Inhibition of hydrocarbon autoxidation by nitroxide-catalyzed cross-dismutation of hydroperoxyl and alkylperoxyl radicals†

Kareem A. Harrison, Evan A. Haidasz, Markus Griesser  and Derek A. Pratt *

Nitroxides are putative intermediates in the accepted reaction mechanisms of the diarylamine and hindered amine antioxidants that are universally added to preserve synthetic and natural hydrocarbon-based materials. New methodology which enables monitoring of hydrocarbon autoxidations at low rates of radical generation has revealed that diarylnitroxides and hindered nitroxides are far better inhibitors of unsaturated hydrocarbon autoxidation than their precursor amines, implying intervention of a different mechanism. Experimental and computational investigations suggest that the nitroxides catalyze the cross-dismutation of hydroperoxyl and alkylperoxyl radicals to yield O₂ and a hydroperoxide, thereby halting the autoxidation chain reaction. The hydroperoxyl radicals – key players in hydrocarbon combustion, but essentially unknown in autoxidation – are proposed to derive from a tunneling-enhanced intramolecular (1,4-) hydrogen-atom transfer/elimination sequence from oxygenated radical addition intermediates. These insights suggest that nitroxides are preferred additives for the protection of hydrocarbon-based materials from autoxidation since they exhibit catalytic activity under conditions where their precursor amines are less effective and/or inefficiently converted to nitroxides *in situ*.

Introduction

Autoxidation, the archetype free radical chain reaction, limits the lifetime of all hydrocarbon-based materials – natural products such as lipids and terpenes as well as synthetic products such as plastics and lubricants. Unsaturated moieties within these materials render them particularly sensitive to autoxidation; they are activated toward H-atom abstraction by chain-carrying peroxyl radicals and also undergo addition reactions to propagate the chain process (Fig. 1A). Diarylamines and hindered aliphatic amines comprise two of the three key types of radical-trapping antioxidants (RTAs) commonly added to preserve hydrocarbon-based materials.^{1,2} Extensive investigations since the mid-1950s have established that diarylamines trap 2 peroxyl radicals at ambient temperatures,^{3,4} but at elevated temperatures trap far more⁵ by a catalytic mechanism (the “Korcek cycle”, Fig. 1B)^{6,7} involving the formation of diarylnitroxide intermediates.^{8,9} In contrast, hindered amines are not RTAs at ambient temperatures, but at elevated temperatures or prolonged irradiation⁵ they lead to nitroxides which trap radicals in a distinct, but still catalytic manner (the “Denisov cycle”, Fig. 1C).^{10,11}

Although nitroxides are key intermediates in both the Korcek and Denisov cycles, they do not react with peroxyl radicals directly in these mechanisms – and thereby adhere to the longstanding dogma that nitroxides do not react with oxygen-centered radicals. This belief is based largely on the seminal work of Thomas⁸ and Ingold,¹² who showed that diphenylnitroxide and 4-oxo-2,2,6,6-tetramethylpiperidin-1-oxyl were not particularly effective inhibitors of the autoxidation of cumene and styrene, respectively. Instead, it was proposed that they only retard the autoxidation by competing with O₂ for the chain-carrying alkyl radicals – a difficult competition since the reaction of nitroxides with alkyl radicals is at least an order of magnitude slower^{13,14} than that of O₂.¹⁵ Paradoxically, this reaction is invoked in both the Korcek and Denisov cycles, implying that catalytic RTA activity arises only when the nitroxide concentration exceeds that of O₂.

We recently made the stunning observation that diarylnitroxides and hindered nitroxides are far better inhibitors of unsaturated hydrocarbon autoxidation than are their precursor amines at ambient to moderate temperatures (*vide infra*). These results were obtained at lower rates of radical generation than those typically employed in laboratory experiments, implying that the mechanism responsible operates at lower steady state concentrations of radicals – a situation representative of most ‘real world’ applications. Moreover, these results suggest a different mechanism of antioxidant activity for the nitroxides than in the Korcek and Denisov mechanisms – insight which could be leveraged for the design and development of badly

needed new antioxidant technology. Our observations are presented below, alongside our efforts to elucidate the mechanism and a discussion of the practical implications of these insights: most importantly, that nitroxides should be considered as additives to increase the longevity of both natural and synthetic hydrocarbon-based materials *in lieu* of currently used amines.

Results

I. Nitroxides are good inhibitors of styrene, but not cumene, autoxidations at low rates of radical generation

We recently reported a method to monitor inhibited autoxidations of hydrocarbons which makes use of highly absorbing and highly autoxidizable probes as signal carriers (*e.g.* STY-BODIPY, Fig. 2A).¹⁸ The consumption of the probe is monitored by conventional spectrophotometry, and since its reactivity toward peroxy radicals can be independently determined (*e.g.* $k_{\text{STY-BODIPY}} = 4012 \text{ M}^{-1} \text{ s}^{-1}$ in styrene/chlorobenzene at 70 °C, see ESI†), the inhibition rate constant (k_{inh}) of an added RTA and the stoichiometry of the inhibition (n , *i.e.* how many chain-

carrying radicals are trapped by each molecule of RTA) can be easily derived from the data as in Fig. 2B. During our efforts to validate this approach – by comparison to measurements using the venerable O₂ uptake method^{19–21} – we obtained unexpected results in autoxidations of styrene inhibited by 4,4'-di-*tert*-butyldiphenylamine and its corresponding nitroxide (hereafter Ar₂NH and Ar₂NO, respectively). To our great surprise, the nitroxide was a significantly better RTA than the amine (Fig. 2C) – not just in terms of its kinetics (apparent $k_{\text{inh}} = 7.9 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for Ar₂NO compared to $k_{\text{inh}} = 7.9 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ for Ar₂NH),²² but in that the nitroxide trapped significantly more radicals than the amine ($n = 10.6 \pm 0.2$ for Ar₂NO compared to $n = 2.1 \pm 0.2$ for Ar₂NH). These results stand in stark contrast to the seminal results obtained by Thomas⁸ and Ingold.¹² Since Thomas had used cumene as the autoxidizable substrate, we carried out autoxidations of cumene as well, again using STY-BODIPY as the signal carrier,¹⁸ but under otherwise identical conditions to Thomas (0.29 M cumene in chlorobenzene, initiated by 1.0 mM AIBN at 68.5 °C and inhibited by 50 μM of diphenylamine). Our results were fully consistent with Thomas'

Fig. 2 Preliminary studies. (A) STY-BODIPY and PBD-BODIPY can be used as signal carriers in the autoxidation of organic substrates. (B) The rate constants (k_{inh}) and stoichiometries (n) for the reactions of inhibitors (RTAs) with chain-carrying peroxy radicals can be derived from the initial rate of probe consumption and the duration of the inhibited periods (t_{inh}), respectively. (C) Co-oxidations of styrene (3.5 M) and STY-BODIPY (10 μM) in PhCl initiated with di-tert-butylperoxide (218 mM) at 70 °C (black) and inhibited by Ar₂NO, Ar₂NH and TEMPO (2 μM). (D) Stoichiometry of peroxy radical-trapping by Ar₂NO, TEMPO and PMC as a function of rate of initiation of styrene autoxidations at 70 °C (obtained using 62.5, 125, 250, 375 and 1000 μM AIBN). Reaction progress was monitored at 571 nm ($\epsilon = 97\,235\text{ M}^{-1}\text{ cm}^{-1}$).

observations, in terms of both reactivity and stoichiometry, *i.e.* $n = 2.3 \pm 0.1$ for Ar₂NH and $n = 1.1 \pm 0.1$ for Ar₂NO (Fig. S1†).

Recognizing that Ingold's styrene autoxidations had been carried out under significantly different conditions from our own, we attempted experiments using Ingold's conditions (7.24 M styrene in *o*-dichlorobenzene, initiated by 4.3 mM AIBN at 65 °C and inhibited by 4.3 mM antioxidant). Unfortunately, it was impossible to monitor reaction progress by STY-BODIPY consumption due to the absorbance of the massive amounts of antioxidant and/or its oxidation products. However, when the antioxidant and initiator concentrations were reduced to those of Thomas (50 μM and 1 mM, respectively), we observed a relative reactivity that was consistent with what had been reported by Ingold, *i.e.*, Ar₂NH was more reactive than Ar₂NO (Fig. S2†). Interestingly, the nitroxide still possessed a longer inhibition time than the amine. Ingold wasn't able to report on the stoichiometry of the inhibition due to the length of the inhibited time at the antioxidant concentrations he employed.

Given these results, corresponding data were obtained with 2,2,6,6-tetramethylpiperidine-*N*-oxyl (hereafter TEMPO), the quintessential nitroxide. The results are shown alongside those for Ar₂NO in Fig. 2C (the corresponding tetramethylpiperidine was not investigated as it is known to be unreactive to peroxy radicals; its N-H BDE is *ca.* 10 kcal mol⁻¹ higher than that of diphenylamine).²³

Consistent with previous work,²⁶ TEMPO was unable to inhibit the autoxidation of cumene (data not shown), but consistent with the foregoing results, it inhibited the autoxidation of styrene with kinetics and stoichiometry similar to those observed for Ar₂NO, *i.e.* apparent $k_{inh} = 2.1 \times 10^6\text{ M}^{-1}\text{ s}^{-1}$ and $n = 9.3 \pm 0.9$. Thus, it would appear that the RTA activity is

largely independent of the nitroxide structure, but strongly dependent on both the structure of the substrate and the rate of initiation of the autoxidation. This last point can be seen clearly from the results in Fig. 2D, where the stoichiometry determined from a series of nitroxide-inhibited autoxidations of styrene are plotted as a function of the rate of initiation (through an [AIBN] range of 62.5 μM to 1 mM). The variation in n is remarkable, spanning $n = 18.3 \pm 0.5$ and 21.9 ± 1.4 at $R_i = 3.7 \times 10^{-9}\text{ M s}^{-1}$ to $n = 1.9 \pm 0.2$ and 2.1 ± 1.4 at $R_i = 6.1 \times 10^{-8}\text{ M s}^{-1}$ for Ar₂NO and TEMPO, respectively. Laboratory autoxidations are generally carried out at the high end of this range of rates of initiation for practical reasons (ease of measurement by established methods, convenient timescale). In the 'real world', autoxidations proceed relatively slowly. It is important to note that the foregoing experiments were carried out at 70 °C to facilitate comparison with Thomas and Ingold's seminal data. Corresponding experiments carried out at 37 °C yielded similar trends, albeit with lower values of n for similar R_i (*e.g.* $n = 10.9 \pm 0.1$ and 10.1 ± 0.1 at $R_i = 2.8 \times 10^{-9}\text{ M s}^{-1}$ for Ar₂NO and TEMPO, respectively – see ESI† for additional data).

II. Nitroxides are effective inhibitors of unsaturated, but not saturated, hydrocarbons

To better understand the substrate dependence of this reactivity, investigations were expanded to include autoxidations of other activated hydrocarbons. Since styrene and cumene differ in the presence/absence of a reactive alkene, autoxidizable substrates were selected that either possess an alkene (cyclooctene and norbornene) or do not (ethylbenzene and dioxane). Representative results for these substrates are shown in Fig. 3.

In a strikingly consistent fashion, autoxidations of the substrates that possess an unsaturation were very effectively inhibited by the nitroxides whereas those lacking one, were not. Moreover, while the diarylamine expectedly inhibited the autoxidation of all the substrates, it was noticeably more effective in the unsaturated ones, retarding the autoxidations well past the initial inhibited periods corresponding to $n = 2$. Since diarylamines are known to be converted to diarylnitroxides under autoxidative conditions (*i.e.* Fig. 1B), this suggests that the retardation of autoxidations of cyclooctene and norbornene beyond the nominal inhibition period result from the *in situ* formation of nitroxide. Indeed, when the autoxidations were followed by EPR spectroscopy, significant concentrations of nitroxide were observed, reaching a steady-state concentration (*ca.* 50% and 20% of the initial amine concentration for cyclooctene and norbornene, respectively) around the same time as the autoxidation rate became constant. Taken together, these results suggest that, in unsaturated hydrocarbons, nitroxides must be converted to very efficient RTAs.

III. The *in situ* formation of hydroxylamines accounts for the observed inhibition of autoxidation unsaturated substrates

Since nitroxide-derived alkoxyamines have long been implicated as key intermediates in the RTA activity of diarylamines (Fig. 1B) and hindered amines (Fig. 1C), we sought to determine

if they contribute to the observed reactivity in styrene. Thus, *O*-phenethyl *N,N*-(4-*tert*-butylphenyl)hydroxylamine and the corresponding *O*-phenethylated 2,2,6,6-tetramethylpiperidine-*N*-ol were synthesized (see ESI†) and their reactivity in the styrene autoxidations was assessed. The phenethyl substituent was chosen due to its similarity to the propagating benzylic radicals that would combine with the nitroxides in inhibited autoxidations of styrene. The data, which show that the alkoxyamines are unreactive, are given in Fig. 4A and B.

For comparison, we also investigated the corresponding hydroxylamines, which are clearly excellent inhibitors. The initial rates yield $k_{\text{inh}} = (8.5 \pm 1.3) \times 10^6$ and $(3.0 \pm 0.7) \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for Ar_2NOH and TEMPOH, respectively, the latter in excellent agreement with literature precedent ($k_{\text{inh}} = 3.0 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ at 30 °C).²⁶ To the best of our knowledge, this is the first time a rate constant has been determined for a diarylhydroxylamine in a non-aqueous solvent; it is slightly greater than for TEMPOH, likely due to lower steric hindrance. The reaction stoichiometry is essentially +1 radical relative to the nitroxide (*viz.* 11.6 ± 0.1 and 10.0 ± 0.2 , respectively), consistent with an initial H-atom transfer from the hydroxylamine to produce the nitroxide, which then reacts as when it is added directly.

The similar initial rates of the autoxidations inhibited by the hydroxylamines and nitroxides prompted us to consider if nitroxides could be reduced to hydroxylamines *in situ*. Recent work by Litwinienko and Amorati²⁷ has shown that 1,4-cyclohexadiene (hereafter 1,4-CHD) autoxidations are very efficiently

Fig. 3 Substrate dependence. Co-autoxidations of STY-BODIPY (10 μM) and ethylbenzene (3.3 M, (A)), cyclooctene (3.1 M, (B)), norbornene (1.0 M, (C)) and dioxane (2.9 M, (D)) in chlorobenzene initiated with di-*tert*-butylperoxide (87 mM for ethylbenzene, 218 mM for cyclooctene, norbornene and dioxane) at 70 °C (black) and inhibited by TEMPO, Ar_2NO and Ar_2NH (2 μM). Reaction progress was monitored at 569 nm in (A) ($\epsilon = 123\,481 \text{ M}^{-1} \text{ cm}^{-1}$), 568 nm in (B) ($\epsilon = 113\,982 \text{ M}^{-1} \text{ cm}^{-1}$), 568 nm in (C) ($\epsilon = 118\,405 \text{ M}^{-1} \text{ cm}^{-1}$) and 569 nm in (D) ($\epsilon = 122\,873 \text{ M}^{-1} \text{ cm}^{-1}$). (E) Concentration of Ar_2NO determined by EPR (spectrum shown) during Ar_2NH -inhibited co-autoxidations.

(A) Co-oxidations of styrene (3.5 M) and STY-BODIPY (10 μM) in PhCl initiated with di-*tert*-butylperoxide (218 mM) at 70 °C (black) and inhibited by 2 μM of Ar_2NOR (dotted line), Ar_2NH (dashed line), Ar_2NO (solid line) and Ar_2NOH (dotted/dashed line). (B) Co-oxidations carried out under the same conditions and inhibited by TEMPOR (dotted line), TEMPO (solid line) and TEMPOH (dotted/dashed line). Reaction progress was monitored at 571 nm ($\epsilon = 97\,235 \text{ M}^{-1} \text{ cm}^{-1}$). (C) Mechanism of 1,4-cyclohexadiene autoxidation. (D) Co-oxidations of 1,4-CHD (0.26 M) and PBD-BODIPY (10 μM) in chlorobenzene at 30 °C initiated by di-*tert*-butylperoxide (218 mM, black) and inhibited by 2 μM of TEMPO (red line), Ar_2NO (blue line), PMC (orange line) and Ar_2NH (dashed line). Reaction progress was monitored at 591 nm ($\epsilon = 130\,797 \text{ M}^{-1} \text{ cm}^{-1}$). (E) Nitroxide-catalyzed dismutation of hydroperoxyl radicals showing the CBS-QB3-calculated TS structure for the reaction of TEMPO with HOO^\bullet .

inhibited by phenols because the hydroperoxyl radicals (HOO^\bullet) that are known to carry the chain reaction (Fig. 4C)²⁸ can regenerate the phenol. Amazingly, 1,4-CHD/PBD-BODIPY co-oxidations were perpetually inhibited by either TEMPO or Ar_2NO (Fig. 5C). Both nitroxides were demonstrably better than PMC, a truncated analog of vitamin E and one of the most reactive phenolic antioxidants known. (Phenols are the other key type of RTA commonly added to preserve hydrocarbon-based materials.) This is presumably due to the more efficient conversion of nitroxides to chain-breaking hydroxylamines upon reduction by HOO^\bullet compared to the PMC-derived radical, which can also react *via* addition to the aryl ring giving inactive peroxy-phenoxyl adducts.²⁷ TEMPO was observed to be a slightly better inhibitor than Ar_2NO , perhaps since the latter can (like the PMC-derived phenoxyl) undergo competitive addition of HOO^\bullet to the aryl ring. It is interesting that this reactivity trend is opposite of what is observed in styrene and norbornene, where Ar_2NO is more effective than TEMPO, perhaps because alkylperoxyl addition is more reversible than HOO^\bullet addition.

Although the O–H bonds of hydroxylamines are considerably weaker than the O–H bonds of even the most reactive phenols (compare BDEs of 70 and 78 kcal mol^{-1} in TEMPOH²⁹ and PMC,³⁰ respectively), the reaction is still highly exothermic. The barrier for the H-atom transfer from HOO^\bullet to TEMPO is predicted by CBS-QB3 (ref. 31) to be $\Delta G^\ddagger = 2.9 \text{ kcal mol}^{-1}$, corresponding to a rate constant of $2 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ upon

application of transition state theory. Thus, the reaction is predicted to be diffusion-controlled.³² It is interesting to note the *syn* orientation of the substituents on the oxygen atoms between which the H-atom is being transferred (Fig. 4E). Although this is unexpected based on steric considerations, it is typical of reactions of peroxy radicals with H-atom donors that possess an α -heteroatom (e.g. $\text{ROO}^\bullet + \text{H-OSR}$,³³ H-OSeR ,³⁴ H-SSR ³⁵) or unsaturation (e.g. H-OAr ,³⁶ H-NHAr ³⁷) due to secondary orbital interactions between the substituents.

IV. Computations suggest a tunneling-enhanced 1,4-HAT/elimination sequence leads to hydroperoxyl formation in unsaturated hydrocarbon autoxidation

To the best of our knowledge, there has been no investigation of the intervention of HOO^\bullet in the propagation of autoxidation of simple monounsaturated hydrocarbons such as styrene, cyclooctene and norbornene. To assess whether HOO^\bullet could be formed from chain-propagating intermediates in the autoxidation of these substrates, we turned to computation. It has been suggested that hydroperoxyl radicals contribute to the propagation of autoxidation of activated unsaturated substrates, such as acrylates and substituted 1,3-butadienes. Multiple mechanistic possibilities were advanced.⁷³ However, prior to investigating these reactions, we sought to clarify the pathway operating in the autoxidation of 1,4-CHD.

Fig. 5 Computational investigations. (A) CBS-QB3-computed free energy profile for HOO• formation from peroxy radical intermediates arising in styrene autoxidation. Energy of the tunneling-enhanced 1,4-HAT TS is given by the dashed line. Methylperoxy and methoxy are used as models of chain-propagating alkylperoxy and alkoxy radicals, respectively. Transition state structures for the 1,4-HAT in the β-alkoxyperoxy radicals derived from styrene (B), norbornene (C) and cyclooctene (D).

The precise mechanism of HOO• formation in 1,4-CHD autoxidation has been a matter of some debate. Howard and Ingold had originally proposed a unimolecular elimination from the cyclohexadienylperoxy radical (as shown in Fig. 4C).²⁸ Hendry and Schuetzle subsequently argued that the reaction must involve direct H-atom transfer from the cyclohexadienyl radical to O₂.⁴⁰ Subsequent reports seem split between the two mechanisms.^{41–45}

Our CBS-QB3 calculations suggest that the cyclohexadienylperoxy is a bound structure that leads to HOO• and benzene *via* a concerted 1,4-HAT/elimination transition structure that intrinsic reaction coordinate (IRC) calculations confirm connects the two stationary points. No transition state structure was identified for the direct H-atom transfer mechanism.⁴⁶ The predicted barrier for this process ($\Delta G^\ddagger = 15.4 \text{ kcal mol}^{-1}$) is strikingly similar to that of the bimolecular propagation reaction of hydroperoxy and 1,4-cyclohexadiene ($\Delta G^\ddagger = 15.2 \text{ kcal mol}^{-1}$). Confidence in the calculations comes from the excellent agreement between the predicted rate

constant for the latter reaction and the known k_p for 1,4-CHD autoxidation ($1610 \text{ M}^{-1} \text{ s}^{-1}$ vs. $1400 \text{ M}^{-1} \text{ s}^{-1}$,²⁸ respectively), as well as the thermodynamics of that step ($\Delta G = -14.2 \text{ kcal mol}^{-1}$), which is fully consistent with the difference in bond dissociation enthalpies (BDEs) between 1,4-CHD ($74.5 \text{ kcal mol}^{-1}$)⁴⁷ and H₂O₂ ($87.5 \text{ kcal mol}^{-1}$).⁴⁸

In contrast to 1,4-CHD, styrene is well known to propagate by addition.⁴⁹ Thus, the analogous 1,4-HAT/elimination process to produce HOO• may be expected to come from the propagating peroxy radical shown on the top left in Fig. 5A. A transition state structure for the 1,4-HAT in this intermediate was readily identified, but *in lieu* of being concerted with HOO• elimination as for 1,4-CHD, IRC calculations indicate that no stationary point connects it and the transition state for β-fragmentation of the neighbouring O–O bond. Although a transition state structure could be identified for the elimination of HOO•, it is $15.3 \text{ kcal mol}^{-1}$ higher in energy.

The propagation of styrene autoxidation by peroxy radical addition competes with the intramolecular S_Hⁱ reaction that

yields styrene epoxide and an alkoxy radical which subsequently adds to styrene to continue the chain. Styrene oxide has been reported to account for as much as 39% of the products in a styrene autoxidation,⁵⁰ and is expectedly influenced by the partial pressure of O₂.⁵¹ The alkoxy radicals formed as a result – as well as alkoxy radicals formed simply from homolysis of the styrene/oxygen copolymer products – add to styrene to yield a benzylic radical that is subsequently oxygenated to yield the chain-propagating peroxy radical shown on the bottom left of Fig. 5A. A transition state structure for the 1,4-HAT from this intermediate was also readily identified, but this time IRC calculations connect it to a bound α -alkoxyalkyl radical. From this intermediate, HOO[•] elimination proceeds in favour of the β -fragmentation of the alkoxy C–O bond ($\Delta G^\ddagger = 13.3$ kcal mol^{−1} for the former compared to 23.1 for the latter). The preceding 1,4-HAT has a much higher barrier, but is predicted to be greatly enhanced by quantum mechanical tunneling with $k = 4.4$ s^{−1} (70 °C).

Corresponding calculations for cyclooctene and norbornene provide similar insight: elimination from the oxygenated intermediate arising from alkoxy addition to the double bond is predicted to be a viable route to HOO[•] formation, with similar (tunneling-corrected) rate constants of 13 and 0.56 s^{−1} (70 °C), respectively. It should be noted that autoxidations of norbornene^{52,53} and cyclooctene^{54,55} are known to produce even more

epoxide than styrene. Complete potential energy surfaces for the relevant chain-propagating steps of cyclooctene and norbornene autoxidation are given in the ESI.†

V. Kinetic isotope effects support the proposed mechanism

If hydroperoxyl radicals are the stoichiometric reductants in nitroxide-inhibited autoxidations of unsaturated hydrocarbons, a kinetic isotope effect should be observed upon the addition of an acidic deuterium source to the medium due to the HOO[•]/DOO[•] equilibrium (the pK_a of HOO[•] is 4.9).³⁸ Thus, TEMPO-inhibited and Ar₂NO-inhibited styrene/STY-BODIPY co-oxidations were repeated in the presence of either 1% MeOH or MeOD. The results are shown in Fig. 6A. In both cases, the addition of MeOD had a pronounced effect on both the initial rate of the autoxidation and the duration of the inhibited period. From the initial rates, DKIEs of $k_H/k_D = 4.2$ and 3.3 can be calculated for TEMPO and Ar₂NO, respectively. The magnitude of these DKIEs are very similar to those reported by Brownlie and Ingold for inhibition of styrene autoxidations by structurally-related hydroxylamines.¹² These results are consistent with equilibration of HOO[•] with TEMPO/Ar₂NO to produce TEMPOH/Ar₂NOH as the chain-breaking antioxidant *in situ* (Fig. 6B).^{39,69,71}

Given the computational prediction that HOO[•] can be formed from unsaturated hydrocarbons by a quantum

Fig. 6 Kinetic isotope effect studies. (A) Co-oxidation of styrene (3.5 M) and STY-BODIPY (10 μM) in PhCl initiated with di-*tert*-butylperoxide (218 mM) at 70 °C (black) and inhibited by either Ar₂NO (2 μM, blue) or TEMPO (2 μM, red) in the presence of 1% v/v MeOH (dashed lines) or MeOD (solid lines). Reaction progress was monitored at 571 nm ($\epsilon = 97\,235$ M^{−1} cm^{−1}). (B) Dynamic exchange of the acidic proton in HOO[•] with the acidic deuterium in MeOD is expected to precede the nitroxide-catalyzed cross-dismutation of hydroperoxyl and alkylperoxyl radicals, leading to the observed kinetic isotope effects. (C) Synthesis of 1,2-d₂-cyclooctene and the predicted kinetic isotope effect on HOO[•] production. (D) Co-oxidation of cyclooctene or 1,2-d₂-cyclooctene (3.1 M) and STY-BODIPY (10 μM) in PhCl initiated with di-*tert*-butylperoxide (218 mM) at 70 °C (black line) and inhibited by 2 μM of either Ar₂NO (blue line), TEMPO (red) or Ar₂NH (dashed blue line). Corresponding traces with deuterated substrate are represented by dotted lines. Inset: expansion of the initial portion of the autoxidation. Reaction progress was monitored at 568 nm ($\epsilon = 118\,405$ M^{−1} cm^{−1}).

tunneling-enhanced intramolecular 1,4-HAT from a β -alkoxyalkylperoxyl intermediate, we sought to replace the vinylic H-atoms of one of the substrates above with deuterium to suppress the ability of nitroxides to inhibit the autoxidation. We selected cyclooctene for these experiments since 1,2-d₂-cyclooctene could be easily accessed simply by catalytic deuteration of cyclooctyne over Lindlar's catalyst (Fig. 6C). The results of STY-BODIPY/1,2-d₂-cyclooctene co-autoxidations inhibited by TEMPO and Ar₂NO are plotted alongside the corresponding data for cyclooctene in Fig. 6D.

The difference in the cyclooctene and 1,2-d₂-cyclooctene data could not be more dramatic. Substitution of the nominally unreactive alkene H-atoms of the substrate with deuterium atoms all but precludes inhibition of the reaction by the nitroxides. The very small effect of the nitroxides on the reaction progress in the autoxidation (which is visible only upon expanding the initial portion of the reaction progress data as in the inset to Fig. 6D) is presumably due to the formation of a small amount of HOO• from the residual protiated cyclooctene also undergoing autoxidation. Although catalytic deuteration of cyclooctene is essentially quantitative to prepare 1,2-d₂-cyclooctene, the starting cyclooctyne is prepared from cyclooctene, which is difficult to remove (see ESI† for more details). In stark contrast, the initial rates of the Ar₂NH-inhibited autoxidations of cyclooctene and 1,2-d₂-cyclooctene are very similar (see inset to Fig. 6D) and the reaction progress only diverges once the nitroxide formed *in situ* is responsible for inhibition of the autoxidation (evident over the longer reaction time shown in Fig. 6D). Overall, these results are fully consistent with the intramolecular 1,4-HAT of the β -alkoxyalkylperoxyl intermediate being key to the activity of the nitroxides, and that the contribution of this reaction to the propagation of autoxidation of these substrates is greatly enabled by quantum mechanical tunneling.

Discussion

Hindered aliphatic nitroxides such as TEMPO have long been considered unreactive to alkylperoxyl radicals, and as such, are not generally considered inhibitors of hydrocarbon autoxidation under most conditions (except at low partial pressures of O₂, where alkyl radicals can be trapped). In contrast, diarylnitroxides have been shown to react with peroxyl radicals, albeit it more slowly than their parent amines. Given the difference in reactivity of hindered nitroxides and

diarylnitroxides, it was proposed that peroxyl radical addition to one of the aryl rings of the diarylnitroxide is possible (Scheme 1).¹²

In recent years, some exceptions to this dogma have begun to appear (*i.e.* nitroxides undergo electron transfer to peroxyl radicals in aqueous solution,^{17,56} and nitroxides undergo acid-promoted reactions with peroxyl radicals in organic solution^{16,26}), but they are under specific conditions. As such, we were initially very surprised to obtain the results in Fig. 1, where both hindered aliphatic nitroxides and diarylnitroxides are similarly good inhibitors of styrene autoxidation – better even than the corresponding diphenylamine. The results of subsequent experiments have clarified that nitroxides are excellent inhibitors of unsaturated hydrocarbon autoxidation at low rates of radical generation. Mechanistic studies have enabled the proposition of a mechanism that does not require the reaction of a nitroxide with an alkylperoxyl radical, but rather, a hydroperoxyl radical. Reaction of the resultant hydroxylamine with an alkylperoxyl radical traps a second chain-carrying radical and regenerates the nitroxide. The similarity in the apparent k_{inh} observed for the nitroxides and the k_{inh} observed for the authentic hydroxylamines implies that the reaction of nitroxide with HOO• is faster than hydroxylamine + ROO•, such that hydroxylamine accumulates to serve as the key chain-breaking species.⁷² Overall, this mechanism can be characterized as a nitroxide-catalyzed cross-dismutation of hydroperoxyl and alkylperoxyl radicals. A similar reaction sequence was once proposed to explain the superoxide dismutase activity of hindered nitroxides in aqueous solution,⁵⁷ but was subsequently dismissed on kinetic grounds in favour of the half reactions involving conversion of TEMPO to its corresponding oxoammonium ion and back.⁵⁸

More than a century of research in combustion chemistry has shown that the major initial products formed in the high temperature (>300 °C) gas phase oxidation of simple alkanes are alkenes containing the same number of carbons. This observation has been ascribed to the elimination of HOO• from alkylperoxyl intermediates.⁵⁹ The 1,4-HAT/elimination sequence connecting the alkylperoxyl radicals and alkenes have been the subject of extensive investigations, particularly for ethylperoxyl radicals due to their computational tractability.⁶⁰ There would appear to be a consensus that, in the case of simple alkylperoxyl radicals, the 1,4-HAT and elimination take place in a concerted fashion. However, as the putative β -hydroperoxyalkyl radical is more stable both pathways are possible,⁶¹ or the step-wise process dominates.⁶² The step-wise path is anticipated to be greatly enhanced by quantum mechanical tunneling since the transition state involves little atomic movement other than the H-atom being transferred. Indeed, kinetic isotope effects derived for the 1,4-HAT in the step-wise formation of hydroperoxyl from *n*-propylperoxyl are predicted to decrease with temperature from 9.5 at 648 K to 6.2 at 703 K (ref. 63) – implying that at ambient temperatures they would be massive. Indeed, our calculations suggest that elimination of HOO• from chain-propagating alkylperoxyl radicals in unsaturated hydrocarbon autoxidation is step-wise and greatly enhanced by tunneling. Furthermore, the lack of inhibition of

Scheme 1 Hindered aliphatic nitroxides do not react with alkylperoxyl radicals; (di)arylnitroxides react by addition to the aryl ring(s).

Fig. 7 (A) Co-oxidation of 1-hexadecene (2.68 M) and PBD-BODIPY (10 μ M) in PhCl initiated with dicumyl peroxide (1 mM) at 100 $^{\circ}$ C (black line) and inhibited by 2 μ M of Ar_2NO (blue line), TEMPO (red line) or Ar_2NH (blue dashed line). Inset: expanded timescale showing the end of the inhibited periods for Ar_2NO and Ar_2NH . Reaction progress was monitored at 586 nm ($\epsilon = 119\,166\text{ M}^{-1}\text{ cm}^{-1}$). (B) Relevant steps for HOO^{\bullet} formation in a 1-hexadecene autoxidation along with the calculated transition state structure and activation parameters for the key 1,4-HAT reaction for comparison with corresponding processes in for styrene, cyclooctene and norbornene (Fig. 5B–D).

nitroxides in autoxidations of d_2 -cyclooctene clearly corroborate the prediction that the reaction is greatly enhanced by tunneling.

In the condensed phase, the elimination of HOO^{\bullet} from alkylperoxyl intermediates formation is known only for very specific hydrocarbons, *e.g.* 1,4-CHD and 1,4-dihydronaphthalene.²⁸ Ingold first demonstrated that the autoxidation of these substrates is propagated primarily by HOO^{\bullet} ; initially due to their extremely rapid termination rate constants ($k_t = 6.3 \times 10^8\text{ M}^{-1}\text{ s}^{-1}$ in chlorobenzene at 30 $^{\circ}$ C; >200-fold greater than that measured for cyclohexene), and subsequently confirmed his assertion simply by washing the solutions with water and determining H_2O_2 by iodometric titration (which corresponded to *ca.* 95% of all the peroxide formed). The identification of substrates that propagate to only a small extent by hydroperoxyl radicals would have been extremely challenging due to their small contribution to k_t and low yields of H_2O_2 . Instead, the foregoing suggest that these substrates can be revealed indirectly by the ability of nitroxides to inhibit their autoxidation.

At first glance, the relative contribution of the 1,4-HAT/elimination pathway that is proposed to yield HOO^{\bullet} from chain-propagating alkylperoxyl radicals may be reflected in the relative efficacy of the nitroxides as inhibitors of autoxidation. Indeed, we find that while 1,4-CHD autoxidation is perpetually inhibited by the addition of TEMPO, the nitroxide is relatively less effective in styrene, norbornene and cyclooctene. However, rationalizing the trends observed for styrene, norbornene and cyclooctene is complicated by the fact that styrene and norbornene propagate exclusively by addition (necessary to produce the intermediate peroxy radical from which the 1,4-HAT/elimination is proposed to take place), whereas cyclooctene propagates largely, but not exclusively, by addition.^{54,55} Moreover, because the 1,4-HAT and subsequent elimination is competitive only at low rates of initiation where radical–radical reactions are minimized, the differences in termination rate constants are also expected to contribute. Nevertheless, it appears that of the three substrates, the nitroxides are most effective in cyclooctene, perhaps because (as predicted by theory), the rate constant for the key 1,4-HAT is largest. Overall,

it seems reasonable to propose that any substrate from which epoxides have been observed in autoxidations – even as minor products – should yield at least some HOO^{\bullet} and therefore, be protected by nitroxides.

Since linear unsaturated hydrocarbons such as those which are abundant in petroleum-derived products and biological lipids autoxidize largely by H-atom abstraction, it is unclear from the foregoing if the proposed mechanism contributes to their autoxidation and, thus, that they can be inhibited efficiently by nitroxides. Therefore, we carried out co-oxidations of 1-hexadecene and PBD-BODIPY to find that not only are they inhibited by the addition of each nitroxide (Fig. 7), but that the inhibited periods correspond to massive stoichiometric factors: $n = 117 \pm 7$ for Ar_2NO and even greater for TEMPO. For comparison, Ar_2NH is characterized by $n = 23 \pm 3$, which presumably arises since (some of) the amine is converted to the nitroxide *in situ* (detected by EPR, see ESI†). This is a striking result; the catalytic radical-trapping antioxidant activity of diarylamines is almost universally ascribed to the Korcek cycle (Fig. 1B), but at these temperatures, Ar_2NOR is not readily converted to Ar_2NH ,⁷ and even if it were, Ar_2NH is still significantly less effective than Ar_2NO .⁶⁴

It must be emphasized that this is not the only evidence that diarylamines and/or diarylnitroxides catalytically trap radicals *via* an alternative to the Korcek cycle. For example, an oft-overlooked result of the seminal work of Bolsman *et al.*⁶⁵ is that 4',4'-dinitrodiphenylnitroxide is a catalytic inhibitor of paraffin autoxidation at 130 $^{\circ}$ C, while the corresponding amine is completely ineffective. This could not be explained by the Korcek mechanism, and lead the authors to argue that the amines themselves are not involved in the catalytic cycle of diarylamine antioxidants, but need to be 'activated' to the catalytic radical-trapping antioxidant: the nitroxide. It is tempting to suggest that the paraffin oil used by Bolsman *et al.* (Shell ONDINA 33) contained sufficient unsaturation to produce HOO^{\bullet} and enable protection by the nitroxide.

Likewise, this mechanism can account for the 'non-classical' stoichiometries (*i.e.* $n > 2$) observed for diarylamines in autoxidations carried out at ambient temperatures. For example,

some time ago, Lucarini and co-workers reported that phenoxazine was not only among the fastest RTAs ever reported ($k_{\text{inh}} = 2.9 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$), but that it trapped an amazing 5 radicals in styrene autoxidations (at 50 °C).⁴ Very recently, we revisited this chemistry⁶⁶ and found that phenoxazine trapped 10 radicals in styrene at 37 °C – a result which can now be readily explained by the fact that our rate of initiation was lower than Lucarini's, enabling 1,4-HAT/elimination to contribute more to the autoxidation. Interestingly, in our recent studies we were also able to see two distinct phases within the inhibited period of the autoxidation, which can now be understood as an initial phase in which the parent amine traps peroxy radicals, and a secondary phase wherein the amine-derived nitroxide reacts with HOO^\bullet and traps peroxy radicals as the corresponding hydroxylamine.

Conclusions

Autoxidations of unsaturated hydrocarbons are very efficiently inhibited by nitroxides and/or compounds which react readily to produce nitroxides under autoxidative conditions. The utilization of HOO^\bullet formed *in situ* as the stoichiometric reductant accounts for the catalytic behaviour of the nitroxides and/or their precursors without invoking a mechanism that requires the formation – and decomposition – of alkoxyamines. Alkoxyamine intermediates are invoked in the Korcek and Denisov mechanisms that have been widely accepted to account for the catalytic active of diarylamines and hindered aliphatic amines, respectively. However, these mechanisms can be expected to apply only when the nitroxide is present at much higher concentrations than O_2 , since alkoxyamine formation requires that the nitroxide react with an alkyl radical despite the fact that this reaction is characterized by a rate constant that is 10-fold lower than that of the reaction of alkyl radicals with O_2 . Moreover, elevated temperatures are required to convert the alkoxyamine back to the amine at a relevant rate, making it impossible to explain the catalytic reactivity of nitroxides and/or their precursors at ambient to moderate temperatures. The nitroxide-catalyzed cross-dismutation of HOO^\bullet and ROO^\bullet can account for observations that cannot be explained by the Korcek and Denisov cycles. This mechanism may be most relevant for hindered aliphatic amines/nitroxides since they are used in more applications at ambient temperatures where the rate of initiation is low, and radical–radical reactions are minimized.

Experimental section

I. Inhibited autoxidations

The co-autoxidations described here were carried out according to our previously published methodology.¹⁸ Briefly, the substrate (1–2 mL) was loaded into a 3 mL cuvette along with the appropriate volume of PhCl such that the final volume of the sample was 2.5 mL. The cuvette was placed into the thermostatted sample holder of a UV-vis spectrophotometer and equilibrated at the appropriate temperature. STY-BODIPY or PBD-BODIPY (12.5 μL of a 2.0 mM solution in 1,2,4-trichlorobenzene) was then added followed by 50–100 μL of a solution of initiator in PhCl.

The solution was thoroughly mixed. The consumption of the probe was monitored for 10–20 min to ensure that the reaction was proceeding at a constant rate, after which the test compound (10 μL of a 500 μM solution) was added, the solution thoroughly mixed and the absorbance readings resumed. Inhibition rate constants (k_{inh}) and stoichiometries (n) were derived from the reaction progress traces analyzed using the equations in Fig. 2B (see ESI† for representative examples).

An analogous procedure was followed when determining nitroxide concentration by EPR in diarylamine-inhibited autoxidations. Reactions were performed under identical conditions in a heat-block at 70 °C and samples taken after the indicated time intervals and transferred to EPR tubes. Spectra were recorded on a Bruker EMXplus (X-band) spectrometer equipped with an ER 4119HS cavity and the radical concentration was determined using the quantitative EPR package of the Bruker Xenon software.

II. Calculations

Calculations were carried out of Skodje, Truhlar and Garrett using the CBS-QB3 complete basis set method³¹ as implemented in the Gaussian 16 suite of programs.⁶⁷ The rate constants were calculated *via* transition state theory at 70 °C. The contribution of quantum mechanical tunneling to the intramolecular hydrogen atom transfer step was estimated using the small curvature tunneling corrections of Skodje, Truhlar and Garrett.⁶⁸ The evaluation of different computational approaches to address this problem was made using the oxidation of 1,4-cyclohexadiene as a model and are described in the ESI.†

III. Synthesis of d₂-1,2-cyclooctene

A flame dried round-bottomed flask with magnetic stirrer was flushed with N_2 , fitted with a rubber septum and charged with cyclooctyne in acetone (1 M). The solution was sparged with N_2 for 5 minutes. Lindlar's catalyst (Pd/CaCO_3 , poisoned with Pb) was added in one portion (10 mol%) and the mixture was sparged for an additional 5 minutes. The atmosphere was evacuated and replaced with D_2 . The reaction was gently warmed to 30 °C and stirred for 36 h. Once the starting material was consumed (as judged by ^1H NMR analysis), the reaction was filtered through a thin pad of Celite/silica gel and the filtrate vacuum distilled. The title product was collected (20 mbar/63 °C) as a clear oil (3 g, 60%) following initial removal of acetone (30 mbar/35 °C).⁷⁰ ^1H NMR (400 MHz; CDCl_3): δ (ppm): 5.62 (m, <0.2H), 2.13 (m, 4H), 1.50 (m, 8H). ^{13}C NMR (101 MHz; CDCl_3): 130.0, 29.5, 26.6, 25.3. HRMS (EI) m/z for $\text{C}_8\text{H}_{12}\text{D}_2$, calc.: 112.1221, found 112.1256.

- 32 Litwinienko and Amorati²⁷ estimated that the analogous rate constant for the reaction of HOO• and the phenoxyl radical derived from PMC is ca. 10⁹ M⁻¹ s⁻¹ based upon competition with hydroperoxyl addition to the ring, for which they estimated that the rate constant was the same as for an alkylperoxyl radical (ca. 10⁸ M⁻¹ s⁻¹). It is likely that HOO• addition is faster than alkylperoxyl radical addition, and that HAT between HOO• and phenoxyl radicals is also diffusion-controlled.

- 71 Although they contribute to the propagation of autoxidation, it is unlikely that reactions of hydroperoxyl and/or alkoxy radicals with the hydroxylamines are relevant under the reaction conditions. Since both alkoxy radicals and hydroperoxyl radicals are more reactive than alkylperoxy radicals, they are less selective for hydroxylamine over the substrate. For example, alkoxy radicals add/abstract from olefins with $k \sim 10^6 \text{ M}^{-1} \text{ s}^{-1}$ and react with hydroxylamines with $k \sim 10^8 \text{ M}^{-1} \text{ s}^{-1}$ (E. Abuin, M. V. Encina, S. Diaz and E. A. Lissi, *Int. J. Chem. Kinet.*, 1978, **10**, 677), whereas alkylperoxy radicals add/abstract from olefins with $k \sim 1 \text{ M}^{-1} \text{ s}^{-1}$, but react with hydroxylamines with $k > 10^6 \text{ M}^{-1} \text{ s}^{-1}$. Given the concentration difference (μM vs. M), only the latter competition will be important.
- 72 Since the calculations predict that nitroxide + HOO^\bullet is diffusion-controlled, inhibition results from the successful competition between the intramolecular 1,4-HAT in the precursor to HOO^\bullet , which is predicted to take place with $k \sim 1$ to 10 s^{-1} depending on the substrate, and hydroxylamine + ROO^\bullet , which we measure to take place with $k \sim 10^6 \text{ M}^{-1} \text{ s}^{-1}$. Although the rate constant for the latter is faster, it depends on [nitroxide] which is $2 \mu\text{M}$ – suggesting that the elimination is competitive under the reaction conditions.
- 73 E. M. Pliss, V. A. Machtin, A. M. Grobov, R. E. Pliss and A. V. Sirick, *Int. J. Chem. Kinet.*, 2017, **49**, 173–181.
