. S4b†). After the full reaction time (15 h), the isolated product yield is 61%. Thus, the reaction appears to proceed beyond the lifetime of Rh$_2$(oct)$_4$, suggesting its role as an initiator rather than as a catalyst for oxidative halogenation (Scheme 3). Accordingly, these data have led us to favor a mechanism for C–H bromination through a chain transfer process involving N- and C-centered radical intermediates, as depicted in Scheme 3. We cannot, however, discount the possibility that the intermediate carbon radical could also react with [Rh$_2$(oct)$_4$Br] to give the brominated product.

To test for a radical chain mechanism, a 1 : 1 mixture of brominated sulfamate 5 and chlorinated sulfamate 10 was stirred with catalytic Rh$_2$(oct)$_4$. ESI-MS analysis of the reaction mixture at 2 h revealed brominated products 2 and 6 and chlorinated products 11 and 12 (Fig. 2 and S5†). Such a product distribution lends strong support to our mechanistic scheme, as only an intermolecular collision between intermediates derived from 5 and 10 could lead to cross-halogenated products 2 and 12.

As a final piece of mechanistic insight, a kinetic isotope effect (KIE) of $[P_D]/[P_O] = 3$ (Scheme 4 and Fig. S6†) has been measured in a competition experiment between proto- and

![Scheme 1](image1.png)

**Scheme 1** Representative sulfamate displacement reactions.
deutero-sulfamate substrates, 13 and 14. This result suggests that N-centered radical formation is not a committed, irreversible step. Reactions of 15 with a second N-halogenated sulfamate (or HOBr) to form 16 or with solvent to regenerate 13 are possible pathways that apparently compete with intramolecular γ-C–H abstraction, thus giving rise to a non-unitary KIE value in the competition experiment.59

Given a radical chain mechanism for C–H halogenation, it is possible that metal complexes other than Rh2(oct)4 could serve as initiators. We have found that treatment of 5 with a combination of 15 mol% CuBr2 and 1,10-phenanthroline forms the tertiary bromide product 6 in 31% yield (Scheme 5 and Fig. S7†).60 While the efficiency of this reaction is lower than that with Rh2(oct)4 (Scheme 2), formation of 6 suggests that, at least in principle, new reaction manifolds utilizing first-row transition metals can be optimized for the oxidative halogenation of sp3 C–H bonds.

Conclusions
A method for site-selective bromination of sp3 C–H bonds using N-methyl sulfamate substrates is presented. Following halogenation, the sulfamate directing group can be displaced with nucleophiles to generate value-added alkylbromide products. The scope and predictability of this oxidation reaction distinguish these findings. UV/visible spectroscopy, ESI-MS analysis, and substrate probe experiments implicate a radical chain mechanism for C–H halogenation, initiated by Rh2(oct)4. Further exploration of sulfamate directing groups in C–H functionalization catalysis is warranted and should lead to high-precision methods for modifying sp3 carbon centers.
