Charge reduction and neutralization of electro-sprayed peptides are realized by selective gas-phase photocleavage of tailored covalent tags. The concept is demonstrated with four model peptides in positive and negative ion modes and tagged insulin as the largest construct.

Already thirty years ago, electrospray ionization, ESI,¹ and matrix-assisted laser desorption ionization, MALDI,^{2,3} were established as efficient ways of transferring charged macromolecules into the gas phase for mass spectrometry. ESI excels in producing continuous beams of highly charged and even massive biomolecules under mild conditions and it is readily coupled with on-line separation methods, such as high-performance liquid chromatography. MALDI, on the other hand, transfers short pulses of mostly singly charged macromolecules into the gas phase. Both techniques complement each other and have become essential in biomolecular analysis. A high charge-per-mass value favours a high velocity in time-of-flight mass spectrometry (TOF-MS) and thus boosts the detection efficiency for heavy molecules. On the other hand, a low charge value and a narrow charge distribution simplify the mass spectrum of complex molecular mixtures.⁴

Even though MALDI⁵ produces a substantial fraction of neutral material, mostly trapped in nanoparticles or droplets, the controlled preparation of neutral mass-selected peptide or protein beams has remained a challenge, up to now. If this technology becomes available, it is expected to open a new window to electric and magnetic beam deflection,^{6,7} action-free single-photon recoil spectroscopy^{8,9} as well as a new branch of molecular quantum optics with proteins.¹⁰ While aqueous

Neutralization of insulin by photocleavage under high vacuum†

solutions are the normal habitat of biomolecules in nature, gas phase studies on isolated specimens of selectable charge states, including neutrals, will add to our overall understanding of the electronic and structural properties of this important class of organic molecules.¹¹

The goal of our present work is to establish a chemical and optical strategy to volatilize complex biopolymers, to control their motion and their charge at a given time and position using photo-induced cleavage of charged tags. Photocleavage itself is an established technique, recently studied in a variety of experiments on trapped ions, for instance to prepare diagnostic fragments for molecular structure determination.^{12–14} Signal depletion of laser desorbed, non-peptidic model compounds was observed after irradiation.¹⁵ Similar observations were made with peptides, launched by ESI where additionally clean cleavage was confirmed.¹⁶

Here we introduce photocleavable tags with charge-decorated leaving groups for peptides and proteins. They can be removed in an overall non-heterolytic process that reduces the peptide charge stepwise by one unit:

Two possible cleavage outcomes were observed for the tags with charge-decorated leaving groups: processes we term (i) H-transfer and (ii) homolysis.

In contrast to that, earlier studies found that a similarly structured neutral leaving group **neuLG** cleaves heterolytically for tripeptides and mostly *via* H-transfer for longer peptides, thereby limiting the applicability for charge reduction by photocleavage to small peptides in the negative ion mode (Scheme 1).¹⁶

In our present work, fluorinated phenols with either a positive tetraalkylammonium (**posLG**⁺) or a negative sulfonate (**negLG**[−]) group are explored as leaving group motifs.^{15,16} They are bound to a set of tri- and nonapeptides **1** and **2** (sequences: KAL and KALGALGAL, respectively) shown in Scheme 1, which contain only non-aromatic amino acids to minimize absorption.

Scheme 1 Model peptides for charge-controlled photocleavage. Tripeptides **1** ($n = 0$) and nonapeptides **2** ($n = 2$) are modified by an *ortho*-nitroarylether group^{17,18} connected to a neutral (**neuLG**), negative (**negLG⁻**) or positive (**posLG⁺**) leaving group.

Because of this choice, the phototag is the strongest absorber in the molecule at 266 nm.

The photocleavable group is based on the well-established *ortho*-nitrobenzyl ether motif.^{17,18} Although there is only limited information on its gas-phase cleavage behaviour available, it seems reasonable to assume that the cleavage under H-transfer results in the formation of a nitrosobenzaldehyde moiety as is observed in solution. The homolytic and heterolytic pathways might likewise proceed *via* a cyclic intermediate. Further studies are however required to elucidate the underlying mechanisms of the observed processes.

The peptides are volatilized using micro-electrospray in a Waters Q-TOF mass spectrometer, which we upgraded using a high voltage corona discharge chamber to reduce the peptide charge in collision with bi-polar air.¹⁹ The molecules are then guided into high vacuum where they are selected using a quadrupole mass filter, which was upgraded for high mass-to-charge states, up to 30 000 u e⁻¹. The ions pass on to a hexapole guide for collisional cooling and/or dissociation in a dilute argon buffer gas. A beam of short-pulse (10 ns) ultraviolet (266 nm) laser light is aligned collinearly with the ion beam to induce the photocleavage of the peptides when they leave the collision cell. The laser was kept at a pulse rate adjusted to the speed of the molecules (see the ESI[†]) and at an intensity of 0.5–1 mW cm⁻². The parent ions and their cleavage products are then analysed by high-resolution time-of-flight mass spectrometry.¹⁶

The data of Fig. 1 show that our model compounds fulfill their design specifications well: the charged leaving groups **negLG⁻** and **posLG⁺** cleave under H-transfer or homolytically,

Fig. 1 Photocleavage pathways for peptides with charged leaving groups. The peptides were initially mass selected to the single parent peak. All additional peaks are caused by the interaction with the laser light. Cleavage of negative model peptides (A) **1-negLG⁻** and (B) **2-negLG⁻**, positive model peptides (C) **1-posLG⁺** and (D) **2-posLG⁺**, and doubly charged peptides (E) **2-negLG²⁻** and (F) **2-posLG²⁺** takes place. All insets identify the leaving groups and allow estimation of the fraction of cleavage under homolysis and H-transfer. A signal at 996 amu (i) in panel (B) indicates a peptide whose charge is located on the peptide fragment rather than the leaving group. Signals (ii) and (iv) in (C) and (F) indicate loss of NMe₃ from the leaving group. The signal (iii) indicates the additional formation of a 16 amu lighter fragment as observed previously.¹⁶ The vertical figure axes were cut to facilitate a comparison of the peaks.

without resulting in charge transfer between the dissociating partners. Both processes reduce the charge of the peptide moiety in a controlled fashion.

Cleavage of both the negative tripeptide **1-negLG⁻** and the nonapeptide **2-negLG⁻** results in a clean mass spectrum, containing the parent and the leaving group (Fig. 1(A) and (B)), but no or little of the mass-reduced peptide moiety. This corroborates that the negative charge stays on the leaving group and the neutral peptide remains undetected. A comparison of the mass peaks shows that homolysis (h) and H-transfer (H) contribute with a ratio between h/H ≈ 2 : 1 and 1 : 1 to the dissociation process.

In contrast, the positive ions **1-posLG⁺** and **2-posLG⁺** cleave preferentially under H-transfer, with a ratio of h/H = 1 : 5 to 1 : 10. Heterolytic cleavage into a neutral **posLG⁻** and a positive peptide was never observed in our studies. Again, the absence of charged peptide fragments in Fig. 1(C) and (D) indicates that they are neutral. To corroborate this statement and to test for possibly competing fragmentation pathways we performed experiments on the doubly charged nonapeptides **2-negLG²⁻** and **2-posLG²⁺**. They hold one charge on the leaving group and one on the peptide moiety and both the LG fragments and the peptide are observed as singly charged peaks in Fig. 1(E) and (F).

Even though homolytic cleavage generates radicals, we do not observe any excessive fragmentation. By analogy, we assume that neutral peptides generated in a photocleavage process will not further dissociate either.

While an earlier study using neutral tags reported that the cleavage mechanism can change with peptide length, all phototags of our present study consistently cleave without charge transfer for tripeptides as well as for nonapeptides. It is therefore intriguing to explore whether our new tags allow a controlled charge reduction of even large polypeptides or proteins. This has motivated our study on insulin, tagged with three negative leaving groups, here termed **negIns**. The tags were introduced by reactions with the corresponding NHS-esters and are assumed to be located at the two N-termini and the single lysine residue (see the ESI†).

Insulin contains seven aromatic amino acids, four tyrosine and three phenylalanine residues, which compete with the phototags for UV absorption. However, their combined extinction coefficient in solution amounts to $\epsilon \sim 4200 \text{ M}^{-1} \text{ cm}^{-1}$ and is small in comparison with the combined extinction coefficient of all nitroaryl groups $\epsilon_{\text{nitrobenzene}} \sim 20\,000 \text{ M}^{-1} \text{ cm}^{-1}$.^{20,21}

The desired initial charge state is optimized by guiding the electrosprayed insulin through bipolar air in a high-voltage DC discharge.¹⁹ Subsequent high-pass mass filtering before the molecule-laser interaction ensures that all subsequently detected low-mass molecules are due to photocleavage.

In Fig. 2 we show the photo response of **negIns** for the initial charge states $q = -7$ to $q = -2$.

In panel (A) we observe photocleavage of a singly charged leaving group (peak v), electron photo-detachment (vi), cleavage of two charged leaving groups (M-2LG)⁵⁻ (vii) as well as mixed processes, such as the cleavage of one tag and the emission of an electron resulting in (M-LG-e)⁵⁻ (viii) and photocleavage of all leaving groups (M-3LG)⁴⁻ (ix). Most processes, listed for the 7-fold charged anion, also occur in less highly charged molecules but decrease with molecular charge and become irrelevant below $q = -4$. This is consistent with earlier photodetachment studies of insulin in ion traps.²²

The experimental results confirm the design purpose of our molecular tags: for insulin in a low initial charge state, controlled photocleavage is the only relevant charge reduction process.

Photodepletion of the parent ion peak – here defined as $1 - M/M_0$ where M/M_0 is the ion signal with/without laser irradiation – attained values as high as 30% on the doubly charged insulin anion and 40–60% for insulin with charge states $q = -4$ to $q = -7$ (Fig. 3B).

Photocleavage even enables efficient neutralization of insulin (Fig. 3A).

This is shown in Fig. 3A, where the triply tagged, singly charged molecule is neutralized by removing a singly charged leaving group.

The remaining insulin is still decorated with 2 PCTs and a small PCT fragment. One may expect that such small tags, similar in size to fluorescent labels used in biology, will influence the molecular structure only little.

Summarizing, we have designed and synthesized a new set of charged molecular tags that allow one to control the

Fig. 2 Charge reduction of an insulin ion beam by controlled photocleavage. **NegIns** dissociates in defined fragments under irradiation by 266 nm light. The panels (A–F) represent different initial charge states from $q = -7$ down to $q = -2$. In all charge states we can observe similar processes. (v) The charge of the parent molecule M^{-N} is reduced by the loss of **negLG**⁻ (M-LG)^{-N+1} and thus appears at higher m/z values. (vi) Electron detachment (M-e)^{-N+1}. (vii) Two leaving groups (M-2LG)^{-N+2} are removed from highly charged insulin M^{7-} – M^{5-} . (viii) Cleavage and detachment can occur together (M-LG-e)^{-N+2}. (ix) A tiny amount of (M^{7-}) molecules even splits off three charged leaving groups to yield (M-3LG)^{-N+3}. (x) (M-2LG-e)^{-N+3}. (v*) The loss of **negLG** with a protonated sulfonate is observed in small amounts (M-LG)^{-N}. Black lines: mass spectra without laser irradiation. Red line: mass spectra with laser irradiation, upshifted by 50 counts for clarity.

Fig. 3 Photocleavage neutralization of **negIns**. (A) The mass spectrum of **negIns**⁻ with (red) and without (black) laser irradiation. The appearance of **negLG**⁻ upon laser irradiation indicates the formation of neutral insulin (**negIns-LG**)⁰. (B) The depletion efficiency decreases as a function of the charge state.

photocleavage of peptides generically, from small tripeptides up to a complex biopolymer as massive as insulin with 51 amino acid residues. Contrary to earlier observations with neutral tags, where the cleavage mechanism varied with peptide size, the charged tags used in our present study enable efficient photocleavage charge reduction over a wide scale of molecular mass and over many amino acid residues. We have proven this for the mass range of 1–7 kDa and for charge states from one to seven.

To our knowledge, this is the first evidence for controlled photocleavage neutralization of a high-mass polypeptide such as human insulin under high vacuum. First experiments for charge reduction with an analogous positively charged insulin construct (**posIns**) suggest that the methodology can be equally applied in a positive ion mode (see the ESI[†]).

Future studies will explore the reionization of neutral proteins *via* a second photocleavable tag tailored for a second wavelength. The efficiency of the process will be substantially enhanced using laser light in a cross-beam enhancement cavity or using intense ultrafast laser pulses with high repetition rates. By appropriate design of the photo-cleavable chromophore it will be possible to choose a laser wavelength beyond the natural absorption profile of the biopolymer. This shall become the basis for preparing continuous cold beams of mass-selected neutral proteins for UV/VIS/IR spectroscopy, deflectometry and quantum interferometry as well as new techniques for photo-cleavage assisted mass spectrometry.
