Frontiers in electrochemical sensors for neurotransmitter detection: towards measuring neurotransmitters as chemical diagnostics for brain disorders

Unlike disorders in the periphery, it is extremely challenging to chemically diagnose disorders of the brain. There is thus great interest in designing and optimizing tools for direct detection of chemical biomarkers implicated in neurological disorders to improve diagnosis and treatment. This critical review highlights significant technical advances and *in vivo* studies from the last five years that will facilitate the development of diagnostic tools for brain disorders. Although none of these devices are currently used for diagnostic purposes, these cutting-edge technologies are promising more sensitive, selective, faster, and less invasive measurements.

Frontiers in electrochemical sensors for neurotransmitter detection: towards measuring neurotransmitters as chemical diagnostics for brain disorders

Yanguang Ou, Anna Marie Buchanan, Colby E. Witt and Parastoo Hashemi *

It is extremely challenging to chemically diagnose disorders of the brain. There is hence great interest in designing and optimizing tools for direct detection of chemical biomarkers implicated in neurological disorders to improve diagnosis and treatment. Tools that are capable of monitoring brain chemicals, neurotransmitters in particular, need to be biocompatible, perform with high spatiotemporal resolution, and ensure high selectivity and sensitivity. Recent advances in electrochemical methods are addressing these criteria; the resulting devices demonstrate great promise for *in vivo* neurotransmitter detection. None of these devices are currently used for diagnostic purposes, however these cutting-edge technologies are promising more sensitive, selective, faster, and less invasive measurements. *Via* this review we highlight significant technical advances and *in vivo* studies, performed in the last 5 years, that we believe will facilitate the development of diagnostic tools for brain disorders.

Introduction

Unlike illnesses of the body, such as diabetes or cancer, disorders of the brain, such as depression, do not have defined diagnostic protocols with quantifiable chemical biomarkers. The inability to definitively diagnose mental disorders means that it is also difficult to effectively treat them: antidepressants, for example, are largely ineffective for the majority of patients.¹ There is, thus, enormous interest by us and others to identify chemical biomarkers of brain disorders so that illnesses of the brain can be better diagnosed and treated.

Biomarkers of brain disorders have been difficult to identify for two primary reasons. First, the blood brain barrier maintains strict and different chemical climates between the brain and the periphery, such that peripheral blood does not reflect the brain's chemical microenvironment. Secondly, it is extremely difficult to probe the chemistry, namely neurotransmission, of an intact brain (*in vivo*). Analysis of neurotransmission necessitates micro or nano level spatial resolution, which is particularly challenging given the intricate nature of brain tissue. Additionally, the brain is chemically harsh and complex and neurotransmission is dynamic (occurring on the sub-seconds).

In the last decade, microengineering is the cutting-edge method to produce devices that are small, fast, and chemically reactive enough to meet some of the challenges of

measuring neurotransmitters *in vivo*. There are three main categories of *in vivo* neurotransmitter detection devices; fluorescence probes, sampling (e.g. microdialysis), and electrochemistry. There are distinct pros and cons for each class of method, however electrochemical methods are particularly suited to *in vivo* sampling because they are able to perform direct chemical measurements in deep brain tissue without the need for artificial tags or sample treatment/analysis.

Via this review, we highlight the most recent advancements in the development of electrochemical microdevices over the last five years in the detection and quantitation of various important neurotransmitters to brain disorders, including glutamate (Glu), acetylcholine (ACh), dopamine (DA) and serotonin (5-HT). We focus mostly on amperometric biosensors and voltammetry in this review. While most of the literatures cited are primarily performed *in vivo*, we choose to highlight some *in vitro* and *ex vivo* work that further the progress of the field as well as display promising potential for future *in vivo* experiments.

While few of the reviewed methods have been implemented in humans and none have been used for diagnostics, we believe these devices show promise towards rapidly enabling chemical biomarker identification in the brain. Such a transition will revolutionize diagnosis and treatment of disorders of the brain.

Monitoring neurotransmission

Neurotransmitters are small molecules that relay chemical messages between brain cells *via* a process called neurotransmission (Fig. 1). As such, the intricacies of neurochemical

Department of Chemistry and Biochemistry, University of South Carolina, Columbia, SC, USA. E-mail: parry.hashemi@gmail.com

Fig. 1 Illustration of a synapse. Presynaptic cell is on the left and postsynaptic cell is on the right. Green spheres represent neurotransmitters. Autoreceptors are shown in orange and postsynaptic receptors in purple.

signaling are of particular interest in the diagnosis and treatment of psychological disorders. Neurotransmission is rapid (milliseconds) and occurs over several general steps. First, the transmitter is synthesized *via* presynaptic processes. Release of neurotransmitter from the presynaptic cell into the synaptic space is *via* Ca^{2+} initiated exocytosis. Following release, the transmitter binds to receptors on the postsynaptic cell or to autoreceptors on the presynaptic cell. Finally, the signal is terminated through reuptake back into the presynaptic cell by a transporter, followed by intracellular catabolism or *via* direct extracellular catabolism.

Classical neurotransmission is mediated by excitatory neurotransmitters such as Glu and ACh and the inhibitory neurotransmitter gamma-aminobutyric acid (GABA), which, because of their potency and cytotoxicity, are confined to the

synaptic space. Neuromodulators, such as DA, 5-HT, norepinephrine, and histamine (HA), are types of neurotransmitters that signal through “volume transmission.” Unlike Glu, ACh and GABA, these molecules diffuse outside of the synapse exerting influence over many cells over a large spatial area.

This review explores electrochemical neurotransmitter measurements in the context of neurotransmission. Two categories of electrochemical techniques are of particular interest: voltammetry and biosensors.

Voltammetry

A variety of voltammetric techniques are utilized to directly detect electroactive molecules. These techniques are characterized by the application of a potential waveform to an electrode and the measurement of the resulting current.² Because of the rapid time frame of neurotransmission, fast-scan cyclic voltammetry (FSCV) is of particular interest throughout this review. In FSCV, a waveform with a fast scan rate is applied to a microelectrode, at high frequency (typically 10 Hz), affording measurements with millisecond timescale.³ This method is coupled to carbon fiber microelectrodes (CFMs) of 5–7 μm in diameter. This small probe size promotes high spatial resolution and negligible tissue damage.⁴ Fig. 2 shows the two electron oxidation/reduction of DA at a CFM that results in a stereotypical DA fast scan cyclic voltammogram. There are some drawbacks to FSCV measurements. Firstly, a limited number of neurotransmitters have electroactivity that lends itself to FSCV detection. This issue has made detection of neurotransmitters such as Glu, GABA, and ACh difficult. Selectivity is also a concern; the monoamines DA, 5-HT, and norepinephrine oxidize at similar potentials and are colocalized in many of the same brain regions. In many cases, waveform optimization and pharmacological manipulation are implemented to differentiate between the molecules and to reduce

Fig. 2 Schematic of FSCV at CFMs. The top shows the waveform. The blue box shows the parameters of the waveform. In the middle is an illustration of a CFM performing a two-electron oxidation/reduction of DA with a representative cyclic voltammogram to the right.

signals due to other interferences. This review will explore advancements made in FSCV to address existing limitations and to provide additional insight into the complexities of neurotransmission.

Biosensors

When the analyte of interest is not easily electroactive, biosensors can be applied. Biosensors are devices that create an electrical signal in response to the analyte *via* a biocatalyst such as an enzyme, antibody or DNA.⁵ Electrochemical biosensors commonly involve immobilization of an enzyme at an electrode surface. This enzyme is selective for an analyte of interest. As an example, the enzyme Glu oxidase oxidizes Glu and reduces O₂ to H₂O₂. While Glu is not readily electroactive, H₂O₂ can be easily oxidized. Thus amperometry (current measured at constant potential) can quantify Glu *via* H₂O₂ oxidation. A generalized biosensor scheme is shown in Fig. 3. The major advantages of biosensors are the high selectivity afforded by the biological molecule and electrochemical detection of chemicals that are not electroactive within the potential window of traditional electrode materials. However, the use of enzymes produces many challenges. Sufficient enzyme loading for high sensitivity, membranes and immobilizing matrices often necessitates large probes, which is undesirable for measurement in delicate brain tissue.⁶ Additionally, immobilization methods can cause

conformational changes in the enzyme, lowering catalytic activity, stability and shelf-life.⁷ Efforts to overcome these obstacles for *in vivo* measurements are highlighted throughout this review.

Glutamate (Glu)

Structure 1. Glu Molecule

Introduction

Glu is one of the most ubiquitous neurotransmitters⁸ that binds to NMDA (*N*-methyl-D-aspartate), kainate, AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid), and metabotropic receptors.⁹ Because Glu is highly excitatory, this messenger can exert excitotoxic effects and is thus rapidly taken *via* excitatory amino acid transporters located on the plasma membrane of astrocytes and neurons.^{10,11} This high level of regulation presents difficulties for analytical Glu measurements since Glu cannot readily escape the synapse like the neuromodulators described later in this review. Additionally, Glu is not electroactive within the potential window of conventional electrode materials. These two phenomena present unique challenges for Glu detection.

The extraction and purification of Glu oxidase¹² enabled development of selective Glu biosensors, the frontline electrochemical Glu detection devices. Working electrodes in these sensors can be made from carbon fiber¹³ or diamond¹⁴ but are most commonly composed of platinum.¹⁵ Substrate materials for creating sensing platforms, including arrays, are primarily silicon or ceramic.¹⁶ Strategies for immobilizing the enzyme onto the electrode surface include direct adsorption, covalent binding, cross-linking,¹⁷ and entrapment in polymers (reviewed in Scoulen *et al.*,¹⁸ Freire *et al.*,¹⁹ Putzbach *et al.*,²⁰ and Hughes *et al.*²¹). Immobilization of enzymes in polymeric membranes, especially electrochemically deposited polymers,^{22–34} gained increasing attention due to a variety of factors,²³ particularly the ability to prevent interfering molecules from reaching the electrode. Self-referencing is another strategy used to reduce signals from other electrochemically active species.^{34–36} This approach involves a second electrode that mimics the working electrode in all respects but does not contain enzyme. This ensures that signals from any non-selective binding of species to the electrode surface can be subtracted out.

One major limitation for biosensors is poor electron transfer between the enzyme and the electrode due to the tunneling

Fig. 3 Schematic of an electrochemical biosensor. A typical biosensor consists of a biorecognition element selective for the molecule of interest (blue triangles) within a given matrix (red squares and green circles), a transducer that converts the input into a measurable signal, and signal processing and output components.

distance between the enzyme's electron transfer center and the electrode. To improve signal transduction, various functional nanomaterials^{37–40} and redox mediators^{41–43} were incorporated into the electrode design.⁴⁴ Using these general strategies, Glu biosensors were utilized to investigate the dynamics of this messenger in the brain.

Glutamate in sleep/wake and reward

Electrochemical measurement of Glu could have implications for diagnosis of sleeping and addictive disorders. Glu biosensors have been used in the mouse prefrontal cortex (PFC) to investigate Glu's roles in the sleep/wake cycle. For example, Naylor *et al.* found that extracellular Glu levels correspond well to the sleep/wake cycle. Glu levels were higher during the awake state and lower during the sleep state with transients during periods of REM sleep.⁴⁵ Further work found chronically high levels of extracellular Glu in the same brain region in animal models with Rett syndrome, which is marked by severe sleep deprivation-like symptoms.⁴⁶

Glu biosensors have also been utilized to investigate reward circuitry. An initial dose of nicotine induced rapid, transient Glu release in the ventral tegmental area and the nucleus accumbens, regions that make up the mesolimbic system, a neural system highly implicated in reward.⁴⁷ Cocaine administration induced similar phasic Glu release in the nucleus accumbens shell.⁴⁸ Repeated doses of nicotine increased tonic Glu that correlated with drug-induced hyperlocomotion.⁴⁷ Repeated doses of cocaine had similar effects in the dorsal striatum⁴⁹ and an interesting biphasic release profile in the nucleus accumbens shell.⁴⁸ Wassum *et al.* measured rapid Glu transients prior to lever pressing in rodent models of reward-seeking behavior.^{33,50} These studies generally implied a role for Glu in cue-evoked reward behaviors; however, a 2015 study showed that Glu release from selective activation of glial cells inhibited reinstatement of cocaine seeking behavior.⁵¹ Thus, Glu's roles in reward seeking are clearly complicated and warrant more investigations.

Technological advances over the last five years include using novel materials to enhance sensitivity, stability, response time, and cost effectiveness of these sensors. There has also been a push to address the oxygen-sensitivity of glutamate sensors by replacing glutamate oxidase with other enzymes. Additionally, it is clear that other analytes and chemicals work in tandem with Glu. Thus, there is a need for multi-analyte measurements and integrated devices. We review novel technical advancements below.

Novel technical advancements for glutamate biosensors

Materials. Novel materials have been used in recent years to enhance the intrinsic properties of Glu biosensors. The first generation of Glu biosensors utilize molecular oxygen as the electron acceptor to form H_2O_2 , which is electrochemically detected. Accurate measurements of Glu in oxygen-poor environments, such as hypoxia, thus pose a problem. To tackle this, researchers turned to cerium oxide, a co-immobilization material that can trap and release oxygen from its crystalline

structure.⁵² Shi *et al.* developed second generation biosensors using chitosan as a directional immobilization matrix for both Glu oxidase and redox mediators.⁵³ These matrices are particularly useful for small electrode areas that cannot be drop-coated or screen-printed. The group found that immobilization *via* chitosan provided faster response times than sensors cross-linked to the electrode *via* the traditional glutaraldehyde linker.⁵⁴

Weltin *et al.* used a flexible polyimide-based substrate as the wafer for sensor design, instead of the more rigid silicon or ceramic alternatives. The authors pointed out that soft materials cause less tissue damage and demonstrated the utility of this sensor by measuring Glu *in vivo*.⁵⁵ In a follow-up study, the same group created multiparametric devices *via* hybrid thin-film and laminate technology using polyimide substrates.⁵⁶ The device included sensors for Glu, lactate, oxygen, and glucose detection simultaneously.

The polymers used for biosensors are also important. Clay *et al.* recently developed a mathematical model for optimizing conditions of electroenzymatic sensors for optimal Glu detection. The model accurately predicted the sensitivity for Glu sensors made by immobilizing Glu oxidase with various polymeric films. Simulations demonstrated that a significant amount (>95%) of H_2O_2 generated in the thick enzyme layers tend to diffuse back to the sample solution, suggesting that biosensors made with thinner films (1–3 μ m) were optimal. In fact, the simulations showed that these films would yield several-fold improvement in both sensitivity and response time. The model was for a specifically constructed device; however, it can be used as a blueprint for optimizing other enzyme-based biosensors.⁵⁷

Other notable examples of novel materials include hybrid carbon materials by Sainio *et al.*, who demonstrated that electrodes made with tetrahedral amorphous carbon nanofibers had a larger potential window than conventional electrode materials and could measure Glu without enzymes.⁵⁸ Nasr *et al.* developed a borosilicate micropipette-based biosensor covered with self-organized nanostructures, whose large surface area increased sensitivity for Glu detection in stem cell-derived brain organoids.⁵⁹

Enzyme alternatives. Oxygen is an important consideration in glutamate sensing. First-generation sensors require oxygen to function while second-generation sensors use artificial redox mediators, which oxygen competes with. Thus, a limitation of first-generation glutamate sensors is oxygen deprivation while a limitation of second-generation sensors is oxygen interference (reviewed in Jamal *et al.*⁶⁰). One way to overcome these issues is to replace the glutamate oxidase enzyme in these sensors with other enzymes. The most common approach has been to replace glutamate oxidase with glutamate dehydrogenase.^{61–63} Wu *et al.* recently discovered that ferredoxin-dependent glutamate synthase also has bioelectrocatalyst properties and can be tuned to either catalyze glutamate synthesis or glutamate oxidation by careful selection of redox mediators.⁶⁴ This discovery is notable for a new generation of glutamate biosensor design because (1) it overcomes the oxygen sensitivity seen in previous generations and (2) since the redox-active region is

close to the surface of the enzyme, it provides a method that allows for direct electron transfer between the enzyme and the electrode surface.

Multi-modal and integrated glutamate measurements. An ongoing challenge for electrochemical sensor design is to measure both electroactive and non-electroactive neurotransmitters with the same device. Moore *et al.* used a commercially available Glu biosensor, incorporating ascorbic acid (AA) oxidase (to inactivate this interfering species) and measured DA and Glu at constant potential. Although there is less selectivity when using fixed potential instead of FSCV, the authors argued that it is a worthy trade-off to be able to detect multiple neurotransmitters at the same device. The group used this technique to measure phasic and tonic changes in Glu and DA during sexual behavior of hamsters.⁶⁵ In a similar approach, Massicotte *et al.* created a novel complementary metal-oxide-semiconductor amperometric system for multi-electrode measurements of DA and Glu.⁶⁶ Like Moore *et al.*, this group recognized the reduced selectivity with constant potential detection of DA and proposed the use of adaptable carbon nanotube-based coatings for reducing interferences. Ferreira *et al.* created microbiosensors for ascorbate and Glu, and then combined the two in an array for simultaneous measurements *in vivo*.⁶⁷ Fig. 4 shows the CFM (left) modified with Nafion™ and single-walled carbon nanotube (with an LOD of 0.7 μ M) for ascorbate sensing and ceramic microelectrode arrays (right) for Glu sensing. The middle is a micropipette for delivering local stimulus solution.

Electrophysiology is one of the most commonly used techniques in neuroscience and monitors neuronal activity as

a function of a DC shift. Wei *et al.* developed silicon-based implantable microelectrode arrays with a microelectromechanical system technology for simultaneous *in vivo* Glu and electrophysiological recordings in the striatum of anesthetized rats.⁶⁸ In a similar approach, Fan *et al.* created a 16-channel silicon-based array based on microelectromechanical system technology. Twelve of the 16 electrodes were modified with platinum black, a “spongy” electrode material with excellent catalytic properties, for electrophysiological recordings of neural firing. The remaining 4 electrodes were modified with Glu oxidase for Glu measurements *in vivo*. This microelectrode array was implanted into the cortex and hippocampus of mice and Glu concentrations were found to be higher in the hippocampus despite slower firing rates of neurons.⁶⁹

Acetylcholine (ACh)

Structure 2. ACh Molecule

Introduction

ACh binds to two main classes of receptors: nicotinic and muscarinic. Ionotropic nicotinic receptors are present in relatively low abundance in the brain, with the majority of cholinergic receptors being metabotropic muscarinic receptors.⁷⁰ Furthermore, ACh is unique among neurotransmitters because the ACh's signal is terminated exclusively through extracellular degradation of the molecule *via* acetylcholinesterase in the synapse that rapidly breaks down this molecule into choline and acetate. Choline is then taken up by the presynaptic cell. Because ACh is not electroactive within the potential window of most biocompatible materials, efforts to measure the molecule have mostly focused on the exploitation of ACh metabolism. Electrochemical enzyme-based sensors for ACh have been developed using either choline oxidase or a combination of acetylcholinesterase and choline oxidase. Enzymes are immobilized on the electrode surface *via* different approaches and the catalytically generated H_2O_2 is detected amperometrically.⁷¹

Duel-enzyme biosensors measured the sum of choline and ACh signals *via* choline oxidase and acetylcholinesterase enzymes.⁷² To refine this approach, self-referencing sensors, with separate sites for ACh/choline and choline detection, allowed interfering signals to be subtracted out and independently quantify choline and ACh signals *in vivo*.^{73,74}

In terms of unraveling ACh's role in the brain using biosensors, Parikh *et al.* were the first to use a simpler single sensor approach of measuring choline in awake, behaving

Fig. 4 Schematic representation of array composed by ascorbate nanocomposite microsensor (left), Glu microbiosensor (right) and the micropipette (center) for local application of solutions in the extracellular space of the rat hippocampus. Reproduced from Ferreira *et al.* with permission.⁶⁷

animals. The electrode was modified with choline oxidase, assuming choline is a direct index of ACh.⁷⁵ The keynote studies from this group laid the foundation for investigating ACh's roles in attention and memory, the most recent of the findings of which are reviewed below.

Acetylcholine's role in attention and memory

ACh measurements with electrochemical devices may prove critical in diagnosis of attention and memory disorders, including neurodegenerative diseases such as Alzheimer's disease. ACh biosensors have time resolution on the order of seconds or sub-seconds and have been able to capture transient changes in ACh concentration.^{75,76} For example, cholinergic transients associated with attentional performance in cue detection behavioral tasks were measured in the PFC of rodents.⁷⁷ In this experiment, animals responded to a visual light cue by pressing an assigned lever for a food reward. The evidence presented in the paper suggested that choline plays a role in switching from monitoring a response to acting upon it.⁷⁷ In a follow up study, optogenetic stimulation of cholinergic transients increased the probability of correctly acting upon a response.⁷⁸ The same group used combined approaches (choline measurements, electrophysiology and pharmacology) to show that cholinergic transients were concomitant with increased neuronal synchronicity across several neuronal firing frequency bands and the emergence of theta-gamma coupling (a neurophysiologic process underlying working memory).⁷⁹ Thus the group revealed the important role that ACh may play in linking attention to memory.⁷⁹ Synchronized release of ACh has also been observed across brain regions; Teles-Grilo Ruivo *et al.* used a dual-enzyme biosensor to measure coordinated ACh release in the PFC and hippocampus of freely moving mice performing a working memory task.⁸⁰

While there have been exciting advancements in the detection of choline and ACh, there are existing difficulties in *in vivo* measurements. Technological advances in the last five years attempted to address some of these, including probe size, stability, temporal resolution, and toxicity. These are addressed in the following section. Some of the papers described are designed for environmental studies but the technical innovations, we believe, can be applied to future *in vivo* sensor design.

Frontiers in acetylcholine biosensing

Acetylcholine measurements on a nano level. A novel nanopipette-based electrode addressed size limitations associated with ACh measurements.⁸¹ Photograph and scanning electron micrograph of this small probe can be seen in Fig. 5A and B, respectively. This electrode utilized assisted ion transfer at nanopipettes combined with cyclic voltammetry (Fig. 5C) and amperometry. The probe was filled with an organic solvent and implanted into an aqueous environment, which is immiscible with the fill solution in the probe. The pipette supported the interface between two immiscible electrolyte solutions (ITIES) and measured ion transfer across a liquid–liquid interface rather than a redox process, allowing for traditionally non-electroactive molecules to be quantitatively measured. The electrodes ranged in size from ~14 to 70 nm in diameter,

Fig. 5 (A) Photograph and (B) scanning electron micrograph of a nanopipette prepared by a laser-pulled capillary. (C) Cyclic voltammogram of 2 mM acetylcholine (ACh), tetraethylammonium (TEA), and artificial seawater (ASW). TEA was used as an internal standard and ASW was the solvent (background signal). Adapted with permission from Colombo *et al.*⁸¹

significantly smaller than the traditional microelectrode. These nanoITIES electrodes were used to measure ACh release from both the soma and a single synapse of *Aplysia californica* cells.^{82,83} A concentration of $2.7 \pm 1.0 \mu\text{M}$ released ACh was measured from a single soma, with a releasable vesicle density of 25 ± 2 vesicles per μm^2 .

Stability. An ongoing issue with ACh biosensors is poor stability and longevity due to loss of enzyme activity. Baker *et al.* utilized stabilizing agents, including methyl methacrylate, cellulose acetate, bovine serum albumin, glutaraldehyde, and polyethyleneimine that permitted stable, chronic *in vivo* implantation of choline sensors up to 14 days.⁸⁴ Kanik *et al.* used the conjugated polymer poly(4-(2,5-di(thiophen-2-yl)-1H-pyrrol-1-yl)benzamine) to create both mechanically and chemically stable biosensors without the need for redox mediators.⁸⁵ Utilizing carbon nanospheres that create unique 3D structures for high enzyme entrapment, Cai *et al.* created an ACh sensor that maintained 80% of its response after 20 days.⁸⁶ A different approach was to entrap acetylcholinesterase within a hybrid silica mesoporous membrane, which, due to its large interconnected pores, enabled high enzyme loading and minimized denaturing.⁸⁷ This sensor maintained 90% of its response after 60 days of storage. Even longer sensor lifetimes, up to 4 months, have been reported.⁸⁸

Temporal resolution. Santos *et al.* created a choline biosensor with a temporal resolution of 1.4 s.⁸⁹ This sensor was composed of two 50 μm diameter Pt/Ir disks constructed side-by-side with choline oxidase immobilized onto the electrode surfaces with

chitosan as the matrix and *p*-benzoquinone as the linker. This sensor provided high spatiotemporal resolution for spontaneous choline measurements in sub-regions of the hippocampus.⁸⁹ Mousavi *et al.* created a potentiometric ionophore-doped ion-selective electrode which did not require enzyme modification.⁹⁰ The potentiometric method measured the partition of the cationic 5-HT molecule between the sample and a hydrophobic ion-selective membrane doped with calixarene, a hydrophobic molecule whose binding cavity mimics that of acetylcholinesterase. This sensor had a response time of <1 second and was used successfully in rat brain homogenates. Keighron *et al.* modified carbon fiber microdisk electrodes with spatially discrete nanoparticles, onto which acetylcholinesterase and choline oxidase were deposited.⁹¹ The enzyme layer was near monolayer thickness, allowing for rapid (millisecond) response time, the fastest reported for biosensing tools. This technique was used to measure exocytotic ACh release from artificial secretory cells.

Green acetylcholine detection. A fast-growing interest for sensor design is sustainability. For biosensors this means renewable enzyme interfaces for reusable sensors. Zhang *et al.* used the layer-by-layer self-assembly technique to create a renewable ACh biosensor.⁹² The enzyme interfaces were renewed by treatment with NaOH and fresh layers of multi-walled carbon nanotubes with polyethylenediamine and acetylcholinesterase. Researchers are also increasingly interested in the use of safe materials. The immobilization and interference rejection polymer poly-phenylenediamine has been suggested to be carcinogenic.⁹³ Phenol-derived films⁹³ as well as nanocomposites, made of gold-coated iron oxide nanoparticles with chitosan,⁹⁴ show promise for safe materials. Using these materials, Chauhan *et al.* created an iron oxide nanoparticle poly(3,4-ethylenedioxythiophene)-reduced graphene oxide nanocomposite modified fluorine doped tin oxide biosensor for rapid (4 s), sensitive (4 nM) ACh detection in serum.⁹⁵

Dopamine (DA)

Structure 3. DA Molecule

Introduction

DA is a neuromodulator and is released, by the fusion of pre-synaptic vesicles to the cell membrane, in the extracellular space. DA exerts its effects, *via* volume transmission, to modulate the function of other neurotransmitters. DA has five major

receptor subtypes (D₁–D₅) and is regulated *via* autoreceptors, heteroreceptors and transporters.⁹⁶

CFMs were discovered to be useful sensors for *in vivo* DA measurements due to their biological compatibility^{97,98} and renewable surfaces.^{99,100} Early days of DA measurements were plagued by interferences, particularly significant contribution from AA, which is present in much higher quantities in the brain than DA.¹⁰¹ However, it was demonstrated that holding the potential at -0.4 V preconcentrates the positively charged DA ion,¹⁰² and increasing scan rate allows DA oxidation (whose electron transfer kinetics are faster than that of AA) to overshadow AA oxidation.¹⁰³ New instrumentation was created to simplify measurements and data analysis.¹⁰⁴ Dopamine was measured with FSCV as evoked with electrical stimulation,¹⁰⁵ and Rebec *et al.* were the first to observe DA transients during behavior.¹⁰⁶ We know precipitously more about the functions of DA in the brain than other transmitters because of this breakthrough technique, typified by the work of Mark Wightman over the last four decades. These works have enabled routine study of DA by many members of the community.

Dopamine in cognition and reward

Electrochemical devices that measure DA have wide reaching diagnostic potential, for example in addictive and cognitive disorders and neurodegenerative diseases such Parkinson's disease (characterized by loss of DA neurons). DA FSCV technology described above culminated, among other seminal findings, in establishing DA's major roles in reward and cognition.^{107–115} These findings spearheaded an explosion of studies to understand these behaviors in the context of the dopaminergic system. In particular, it was found that the reward-related behaviors described above are controlled by the mesolimbic DA circuits, which are in turn modulated by endogenous factors such as hormones. Naef *et al.* showed that insulin administration reduced DA release in the nucleus accumbens as well as attenuated cocaine-induced DA spikes and locomotor hyperactivity.¹¹⁶ The hormone estradiol was found to increase the DA mediated potency of cocaine,¹¹⁷ a finding that could explain the sexual dimorphism in addiction vulnerability. Another interesting finding has been that the stress hormone corticosterone potentiates DA signaling *via* inhibition of the organic cation transporter (OCT) 3, which may explain stress-induced drug relapse behavior.¹¹⁸

Other notable investigations involving DA FSCV include measuring this modulator in humans playing a reward based investment game during surgery for deep brain stimulation for Parkinson's disease¹¹⁹ and after administration of chemotherapy drugs in a zebra fish model of chemo brain.^{120–122} An additional recent direction is deciphering DA/5-HT modulation in the context of alcohol consumption¹²³ and response to neutral stimuli in animal models.¹²⁴

Recent technical advances in the last five years, including improvement of calibration, measurement of ambient DA levels, monitoring multiple analytes simultaneously, chronic measurements, and integrating *in vivo* voltammetry with other platforms are highlighted below.

Technical advancements

Calibration. Calibration is an ongoing issue for FSCV. CFMs are typically fabricated in-house; thus calibration of each electrode is necessary to ensure quality. There is ongoing discussion in the field as to whether to employ pre- or post-experiment calibrations. In either case, *in vitro* calibrations do not reflect the *in vivo* performance of the electrode. This is because calibrations are performed in buffer solutions that cannot replicate the *in vivo* environment. Additionally, *in vivo* proteins adsorb to and foul electrodes, resulting in loss of sensitivity. Furthermore, in most experiments, the tip of the electrode must be exposed to a high enough potential to lesion the surrounding tissue for location determination, a process that renders post-calibrations impossible.^{125,126} To overcome these issues, various mathematical tactics have been employed.

Via a total-background-current strategy, Roberts *et al.* created a quadratic model relating sensitivity to background current and switching potential.¹²⁵ The group showed that the model was a good predictor of *in vivo* sensitivity. An alternative approach is to use principal component regression, which captured information from the shape of the background current to better provide estimates of sensitivity.¹²⁶ Meunier *et al.* built upon this principal component regression strategy by modeling impedance changes due to electrode fouling with simple circuits, thereby improving the accuracy of predicted background current.¹²⁷

Chronic dopamine measurements. The majority of *in vivo* FSCV studies span 4–8 h. There is great interest to make measurements at a CFM in the same position over an extended period of time to understand neurochemical changes during behavior and/or chronic pharmacological manipulations. Chronic measurements have been a topic of interest for some time, for a discussion of chronic FSCV methods before 2013, we refer the reader to a review by Wightman and colleagues.¹²⁸

One of the chief issues with chronic measurements is the loss of electrode material over time.¹⁰⁰ Nimbalkar *et al.* designed and fabricated a new class of homogeneous glassy carbon neural probes with no adhesion or conducting metal layers, thereby enhancing the lifetime of the probe for long periods of electrical stimulation (for deep brain stimulation, for example).¹²⁹ Interestingly, the same probe materials were capable of stimulating in addition to performing neurochemical measurements.¹²⁹

Another hindrance to using traditional FSCV carbon fiber probes for chronic measurements is the size of the probe shaft, which induced inflammatory responses. While the probe tip was on the order of 5–7 μm , the probe shaft can be as large as 100 μm . Inflammatory responses can foul the electrode surface, reducing the lifetime of the electrode. Schwerdt *et al.* recently replaced the glass shaft of the conventional CFMs with parylene, which provides robustness in a thinly deposited layer surrounding the carbon fiber, resulting in <10 μm size probe shafts. These probes were fabricated into arrays and implanted in rodent,¹³⁰ and non-human primate¹³¹ brains for successful multi-channel simultaneous DA measurements for over 100 days *in vivo*.

Ambient dopamine levels. FSCV is background-subtracted because of a large double layer charging current that results from application of fast scan rates. Because of this, a change must be evoked in the system, usually *via* electrical stimulation. Background subtraction has thus prevented measurement of tonic or ambient, steady state levels of neurotransmitters *in vivo*. In 2012, the Wightman group utilized pharmacology to report tonic DA levels at around 20 nM.¹³² The following text highlights recent approaches to measuring ambient DA levels.

Atcherley *et al.* modified FSCV and coined a novel method, fast-scan controlled-adsorption voltammetry (FSCAV).¹³³ Fig. 6 shows that DA FSCAV takes place over three distinct steps: (1) the triangle waveform (−0.4 to 1.3 V, scan rate = 1200 V s^{-1}) was applied at a high frequency of 100 Hz to minimize adsorption of DA to the electrode surface (A, purple region); (2) a fixed potential (−0.4 V) was applied to the electrode system, allowing for DA to adsorb to the electrode surface for a controlled amount of time (A, blue region); and (3) the waveform was then reapplied at the same frequency to measure the adsorbed DA (A, green region). Fig. 6B shows a representative color plot, from which the first current *vs.* time curve with the representative DA peak (Fig. 6C) is used to quantify the total charge underneath the peak. Total charge was then plotted against concentration (Fig. 6D) to generate a calibration curve.

Atcherley *et al.* reported a tonic concentration of 90 ± 9 nM of DA in the nucleus accumbens core of an anesthetized mouse with a limit of detection of 3.4 ± 0.8 nM and a temporal resolution of 30 s.^{134,135} FSCAV was recently coupled to FSCV to concurrently measure both stimulated release and tonic DA in brain slices.¹³⁵ In an alternate strategy, Oh *et al.* changed the waveform for FSCV into a “Mexican hat” waveform and introduced a dual-background subtraction protocol to measure tonic DA.¹³⁶ They termed this new method charge balancing multiple waveform FSCV. In a follow up study, the group utilized multiple cyclic square wave voltammetry for measuring tonic DA, which, like FSCAV, also utilized a holding potential period to control DA adsorption onto the carbon fiber. In this method, they modeled the fast capacitive current decays using a simple exponential decay equation and subtracted it out from the raw signal.¹³⁷

Other approaches used mathematics to address the issue of the large background current. Johnson and Wightman optimized an experimental protocol in order to simplify background current to those that can be mathematically explained and then used a convolution-based method to predict and remove the resistive-capacitive component of the CFM background current.¹³⁸

Simultaneous measures of other analytes with dopamine. Waveform and enzyme modifications have enabled simultaneous detection of DA with other analytes. The typical DA FSCV waveform has a positive potential limit of +1.3 V.¹³⁹ By scanning more positive than this (+1.4 V) Spanos *et al.* were able to capture an oxidation peak for H_2O_2 in addition to DA.¹⁴⁰ The group found that H_2O_2 levels attenuated both phasic and tonic levels of DA *in vivo* in the rat dorsal striatum. The same group reported that holding the potential of the traditional DA at

Fig. 6 FSCAV was carried out in 3 steps (A): (1) the waveform was applied every 10 milliseconds which minimizes DA adsorption to the electrode. (2) The potential was held at -0.4 V for 10 seconds to allow DA to adsorb to the electrode and reach equilibrium. (3) The waveform was reapplied, and the adsorbed DA was measured. Surface-accumulated DA (Γ_{DA}) is proportional to the tonic concentration [DA] by the strength of adsorption. (B) Resultant color plot from step 3, with voltage on the ordinate, time on the abscissa, and current displayed using false colors. (C) Representative current trace (red) taken 10 milliseconds after the beginning of step 3. The vertical dashed lines show the bounds for integration to quantify adsorbed DA. The grey-dashed triangles illustrate the voltage waveform applied. (D) A calibration plot obtained by FSCAV post implantation ($R^2 = 0.996$, slope = 0.0078 ± 0.0002 pC nm^{-1} ($n = 7$ electrodes)), which when accounting for electrode area and equivalents transferred, corresponds to $b = 0.0037 \pm 0.0002$ cm. Reproduced with permission from Atcherley *et al.*¹³³

-0.2 V (instead of -0.4 V), allowed for simultaneous detection of glucose (*via* H_2O_2 generated from a layer of glucose oxidase on the CFM) and DA.¹⁴¹ They found that stimulated release of DA *in vivo* was followed by an increase in glucose to meet the increased energy demanded by the stimulation. The Cans group constructed an amperometric biosensor by immobilizing an ultra-thin layer of glucose oxidase onto a Au-nanoparticle-covered CFM that permitted the simultaneous monitoring of glucose and DA with millisecond temporal resolution for both analytes.¹⁴²

Other surface modifications have enabled detection of other analytes with DA. Cincotto *et al.* modified glassy carbon electrodes with a hybrid material consisting of mesoporous silica nanoparticles, graphene, and silver nanoparticles for simultaneous electrocatalytic reduction measurements of DA and epinephrine.¹⁴³ Stephen and colleagues modified glassy carbon electrodes with a poly(*o*-methoxyaniline)-gold nanocomposite, which reduced overpotentials and separated overlapping peaks for simultaneous folic acid and DA detection.¹⁴⁴ Si *et al.* used pyrrole and *o*-phenylenediamine monomers to form molecularly imprinted polymers for simultaneous detection of DA, norepinephrine, and epinephrine using differential pulse voltammetry.¹⁴⁵

Other notable multimodal technology include work done by Lee *et al.*, who improved upon a previous generation of their multi-modal device, called WINCS (wireless instantaneous neurotransmitter concentration sensing), by making a multi-channel version called WINCS Harmoni.¹⁴⁶ Fig. 7 shows (A) a photograph of the WINCS Harmoni device, (B) schematic of the functional components, (C) the analog-to-digital converter, and (D) typical calibration curves from each of the four recording channels. The beauty of this device lies in four primary aspects: (1) the wireless component reduces instrumentation clutter, (2) the multi-channel allows for simultaneous FSCV DA recordings in up to four channels, (3) the design allows for concurrent recordings of both striatal DA and 5-HT in the substantia nigra (SNr), and (4) a closed loop paradigm that gives the user the ability to adjust deep brain stimulation parameters *based on* real-time monitoring of neurotransmitter release *in vivo*. The authors successfully demonstrated the versatility of this device in swine, rodent, and non-human primate models.¹⁴⁷

Dopamine measurements integrated with electrophysiology. An integrated measurement platform known as DANA (DA and Neural Activity) was developed by Parent *et al.* to obtain near simultaneous electrophysiological and DA FSCV measurements.¹⁴⁹

Fig. 7 (A) Photograph of the WINCS Haroni device; (B) schematic diagram showing the functional components in WINCS Haroni, including the neurochemical sensing and stimulation boards, charging components, bluetooth transceiver, primary microcontroller, and control software in the base station; (C) image and dimensions of the WINCS Haroni delta sigma ($\Delta\Sigma$) analog-to-digital converter (ADC) that enables four channels of simultaneous neurochemical recordings; (D) typical calibration curves for each of the four neurochemical recording channels in WINCS Haroni showing a linear relationship between DA oxidation current and DA concentration. Reproduced with permission from Lee *et al.*¹⁴⁸

Single-unit and DA measurements were collected in awake and freely moving rats to demonstrate the potential of DANA to connect behavior to physiology and neurochemistry.¹⁴⁹ Work from the Kassegne group created a DA and neural activity platform using four-channel glassy carbon flexible electrode array in four distinct brain regions.¹⁵⁰

Spreading depolarization (SD) is a pathological process characterized by propagating waves of cell firing. SD waves can be diagnostic events for cell death in penumbral tissues but because of the non-specific firing associated with SD waves, multi-modal analyses are necessary for investigation of the phenomenon. Hobbs *et al.* created an integrated multimodal device that monitors oxygen levels (an indicator of cerebral blood flow and energy consumption) concurrently with DA and single unit recordings.¹⁵¹ The benefit of this microdevice is that it eliminated the need for multiple sensors, which are cumbersome but also cause significant tissue damage. The group observed significant oxygen and DA fluctuations during spreading depolarization events.

Other notable publications include a multi-functional microelectrode array that contained nearly 60 000 electrodes and over 2000 electrophysiology channels for stimulation, FSCV, and impedance measurements in rat cortical neurons and cerebellar slices.¹⁵²

Serotonin (5-HT)

Structure 4. 5-HT Molecule

Introduction

5-HT is a neuromodulator with a complex receptor profile. On the postsynaptic cell, 5-HT receptors include 2 inhibitory and 11 excitatory G protein-coupled receptors (GPCRs), and a ligand-gated ion channel (5-HT₃). 5-HT signals are terminated *via* multiple mechanisms:

(a) Reuptake into presynaptic neuron and glia by 5-HT transporters (SERTs), known as Uptake 1.

(b) Reuptake into other neuron types by monoamine transporters (DATs, norepinephrine transporters (NETs) or organic cation transporters (OCTs)), known as Uptake 2.

(c) Presynaptic autoreceptor binding.

(d) Intracellular metabolism by monoamine oxidases.^{153,154}

5-HT is electroactive like DA, however, it has been greatly challenging to apply the tools successful for DA analysis to 5-HT measurements. For many decades, electrochemical 5-HT measurements were limited to *ex vivo* preparations such as cerebral spinal fluid¹⁵⁵ or tissue slice preparations.¹⁵⁶ Direct 5-HT detection *in vivo* was not achieved as early as DA detection because 5-HT oxidation products rapidly polymerize and foul the electrode surface. In 1995, Jackson *et al.* set the groundwork for detecting exogenous 5-HT *in vivo* using FSCV with a novel waveform (+0.2 to +1.0 to -0.1 to +0.2 V, 1000 V s⁻¹), that dramatically decreased electrode fouling.¹⁵⁷ They utilized this waveform in a 'mock' *in vivo* experiment, modeled after an experiment performed by Stamford *et al.*, where dopaminergic neurons were induced to release 5-HT via inhibition of DA synthesis and pre-loading with 5-hydroxytryptophan (5-HTP), the 5-HT precursor.¹⁵⁸ In 2009, Hashemi *et al.* were the first to describe endogenous 5-HT measurements in mammalian models.¹³⁹ They described the primary difficulty of *in vivo* measurements as 5-HT's highly concentrated, electroactive metabolite, 5-hydroxyindoleacetic acid (5-HIAA) (not present in tissue slice preparations). Using a combination of the Jackson waveform and electrodeposition of NafionTM, they were able to measure 5-HT *in vivo* in the rat SNr.¹³⁹ The following section details recent keynote studies utilizing 5-HT FSCV in physiological investigations.

Serotonin's role in affective disorders

Diagnosis of affective (mood) disorders would greatly benefit from electrochemical 5-HT detection. 5-HT is thought to modulate mood; it has long been postulated that 5-HT deficiency underlies the behavioral phenotypes of affective disorders such as depression.¹⁵⁹ However, this hypothesis (the monoamine theory of depression) has been difficult to verify because of the challenge of measuring 5-HT *in vivo* on neurotransmission timescales. Using FSCV it is now possible to measure 5-HT with high temporal and spatial resolution *in vivo*. This has strengthened our knowledge of 5-HT physiology and pharmacology, as reviewed below, and will ultimately enable characterization of 5-HT in affective disease models.

In 2014, Wood *et al.* found that 5-HT in the mouse SNr had three uptake profiles: slow (>20 seconds), fast (<10 seconds), and hybrid (a combination of the slow and fast), with the hybrid mechanism being the most common of the uptake profile encountered *in vivo*.¹⁶⁰ The 'fast' and 'slow' responses were identified as two distinct clearance mechanisms: Uptake 1 (slow), mediated by the SERTs, and Uptake 2 (fast), mediated by other monoamine transporters (DATs, NETs, and OCTs). This study also found that the electrical stimulation created autoreceptor inhibition of 5-HT that lasted tens of seconds.¹⁶⁰ West *et al.* observed a "double peak" phenomenon in the mouse medial prefrontal cortex (mPFC) (Fig. 8),¹⁶¹ in which two 5-HT events were released upon electrical stimulation of the medial

Fig. 8 Schematic showing how each peak in the current vs. time trace corresponds to different uptake mechanisms. Reproduced with permission from West, A., *et al.*¹⁶¹

forebrain bundle (MFB). This is in contrast to the one evoked peak typically seen in other brain regions.^{160,162} Consistently, layers 1–3 of the mPFC produced a single evoked peak, whereas layers 5 and 6 produced a double peak.¹⁶¹ The authors hypothesized two types of 5-HT input to the terminal, linked to discrete reuptake domains. An example of the double peak and the discrete reuptake domains are shown in Fig. 8.

Extracellular 5-HT is thought to be lower during depression,¹⁶³ therefore selective 5-HT reuptake inhibitors (SSRIs), which inhibit the SERTs (presumably increasing extracellular 5-HT levels) are a common treatment. Wood and Hashemi administered acute doses of a common SSRI, escitalopram, to mice. The group found that the effects of this drug on 5-HT were dynamic, not reaching a steady state before drug metabolism.¹⁶⁴ This study suggested that dose-response curves should be redesigned. The Wightman group investigated the effects of SSRIs on autoreceptor-mediated inhibitory feedback and showed involvement of multiple modulatory mechanisms in response to the SSRI.¹⁶⁵ These studies clearly show that SSRI effects on the 5-HT system are complex and in need of further study.

While *in vivo* 5-HT FSCV studies are ongoing recent technical advancements including spatial improvements, simultaneous detection of analytes and ambient 5-HT measurements are enriching the chemical toolbox with which 5-HT can be studied.

Novel technical advancements for serotonin measurements

Serotonin measurements on a nano level. *In vivo*, CFMs are thought to measure from hundreds of synapses.¹⁶⁶ CFMs are too large to probe events *ex vivo* from single synapses. As discussed above for ACh, the Shen lab's nanopipette-based liquid–liquid interface probes are 7–35 nm in radius and can thus probe single synapses.⁸¹ For 5-HT detection, the nanopipettes were filled with an organic phase, 1,2-dichloroethane.⁸¹ Upon the application of a potential, 5-HT was transferred across the ITIES tip into the organic phase. The authors observed that a higher overpotential

was required for transferring 5-HT across the interface compared to tryptamine so the detection of lower concentrations of 5-HT proved to be more difficult. Nonetheless, the authors achieved a limit of detection of 77 μ M with a 21 nm pipette, which is likely sufficient for synaptic measurements.

Simultaneously measuring serotonin with other analytes. An important recent finding is 5-HT's co-modulatory relationship with HA. The axons of these two modulatory systems are highly colocalized,^{167,168} and prior *ex vivo* chemical measurements implied co-modulation.^{169–171} HA measurements are challenging, since HA electrooxidation is not straightforward and likely involves charge transfer.¹⁷² Samaranayake *et al.* optimized a waveform that enabled a robust, faradaic oxidation peak in response to HA with an LOD of 1 μ M and linear dynamic range spanned up to 20 μ M. This was sufficient for measuring HA *in vivo*.¹⁷² Further experiments used this waveform to understand the modulation of 5-HT and HA *in vivo*. The group showed that 5-HT was inhibited by H_3 heteroreceptors on post synaptic neurons.¹⁷² Fig. 9 shows that 5-HT release is inhibited by HA even under varying factors including the stimulation frequency (Fig. 9C), the stimulation pulse width (Fig. 9D) and the stimulation amplitude (Fig. 9E).

Other notable studies include the WINCS Harmoni wireless device created by Lee *et al.*¹⁴⁸ that simultaneously detects 5-HT in the SNr and DA in the striatum. More details on WINCS Harmoni can be found in the DA section of this review (*vide*

supra). The Dayan lab created a mathematical algorithm capable of separating DA and 5-HT signals in humans.¹⁷³ Finally, the Cai and Liu labs are working on electrochemical arrays with the capability of measuring 5-HT with other analytes and the potential for future *in vivo* analysis.^{174,175}

Ambient, steady-state serotonin measurements. As described above, FSCV is background subtracted, thus basal or ambient, steady state 5-HT values cannot be garnered with this method. Abdalla *et al.* optimized FSCAV for 5-HT measurements and reported basal levels of 5-HT in the CA2 region of the hippocampus as 64.9 ± 2.3 nM *in vivo*.¹⁶² The technique shows linearity up to 600 nM with an LOD of 1.5 nM. Instrumentation for FSCAV has recently been simplified such that it can be constructed by non-experts with simple electrical components.¹⁷⁶

Other neurochemicals

As the community develops better tools for defining the roles of neurotransmitters in disease, we can better focus diagnostic tests on neurotransmitters specific to distinct disorders. GABA is the most abundant inhibitory neurotransmitter.¹⁷⁷ Because GABA is not easily redox active, electrochemical analysis of this neurotransmitter is challenging.¹⁷⁸ The Shen lab applied their nanopipette approach to GABA.¹⁷⁹ Unlike the analytes reviewed here, GABA is a zwitterion at neutral pH; this phenomenon makes it very difficult to partition GABA between phases. To

Fig. 9 (A) Representative color plot of the stimulated release of HA and 5-HT inhibition in the premammillary nucleus. (B) Correlation plot between [HA] and [5-HT] for all stimulation parameters. (C) Averaged current versus time traces along the two horizontal dashed lines of HA and 5-HT with respect to different stimulation frequencies ($n = 5$). (D) Averaged current responses to various stimulation pulse widths of HA and 5-HT ($n = 5$). (E) Averaged current responses to various stimulation amplitudes of HA and 5-HT ($n = 5$). facilitate partitioning between phases, octanoic acid was added to lower the pH along with dibenzo-18-crown-6, thus detection of protonated GABA.¹⁷⁹ The Arumugam lab took an interesting electrochemical approach to detecting GABA simultaneously with Glu using a microarray with GABA and Glu biosensors. On site 1 of the array is a Glu biosensor and on site 2 is a GABA biosensor side-by-side with a second Glu biosensor. The group measured the current generated from H_2O_2 oxidation at both electrodes. The current at site 1 was due to Glu only. The current at site 2 was due to Glu and GABA, therefore subtraction of site 1 current from site 2 allowed GABA quantification.¹⁸⁰

Peptides are strings of amino acids that act as signaling molecules in the brain. The Sombers lab created a sawhorse FSCV waveform to detect Met-enkephalins. The detection scheme is shown in Fig. 10. The sawhorse FSCV waveform (Fig. 10B) is modified from the conventional one used for DA detection (Fig. 10A). Using the conventional waveform produced significant electrode fouling (Fig. 10C, asterisk), which was not observed in the color plot for modified sawhorse waveform. Their method has high selectivity, being able to distinguish Leu- and Met-enkephalin, which differ by a single amino acid.¹⁸¹ The group successfully measured norepinephrine and Met-enkephalin release after mild electrical stimulation in adrenal tissue slice.

The Venton group has been successful at measuring a variety of neurotransmitters including octopamine and adenosine.^{182–184} Octopamine is a biogenic amine in invertebrates that regulates intracellular cyclic AMP (adenosine monophosphate) and Ca^{2+} .¹⁸⁵ Pyakurel *et al.* first measured octopamine using FSCV in

the ventral nerve cord of *Drosophila melanogaster* larvae.¹⁸² Octopamine was released *via* optogenetic red light-stimulated release with a total simulation time of 1 s or less.¹⁸² Adenosine is a nucleoside produced from the breakdown of ATP. In the central nervous system, this molecule plays an important role in many biological processes, such as regulating neurotransmission and reducing excitotoxicity.¹⁸³ Nguyen and Venton developed a method for direct adenosine detection using FSCV.¹⁸³ Spontaneous adenosine transients were observed in addition to electrically and mechanically stimulated release.¹⁸³ *In vivo* clearance of spontaneous adenosine was shown to occur through multiple mechanisms in the rat caudate putamen.¹⁸⁴ These mechanisms include reuptake through the equilibrative nucleoside transport 1, as well as metabolism of adenosine by adenosine deaminase and adenosine kinase.¹⁸⁴ Ganesana *et al.* examined spontaneous adenosine transients during cerebral ischemia.¹⁸⁶ They found a 52% increase in the number of adenosine transients and a 53% increase in cumulative adenosine concentration during the early stages of cerebral ischemia as compared to normoxia control rats.¹⁸⁶ Another group that studied adenosine developed synthetic boron-doped diamond-based electrodes for chronic *in vivo* measurements of adenosine in humans undergoing deep brain stimulation¹⁸⁷ surgeries for tremor treatment. These diamond-based electrodes, showing little to no degradation even after 5.2 million cycles of FSCV experiments (144 h at 10 Hz), are two-orders of magnitude more robust than carbon fiber-based electrodes.¹⁸⁷

Fig. 10 (A) Triangular waveform. (B) Modified sawhorse waveform (MSW). (C and D) Representative *in vitro* voltammetric data collected using the waveforms depicted in parts A and B, respectively, where the ordinate is the potential applied to the carbon-fiber electrode, the abscissa is time in seconds, and the current (nA) is depicted in false color.⁵⁵ 2 μM M-ENK was introduced to the microelectrode at the time indicated by the red bar. Displayed voltammograms were extracted at the time indicated by the dashed line. Asterisks indicate electrode fouling. Reproduced with permission from Schmidt *et al.*¹⁸¹

Melatonin is a hormone produced by the pineal gland and lymph nodes¹⁸⁸ and is thought to play a role in regulating circadian rhythm.¹⁸⁹ The Ross lab developed a new waveform to selectively detect melatonin and to reduce fouling otherwise observed with conventional waveforms.¹⁹⁰ The authors successfully used this new waveform for melatonin detection in lymph node tissue slice preparations.¹⁹⁰ In a similar approach, the same group developed a novel waveform for detection of the neuromodulator guanosine.¹⁹¹ Their optimized approach was selective for guanosine over adenosine because two oxidation events were observed for guanosine at +0.8 V and +1.3 V. This method was successfully applied to measuring exogenously applied guanosine in tissue slice preparations.¹⁹¹

Conclusion and future direction

Neurochemical diagnosis for brain disorders is not available due to a lack of *in vivo* sensors capable of monitoring neurotransmitters and neuromodulators. This review highlighted advancements made in the field of electrochemical microdevices over the past five years for detection and quantification of neurochemical biomarkers of brain disorders. The potential for these analytes to act as biomarkers was discussed and novel measurement methods were highlighted. Specifically, we began each neurotransmitter section with a discussion of what we have learned thus far about the role of each of them in various applicable brain physiology using existing and emerging electrochemical techniques. We then focused on emerging biosensor technology for Glu and 5-HT detection and voltammetric methods for DA and 5-HT measurements. We ended the review with discussion about other neuromodulators of interest, *e.g.* peptides, adenosine, *etc.*, and what tools were designed to measure them.

Via this review we highlighted the considerable progress made thus far in the field of electrochemical sensing for *in vivo* neurotransmitters. However, there are still challenges that need to be addressed when moving towards diagnostic devices. First, probe size remains problematic. Implantation is a physical perturbation to brain tissue. Ongoing efforts to make probe sizes comparable to interneuron distances will minimize damage and reduce inflammation. Furthermore, ongoing miniaturization to nanometer scales will allow synaptic measurements. Second, electrochemical sensing is limited to a few electroactive species. Peptides and proteins still evade detection *via* electrochemical sensors and thus cannot be measured with the same spatiotemporal resolution as smaller, more classical neuromodulators. Future horizons for this type of work may include aptamer modifications to electrodes. Lastly, and perhaps the most significant, there exist no clinical measurements in humans but we are confident, due to the rapid progress in the field reviewed here, that such measurements will be facilitated in the near future.

List of abbreviations

Glu	Glutamate
DA	Dopamine

Ach	Acetylcholine
5-HT	Serotonin
HA	Histamine
GABA	Gamma-aminobutyric acid
DNA	Deoxyribonucleic acid
NDMA	<i>N</i> -Methyl-D-aspartate
AMPA	α -Amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid
PFC	Prefrontal cortex
mPFC	Medial prefrontal cortex
AA	Ascorbic acid
ITIES	Interface between two immiscible electrolyte solutions
CFMs	Carbon fiber microelectrodes
FSCV	Fast scan cyclic voltammetry
FSCAV	Fast scan controlled adsorption voltammetry
WINCS	Wireless instantaneous neurotransmitter concentration sensing
SNr	Substantia nigra pars reticulata
DANA	Dopamine and neural activity
SD	Spreading depolarization
5-HTP	5-Hydroxytryptophan
5-HIAA	5-Hydroxyindoleacetic acid
SERTs	Selective serotonin reuptake inhibitors
DATs	Dopamine transporters
NETs	Norepinephrine transporters
OCTs	Organic cation transporters

Conflicts of interest

There are no conflicts to declare.

Acknowledgements

The authors would like to thank Jordan Holmes for making the neurotransmitter molecules and both Jordan Holmes and Shane Berger for their contributions to the TOC image. The National Institutes of Health (R01 MH106563 for P. H.) funded this work.
