We report the high pressure synthesis of a layered perovskite \( \text{Ca}_2\text{GeO}_4 \) which is found to have the Ruddlesden–Popper structure with \( I4_1/\text{acd} \) symmetry. Consonant with our recent predictions [Ablitt et al., npj Comput. Mater., 2017, 3, 44], the phase displays pronounced uniaxial negative thermal expansion over a large temperature range. Negative thermal expansion that persists over a large temperature range is very unusual in the perovskite structure, and its occurrence in this instance can be understood to arise due to both soft lattice vibrations associated with a phase competition and the unusually compliant nature of this structure, which effectively couples thermal expansion in the layer plane to lattice contractions perpendicular to the layering direction via a ''corkscrew'' mechanism.

Recently there has been renewed interest in layered perovskite Ruddlesden–Popper systems due to the improper ferroelectricity discovered in the \( n = 2 \) family member.\(^1\)–\(^5\) In this structure, octahedral rotation and out-of-plane octahedral tilt modes couple to drive polar distortions leading to a ferroelectric ground state.\(^6\) A phase that competes thermodynamically with the improper ferroelectric phase is one with a single out-of-phase rotation of the BO\(_6\) octahedra about the layering axis, \( c \). While this phase is not ferroelectric it does exhibit pronounced uniaxial negative thermal expansion (NTE)\(^7\) that may be tuned systematically through chemical control.\(^8\) We have recently shown that the magnitude of NTE should be maximised for \( n = 1^{11} \) in which an analogous phase competition to that observed in the \( n = 2 \) structure occurs (see Fig. 1). With this in mind, we have synthesised \( \text{Ca}_2\text{GeO}_4 \) using high pressure techniques and show that it has the most pronounced NTE over the largest temperature range recorded to date in these systems.

Olivine \( \text{Ca}_2\text{GeO}_4 \) precursor was prepared with stoichiometric amounts of \( \text{CaCO}_3 \) (99.9965%, Alfa) and \( \text{GeO}_2 \) (99.999%, Alfa). The starting materials were mixed well and heated at 1200 °C for 12 hours, and after intermediate grinding, the mixture was...
then sintered at 1500 °C for a further 24 hours. The obtained precursor was sealed into a platinum capsule, and heated at 1000 °C at 15 GPa for 30 minutes in a Kawai type 2-stage high pressure apparatus. After the heating treatment the sample was quenched to room temperature over 5 minutes and the pressure slowly released. The sample was studied by temperature dependent synchrotron X-ray powder diffraction on beamline 09A of the Taiwan Photon Source, National Synchrotron Radiation Research Center (NSRRC) with a 15 keV incident beam and MYTHEN detector. The obtained Ca$_2$GeO$_4$ powder sample was sealed in a 0.3 mm diameter borosilicate capillary and 0.3 mm quartz capillary for high temperature experiment which was kept spinning during data collection for better averaging. A DynaFlow cryostat (designed and manufactured by ESRF) with dynamic cooling flow of exchange gas was utilised to provide low temperature diffraction data, for which the sample was cooled first to base temperature (10 K) and collect every 2 K on warming to 150 K. A Cryostream 800 Plus (Oxford Cryosystems) was utilised for data collection from 90 K to 480 K, at intervals of every 5 K to 150 K, every 10 K to 300 K, every 20 K to 480 K. A hot air gas blower (FMB Oxford) was utilised for data collection from 400 K to 800 K, at intervals of every 20 K to 600 K and every 50 K to 850 K. A broadening of diffraction peaks was observed around 800 K and the sample was fully decomposed to the olivine ambient pressure phase by 850 K. The collected patterns were analysed with the Rietveld method using TOPAS. First-principles calculations were performed using plane-wave density functional theory (DFT) as implemented in CASTEP v7.0.13 Using the PBEsol functional to describe exchange and correlation. A 1400 eV plane wave cutoff energy was employed for representing the wavefunctions in all calculations, and a 7 x 7 x 2 grid of k-points were used for the I4/mmm unit cell. This grid was scaled appropriately for larger unit cells to approximately maintain the density of grid points in k-space. Norm conserving pseudopotentials were generated using CASTEP v16.0 and the details may be found in the supplementary output files. In all geometry optimisation calculations, forces were relaxed to below 1 meV Å$^{-1}$ and stresses to below 10 MPa.

The preliminary X-ray powder diffraction analysis revealed that the Ca$_2$GeO$_4$ precursor has the olivine type structure in which Ge are tetrahedrally coordinated, with space group $Pmna$. A temperature induced phase transition of olivine phase into glaserite type structure with transition temperature 1453 °C has previously been reported as the only other ambient pressure phase of this system. The desired phase (see Fig. 1), all support this assignment. It is an aristotype (no rotations or tilts) and competing octahedral (rotation about c) and in-plane tilts) shown in Fig. 1. It is an aristotype unit cell) indicating that a structure with an out-of-phase octahedral rotation about the c-axis is adopted (I4/acd, $a = 5.23639(5)$ Å, $c = 23.81675(3)$ Å – see Fig. 1). These peaks are significantly broadened on account of the short coherence length of the octahedral rotations along the layering axis. The presence of an impurity with 10% phase fraction by weight corresponding to the ambient pressure phase of Ca$_2$GeO$_4$ ($Pnma$, $a = 11.404194$ Å, $b = 6.794365$ Å, $c = 5.242485$ Å), significantly convolutes the region of the diffraction pattern 20–23° (see inset of Fig. 2), meaning that these peaks cannot be used to unambiguously assign the symmetry. However, a comparison of the fitting statistics for I4/mmm ($R_{wp} = 2.07$, for two internal degrees of freedom) and I4/acd ($R_{wp} = 2.00$, for three internal degrees of freedom), along with physically unrealistic atomic displacement parameters in the prior refinement, and DFT lattice parameters (see Table 1) and a ground state energy of I4/acd which we find to be 9.1 meV per atom more stable than the I4/mmm phase (see Fig. 1), all support this assignment.

Cation $I4/acd$ (with a frozen rotation about c) is one of several known phases of A$_2$BO$_4$ Ruddlesden–Popper oxides that include the aristotype I4/mmm (no rotations or tilts) and competing Pbca phase (rotation about c and in-plane tilts) shown in Fig. 1. It is an interesting question why Ca$_2$GeO$_4$ crystallises as I4/acd and not alternative phases, despite DFT showing Pbca to be lower in energy. The answer likely relates to vibrational entropy favouring I4/acd over the energetic ground state, however, this discussion is beyond the scope of the current study. It is noteworthy that there is no direct transition between I4/acd and Pbca without unravelling the anti-phase P$_2$ rotations to transform them to in-phase X$_2^*$ rotations. It is this so-called symmetry trapping that we have previously argued prevents the transition to the energetic ground state and thus allowing octahedral tilts that have been shown to drive NTE to remain low in frequency without condensing.
Lattice parameters were extracted from the temperature dependent powder X-ray diffraction data by performing sequential Pawley refinement and are shown in Fig. 3. No discontinuities or anomalies in the lattice parameters were observed. Data collected on warming using the cryostat in the region 10–140 K shows a slight discontinuity with the data collected on cooling (despite normalisation using the volumes at 120 K) evidencing some hysteresis in the thermal expansion behaviour of the sample. This likely arises as a result of individual domains and grains expanding and contracting at vastly different rates along different directions, resulting in substantial macroscopic strain and hysteresis in the sample. Indeed, asymmetric peak broadening and shifts are observed at lower temperature. Fitting a Scherrer particle size Gaussian peak broadening model to the (hkl) l = odd reflections gives an estimate of the domain size of 16.7 (1.4) nm.

Fitting the low temperature a and c lattice parameter data with a single Einstein mode model of the form

\[ x(T) = x_0 + \frac{k_1^2}{\exp\left(\frac{k_2}{T}\right) - 1} \]  

we can obtain an estimate for the characteristic frequency of the vibrations that dominate contributions to the thermal expansion in this material. This model for a and c is plotted against the cryostat data to which it is fitted in the inset to Fig. 3.

We have previously shown that the character of the low energy vibrations giving rise to NTE along c are the same as those giving rise to PTE along a.\(^{10}\) Therefore a and c were fitted in tandem using least squares optimisation where the optimisation function was the sum of the errors normalised by lattice parameter for both a and c. This meant that a single characteristic frequency could be applied to both models. The characteristic phonon frequency, \(k_2\), is found to be 155 K (13.4 meV, 108 cm\(^{-1}\)). Fitting the same single Einstein mode model to a and c from our previous measurements of the isosymmetric system \(\text{Ca}_2\text{MnO}_4\)^{10} over an equivalent temperature range gives a \(k_2\) of 261 K (22.5 meV, 182 cm\(^{-1}\)) which is substantially higher than in \(\text{Ca}_2\text{GeO}_4\) (see Table 2 for full model parameters for both compounds). This is evident both in that the flattening of the NTE occurs at much lower temperatures in \(\text{Ca}_2\text{GeO}_4\) and that it is more pronounced compared to that observed in \(\text{Ca}_2\text{MnO}_4\). The average thermal expansion coefficient along the c direction, \(\kappa_c\), in \(\text{Ca}_2\text{GeO}_4\) (100–400 K) is \(-6.3\) ppm K\(^{-1}\), which is substantially larger than for \(\text{Ca}_2\text{MnO}_4\) measured over the same temperature range (\(\kappa_c = -4.4\) ppm K\(^{-1}\)).\(^{10}\)

It is worth noting that in our previous computational studies of NTE in these systems,\(^10\) we used \(\text{Ca}_2\text{GeO}_4\) as a substitute for \(\text{Ca}_2\text{MnO}_4\) by applying a 4.3 GPa biaxial pressure to account for the in-plane exchange striction associated with Mn sites. The effect of this was to harden the soft phonon modes in our calculations with respect to the unstrained \(\text{Ca}_2\text{GeO}_4\) phase. It is hence to be expected that in the experiment \(\text{Ca}_2\text{GeO}_4\) shows more pronounced NTE than \(\text{Ca}_2\text{MnO}_4\) and the resulting trend is consistent with this picture. \(\text{Ca}_2\text{GeO}_4\) and \(\text{Ca}_2\text{MnO}_4\)^{10,19} are not the only n = 1 family compounds exhibiting uniaxial NTE. Other examples found in the literature include \(\text{Sr}_2\text{IrO}_4\)^{20–22} and \(\text{Sr}_2\text{RhO}_4\)^{23,24} both of which crystallise in the \(I\_4/acd\) phase. However, in this instance the magnitudes of \(\kappa_c\) are much smaller with an average of \(-2.4\) ppm K\(^{-1}\) for \(\text{Sr}_2\text{RhO}_4\) (calculated for 10–300 K from ref. 23) and \(-2.1\) ppm K\(^{-1}\) in \(\text{Sr}_2\text{IrO}_4\) (calculated for 13–295 K from ref. 20). It should be noted that \(\text{Ca}_3\text{RuO}_4\)^{15} and related materials, which crystallise in an orthorhombic space group, exhibit NTE as a result of electronic instabilities and Jahn–Teller ordering, which can be very pronounced effects but which tend to be confined to a relatively narrow temperature range.

Recently, it has been proposed that the quantity $\nu_{\text{NT}}$ given by the product of the average volume thermal expansion coefficient $\nu_{\text{v}}$ and the temperature range over which NTE is observed, can be used as a metric for classifying different regimes of volume NTE\textsuperscript{28} and to help identify systems that exhibit remarkable NTE properties. Within this picture, Ca$_4$GeO$_9$ exhibits linear NTE with $\nu_{\text{v}} = 0.55\%$ measured across the full 10–800 K window of stability of the I4$_1$/acd phase. This compares to $\nu_{\text{NT}} = 2.74\%$ ($\nu_{\text{v}} = 0.93\%$) in the prototypical NTE material ZrW$_2$O$_8$\textsuperscript{28} (note the factor of 3 between linear $\nu$ and volume $\nu_{\text{v}}$). It is, however, as yet unclear whether this metric may be used to meaningfully compare systems exhibiting volume (bulk) NTE and those exhibiting only uniaxial NTE. A recent report of pronounced uniaxial negative linear thermal expansion as large as $-40$ ppm K$^{-1}$ for the orthorhombic (Cmca$_2$) phase in the (110)-cut perovskite LaTaO$_4$ represents possibly one of the largest linear CTEs in hard ceramic materials to date.\textsuperscript{28} This phase, which we have recently shown to be very compliant with respect to coupling expansion along the PTE axis to contraction along NTE axes,\textsuperscript{28} has a $\nu_{\text{NT}} = 0.68\%$, which is larger yet comparable to Ca$_4$GeO$_9$, except here NTE persists over a much narrower temperature range (<300 K). By tuning the chemistry, it should be possible to synthesise an A$_8$BO$_4$ layered perovskite with I4$_1$/acd symmetry which is stable to higher temperatures thus extending the temperature range of NTE. Even down to cryogenic temperatures we find that Ca$_4$GeO$_9$ does not transform into the competing Pbca phase. Therefore it should be possible to tune the tolerance factor to bring the system closer to this transition – thus increasing the thermodynamic driving force for NTE. If either (or both) of these enhancements could be achieved by chemical substitution, it may be possible to engineer a Ruddlesden–Popper possessing a significantly greater magnitude of NTE than LaTaO$_4$ by this $\nu_{\text{NT}}$ metric.

In summary, we have successfully synthesised the layered perovskite Ca$_4$GeO$_9$ showing that it crystallises in the I4$_1$/acd rather than I4/mmm space group. In accordance with our predictions this structure shows pronounced uniaxial NTE over a large temperature range. This phenomenon can be understood to be driven by low energy lattice vibrations related to a thermodynamically competing Pbca phase (shown in Fig. 1) in which these octahedral tilts condense, and the unusually compliant nature of the I4$_1$/acd structure. Single Einstein mode fits of the $a$ and $c$ lattice parameters as a function of temperature provide an upper estimate for the phonon frequency of 155 K (108 cm$^{-1}$) for the characteristic modes driving NTE. The unusually wide temperature range over which these soft phonon modes persist may make them useful in controlling properties associated with thermal expansion, dielectric response and other phonon-mediated properties such as thermal transport, and the thermoelectric effect.
