Cooperative activation of X–H (X = H, C, O, N) bonds by a Pt(0)/Ag(I) metal-only Lewis pair†

Nereida Hidalgo, Celia Maya and Jesús Campos*

Metal-only Lewis pairs made of Pt(0)/Ag(I) combinations have been previously reported, but their cooperative reactivity remains unexplored. Here we demonstrate that these systems are capable of synergistically activating a wide variety of X–H (X = H, C, O, N) bonds, including those in dihydrogen, alkynes, water and ammonia.

Since the seminal works of Werner at the end of the 19th century, the chemistry of transition metal complexes has been mostly defined by the acidic character of the metal centre, to which basic ligands can bind by means of dative bonds. In contrast, the potential of transition metals to behave as electron donors has remained less explored, despite its fundamental role in oxidative addition reactions or in the coordination of π-acidic ligands.1 More recently, the interest in electron-rich transition metal complexes capable of coordinating σ-acceptor ligands (Z-type ligands) has grown enormously.2 This unusual reverse flux of electrons provides the metal centre with uncommon stereoelectronic properties and reactivity patterns.3 In this context, the use of unsaturated transition metal fragments instead of p-block σ-acceptors has become a successful strategy to access heterobimetallic compounds containing M–M dative bonds.4 A fascinating class among these bimetallic entities are metal-only Lewis pairs (MOLPs),5 in which two metal fragments are held together exclusively through a M–M interaction. Within this field, the use of group 11 metals acting as Lewis acids for the synthesis of MOLPs is well-documented.6 In the case of silver, accessing their monometallic parent precursors and provide unusual selectivities.12 On this basis, and following our recent results on bimetallic bond activation using the basic Pt(0) compound [Pt(PBu3)]2 (1) in combination with a sterically crowded electrophilic phosphine gold(i) fragment,13 we decided to investigate the reactivity of Pt(0)/Ag(I) MOLPs. The latter systems find precedent in the recent literature but their cooperative reactivity remains unexplored.14 A prior work demonstrating the cooperative activation of water using (1) and Cu(i) salts, further encouraged us to pursue these research aims.15

The formation of Pt→Ag adducts 2 and 3 proceeds readily in benzene or dichloromethane upon mixing [Pt(PBu3)]2 (1) and the corresponding silver salt in the absence of light (Scheme 1), resulting in the instant coloration of the solution from colourless to bright yellow. A chemical shift towards slightly lower frequencies is recorded by [1P1H] NMR monitoring, accompanied by a pronounced decrease in the JPPt coupling constant (2: δ = 99.6 ppm, JPPt = 3298 Hz; 3: δ = 99.2 ppm, JPPt = 3244 Hz) with respect to precursor 1 (δ = 100.2 ppm, JPPt = 4410 Hz). The diminished JPPt values in 2 and 3 are expected considered the reduced s character of P–Pt bonds as a consequence of the new Pt→Ag interaction. These data are similar to the NMR changes

In addition, TM→Ag dative bonds have served as an experimental gauge to calibrate the basicity of transition metals.10 Moreover, metal–metal interactions involving silver centres are key in catalysis, where the so-called silver effect has been regularly invoked in a variety of transition-metal catalysed transformations.11 Likewise, well-defined silver-based heterobimetallic catalysts can outperform their monometallic parent precursors and provide unusual selectivities.12 On this basis, and following our recent results on bimetallic bond activation using the basic Pt(0) compound [Pt(PBu3)]2 (1) in combination with a sterically crowded electrophilic phosphine gold(i) fragment,13 we decided to investigate the reactivity of Pt(0)/Ag(I) MOLPs. The latter systems find precedent in the recent literature but their cooperative reactivity remains unexplored.14 A prior work demonstrating the cooperative activation of water using (1) and Cu(i) salts, further encouraged us to pursue these research aims.15

observed in the formation of a trimetallic compound of formula ([\text{PCy}_3]_2Pt\text{--}Ag\text{--}Pt([\text{PCy}_3]_2]) previously described by the group of Braunschweig.\textsuperscript{14,15} However, in our case the use of slightly coordinating anions such as triflimide (NTf\textsubscript{2} \textsuperscript{-}, [N(SO\textsubscript{2}CF\textsubscript{3})\textsubscript{2}] \textsuperscript{-} or triflate (OTf\textsubscript{2}, [OSO\textsubscript{2}CF\textsubscript{3}]\textsubscript{2}\textsuperscript{-}) seems to prevent the formation of the trimetallic compound in favour of the bimetallic MOLPs 2 and 3. This was demonstrated by the reaction of 1 with 0.5 equivalents of silver salts AgNTf\textsubscript{2} or AgOTf, which results in the formation of equimolar mixtures of unreacted 1 and compounds 2 and 3, respectively. Interestingly, the use of silver reagents containing less coordinating counteranions (i.e. BF\textsubscript{4}\textsuperscript{-} and PF\textsubscript{6}\textsuperscript{-}) also led to PtAg MOLPs, as inferred from \textsuperscript{31}P\{\textsuperscript{1}H\} NMR studies, but those displayed limited stability. More precisely, they evolved towards the cyclometalation of one of the tert-butyl fragments of a \textsuperscript{3}Bu\textsubscript{3} ligand to yield compounds [Pt\textsuperscript{IV}(\textsuperscript{k\,}2-P\textsuperscript{3}Bu\textsubscript{3}CMe\textsubscript{2}CH\textsubscript{2})\textsuperscript{-}(\textsuperscript{3}Bu\textsubscript{3}Cu)]\textsuperscript{-} \textsuperscript{(δ\textsuperscript{(1)}P\textsuperscript{(\textsuperscript{1}H)}) = 55.9, 23.2 ppm (d, J\textsubscript{HPt} = 319 Hz)} and [Pt\textsuperscript{IV}(\textsuperscript{3}Bu\textsubscript{3}Cu)\textsubscript{2}H\textsuperscript{-}]\textsuperscript{-} (δ\textsuperscript{(1)}P\textsuperscript{(\textsuperscript{1}H)}) = 86.3 ppm, J\textsubscript{PPt} = 2723 Hz; δ\textsuperscript{(1)H} = −33.0 ppm (\textit{J}_{PH} = 2224 Hz).\textsuperscript{15} The same reactivity was noticed upon dissolving compounds 1 or 2 in tetrahydrofuran. An identical transformation was latterly reported using a ferrocenium salt as the one-electron oxidant,\textsuperscript{16} a role presumably played by the silver salt in the compounds reported herein.

The molecular structures of compounds 2 and 3 were authenticated by single-crystal X-ray diffraction studies, confirming the proposed bimetallic formulation of the metal–metal core. While compound 2 crystallized as a monomer in the solid state (Fig. 1), the structure of 3 reveals a dimeric configuration with two triflate anions as bridging fragments (Fig. S1, ESI\textsuperscript{†}). Nevertheless, diffusion NMR experiments ruled out a dimeric formulation as the main species in solution. The structures are otherwise comparable to previous Pt(0) Lewis adducts,\textsuperscript{13,14,17} exhibiting slightly distorted T-shaped conformations around the metal centre (P–Pt–P = 167.07(5) \textdegree) and 174.69(4) \textdegree) (3)). The Pt–P bond distances (2.30–2.32 Å) are elongated in comparison to precursor 1 (2.25 Å).\textsuperscript{18} This may be attributed to the release of electrons from the platinum centre, in analogy to the Pt–P bond lengthening observed upon one-electron oxidation of precursor 1, whose origin is still a matter of debate.\textsuperscript{19}

Given the superior stability of compound 2 over 3, we chose the former to investigate its reactivity and compare the outcomes with its independent components, that is, compounds 1 and AgNTf\textsubscript{2}. We examined the reactivity of 2 towards the activation of hydrogen, alkynes and polar X–H bonds (X = O, N), including those in water and ammonia. Compound 2 cleanly evolves in the presence of H\textsubscript{2} under mild conditions (1 atm, −20 °C) to yield the heterobimetallic Pt(II)/Ag(I) dihydride 4 that contains a terminal and a bridging hydride (Scheme 2). Related PtAg heterobimetallic hydrides have been previously prepared by mixing platinum(II) dihydrides with silver salts.\textsuperscript{20} Nevertheless, it is important to remark that neither precursor 1 nor AgNTf\textsubscript{2} exhibit any reactivity towards dihydrogen even under harsher conditions (4 atm, 60 °C). This demonstrates that both metals are required for the cleavage of the H–H bond to take place. The course of the reaction can be monitored by \textsuperscript{31}P\{\textsuperscript{1}H\} NMR spectroscopy, following the appearance of a new resonance at 94.6 ppm (\textit{J}_{PPt} = 2660 Hz) due to the heterobimetallic dihydride 4. This compound exhibits fluxional behavior in solution, as evinced by a single and distinctive low-frequency \textsuperscript{1}H NMR resonance (−4.89 ppm) at 25 °C due to the two hydride ligands. This signal appears as an apparent double quartet due to coupling to \textsuperscript{137}Ag (\textit{J}_{AgH} = 120 Hz) and \textsuperscript{197}Pt satellites (\textit{J}_{HPt} = 778 Hz). The dynamic process is quenched at temperatures below −50 °C, at which the initial signal is split into two resonances at 3.98 (\textit{J}_{AgH} = 182, \textit{J}_{HPt} = 570 Hz) and −5.21 (\textit{J}_{AgH} = 44, \textit{J}_{HPt} = 984 Hz) ppm due to the bridging and terminal hydrides, respectively (Fig. S4, ESI\textsuperscript{†}).

The barrier for the exchange was determined by standard line-shape analysis (Δ\textit{G}^\ddagger\textsubscript{298} = 13.2 kcal mol\textsuperscript{-1}). It could result from either fast tilting of the square-planar Pt(H\textsubscript{2})(\textsuperscript{3}Bu\textsubscript{3}Cu)\textsuperscript{2} fragment or rapid dissociation/coordination of the silver salt. In fact, the lability of the Pt→Ag bond is attested by the reaction of 1 with 0.5 equivalents of AgNTf\textsubscript{2} under H\textsubscript{2} atmosphere, which forms an equimolar mixture of compound 4 and unreacted 1 after 5 hours and eventually evolves to a ca. 1:1 mixture of the former and Pt(H\textsubscript{2})(\textsuperscript{3}Bu\textsubscript{3}Cu)\textsubscript{2}, along with variable amounts of [Pt\textsuperscript{IV}(\textsuperscript{3}Bu\textsubscript{3}Cu)\textsubscript{2}H\textsuperscript{-}] as a recurrent side-product. Having in mind that precursor 1 does not react with H\textsubscript{2} under our experimental conditions, the

formation of Pt[H][P(Bu)₃]₂ may imply transfer of silver from hydride 4 to unreacted 1 forming compound 2, which could subsequently be hydrogenated by the synergistic action of silver.

We next investigated the reactivity of 2 towards acetylene and phenylacetylene (Scheme 2). Compound 1 acts as a catalyst for the polymerization of C₂H₂, provoking the rapid precipitation of a dark purple solid upon exposure to the gas. The formation of the polymer is, however, visibly inhibited in the presence of the silver salt, in which case the trinuclear [[Pt(Bu)₃]₂(H)Pt(μ-C≡C)Ag(μ-C≡C)Pt(H)[Pt(Bu)₃]] (5) is obtained in almost quantitative spectroscopic yield. Analogous reactivity is derived from the addition of phenylacetylene, resulting in the formation of the heterobimetallic dibridged bisacetylide 6. Similarly to our studies with H₂, neither precursor 1 nor the silver salt exhibit any reactivity towards phenylacetylene as monometallic species. Compounds 5 and 6 are related to other Pt/Ag bridging acetylenes that have been prepared by the addition of silver salts to pre-formed platinum(II) acetylides, an approach that contrasts to the bimetallic cooperative alkyne activation described herein. The new heterobimetallic compounds are characterized by ³¹P{¹H} NMR resonances at 83.4 (5) and 82.8 (6) ppm flanked by ¹⁹⁵Pt satellites (Jₚₚₚ = 2782 and 2759 Hz, respectively), shifted to lower frequencies by ca. 16 ppm with respect to their precursor 2. These compounds are thermally unstable in solution, particularly complex 5. However, we managed to grow single-crystals of the latter species. X-ray diffraction studies revealed the trimetallic formulation of the dibridged σ,π bisacetylide (Fig. 2). The Pt···Ag distance is markedly elongated (3.634(9) Å) compared to the metallic Lewis pair 2 (2.658(1) Å), indicating that the dative Pt···Ag bond is no longer present. The σ,π-bridged acetylide fragments are characterized by short bond distances with the silver nuclei (dₐg- centroid 2.216(6) Å), along with relatively lengthened Pt···C bond distances (dₚt-c 2.107(12) Å) compared to other compounds of formula [Pt(H)(CCR)[PR₃]₂] (ca. 1.9–2.0 Å). The formulation of compounds 5 and 6 as trinuclear bisacetylidyes was corroborated in solution by the reactions of equimolar mixtures of 1 and 2 with the two investigated alkynes, leading to compounds 5 and 6, respectively, accompanied by complete consumption of the two platinum precursors, that is, using only one equivalent of silver per two platinum nuclei.

We additionally tested the reactivity of 2 towards the activation of polar X–H (X = O, N) bonds. Before discussing these results, it is pertinent to highlight that none of the reagents tested for X–H bond cleavage exhibited any reactivity towards precursor 1. However, addition of methanol (5 equiv.) to a C₆D₆ solution of 2 provides formation of the previously reported cationic T-shaped platinum hydride 7 (ca. 80%) after around one hour at 25 °C (Scheme 3). This compound is characterized by a distinctive low-frequency ¹H NMR resonance at −33.0 ppm (Jₚₚₚ = 2224 Hz). Its molecular formulation was further confirmed by X-ray diffraction studies (Fig. S2, ESI†). More interestingly, analogous reactivity arises from the addition of water or ammonia, yielding the corresponding cationic Pt-hydride complexes further stabilized by coordination of a water (8a) or ammonia (8b) ligand, respectively. While the activation of water (50 equiv.) in benzene solution takes up to 12 hours to reach ca. 90% completion, likely due to water immiscibility, using wet acetonitrile yields [PtH(CH₃CN)(P(Bu)₃)]²⁺ (8c) instantly. The reaction with ammonia (1 bar) requires heating at 60 °C to form compound 8b in ca. 60% yield after 16 hours.

The activation of X–H bonds in methanol, water and ammonia is accompanied by the appearance of greyish precipitates that we attribute to the corresponding silver alkoxide, hydroxide or amide salts, respectively. The formation of compounds 8a–c was unequivocally confirmed by ¹H and ³¹P{¹H} NMR spectroscopy. The solid structure of the aquo/hydride complex 8a was validated by X-ray diffraction studies (Fig. S3, ESI†).

As stated in the introduction, the cooperative activation of water using a bimetallic Pt(0)/Cu(I) pair has been recently described. However, the cleavage of N–H bonds in ammonia remains a challenge in transition metal chemistry, where formation of Werner-type adducts is typically preferred. Thus, compound 2 adds to the limited list of transition metal systems capable of activating ammonia under mild conditions by virtue of the synergistic cooperation between the two metals.

![Scheme 3 Reactivity of compound 2 towards polar X–H (X = O, N) bonds.](image)
In summary, the reactivity of the Pt(0)/Ag(I) MOLP 2 markedly differs from that of its independent metal components. Thus, while [Pt(PBu$_3$)$_2$](I) does not react with H$_2$, phenylacetylene, methanol, water or ammonia, the presence of a silver salt readily facilitates the activation of these molecules by X-H (X = H, C, O, N) bond cleavage. These results demonstrate the usefulness of MOLP systems for small molecule activation and, as an immediate consequence, for catalytic applications, a research avenue that we are currently pursuing in our group.
