Evaluating chemical bonding in dioxides for the development of metal–oxygen batteries: vibrational spectroscopic trends of dioxygenyls, dioxygen, superoxides and peroxides†

Petar M. Radjenovic and Laurence J. Hardwick *

Dioxides (dioxygenyl (O_2^+), dioxygen (O_2), superoxide ($O_2^{\bullet-}$) and peroxide (O_2^{2-})) are of immense biological, chemical and environmental importance. The ability to accurately detect and measure the changing strength of their chemical bonding and coordination *in situ* or *operando* is extremely beneficial in order to evaluate their chemical properties, this has been particularly important recently in the field of metal–oxygen batteries, where understanding the reactivity of the $O_2^{\bullet-}$ intermediate is crucial in the development of more stable electrolytes. Meta-analysis of the collated vibrational Raman and IR spectral bands of numerous (>200) dioxygen species was used to interpret the effect that the immediate chemical environment has on the O–O bond. Subsequently, the dioxide vibrational spectral bands were empirically related directly with the bond electron density and other fundamental bond properties, with surprisingly high accuracy, allowing each property to be estimated, simply, from experimental spectroscopic observations. Important chemical information about the strength of secondary interactions between reduced oxygen species and its chemical environment can be also elucidated which provides a convenient method for determining the attractive strength an ion exerts over neighbouring counter ions.

1. Introduction

Oxygen (O) is a reactive and abundant element of immense chemical, biological, and environmental importance, warranting classification as a field of study in its own right similar to organic (carbon) and inorganic (transitional metal) chemistries.^{1,2} Gaseous dioxygen (O_2), composed of two covalently bonded homonuclear atoms, constitutes 20.95% of Earth's atmosphere, providing an oxidising environment and thermodynamic driving force for many biological processes. Crucially, the controlled reaction of O_2 in the oxidation of glucose during aerobic respiration allows life on Earth to thrive. However, living organisms must also possess kinetic barriers to slow oxidation reactions with O_2 to survive. The gradual decay of these kinetic barriers to oxidation in the body is responsible for ageing. In humans, reactive oxide species (ROSS): $O_2^{\bullet-}$, O_2^{2-} , O^{2-} , HO_2 , H_2O_2 and OH^{\bullet} are produced as by-products of normal cell processes and are used in the immune response of white blood cells. However, excessive production of ROSS adds oxidative

stress to cells causing cell and DNA damage (specifically mitochondrial DNA) which is linked to the formation of cancer cells.^{3–5}

Metal–oxygen (M– O_2) batteries have to deal with many of the same problems faced by biological systems, such as controlling the production and side reaction rate of ROSSs. In addition, dioxide ligands are prevalent in organometallic and catalysis chemistry. Therefore, the chemistry of dioxide species' (O_2^x , where $x = -2, -1, 0$ or $+1$) has warranted detailed scientific study in multiple fields.^{1,2,6}

O_2^x are homonuclear molecules that possess covalent O–O bonds and their characteristic symmetric stretching vibrations (ν_{O-O}) are visible spectroscopically. Examining the ν_{O-O} spectral band can provide valuable information about the chemical nature of the O_2^x . The oxidation state and reactivity of O_2^x , depends on the number of electrons occupying the highest occupied molecular orbital (HOMO), which are the $\pi^*(2p_x)$ valence antibonding orbitals (Fig. 1), their spin state(s) and the O–O bond order (B_O , defined as the number of covalent bonds, see eqn (1)). O_2^+ cations possess one electron in the $\pi^*(2p_x)$ antibonding orbital and have a B_O of 2.5. O–O bonding electrons in O_2^+ cations experience high effective nuclear charge from the O nuclei, so have a short O–O bond length (B_L , 1.12 Å) and a high wavenumber ν_{O-O} (1876 cm^{-1}) value.^{7,8} From O_2^+ to O_2^{2-} ,

† Electronic supplementary information (ESI) available: Tabulated data from meta-analysis. See DOI: 10.1039/c8cp04652b

Fig. 1 Molecular orbital diagram of O_2^x species based on filled $\pi^*(2p_{xy})$ valence orbitals: O_2^+ (black arrow only), high-energy singlet ($^1\Sigma_g^+$) O_2 (black and orange arrows only), singlet ($^1\Delta_g$) O_2 (black and green arrows only), triplet ($^3\Sigma_g^-$) O_2 (black and red arrows only), $O_2^{\bullet-}$ (black, green, red arrows only) and $O_2^{\bullet 2-}$ (black, green, red, orange arrows).

the B_O decreases by 0.5 for each electron added into the $\pi^*(2p_{xy})$ orbital. As an electron is added to the $\pi^*(2p_{xy})$ orbital, increased antibonding and Coulombic repulsion between bonding electrons cause the O–O B_L to increase and the ν_{O-O} to red-shift. O_2^{2-} possesses a B_O of 1 and has the longest O–O bond (1.49 Å) of the homonuclear dioxides with the lowest ν_{O-O} value ($\sim 743 \text{ cm}^{-1}$).⁹ In addition to O–O bond lengthening and the characteristic red shifts in ν_{O-O} spectra, each electron transferred to O_2^x causes a decrease in the bond force constant (B_k) and a drop in the bond dissociation enthalpy (B_H) of the O–O bond, discussed in more detail later.

$$B_O = \frac{(q - q^*)}{2} \quad (1)$$

where B_O = bond order, q = number of bonding electrons, q^* = number of antibonding electrons.

Neutral O_2 contains two electrons in the $\pi^*(2p_{xy})$ orbital(s) that can occupy three different spin states (Fig. 1); high-energy singlet ($^1\Sigma_g^+$), singlet ($^1\Delta_g$) and triplet ($^3\Sigma_g^-$). Unlike many common diatoms and organic molecules, which favour the $^1\Delta_g$ state, the $^3\Sigma_g^-$ state is the lowest energy ground state of O_2 with two electrons in degenerate orbitals with the same spin. The $^3\Sigma_g^-$ O_2 orbital structure complicates coupling with other molecules in the $^1\Delta_g$ state, which adds to the chemical stability of $^3\Sigma_g^-$ O_2 . It is the: one-electron, two-electron or four-electron transition from $^3\Sigma_g^-$ O_2 to: $O_2^{\bullet-}$, O_2^{2-} or O_2^{2-} , respectively, and back again, that underpins the oxygen reduction and evolution reactions (ORR/OERs). For non-aqueous lithium oxygen (Li– O_2) batteries, *in situ* surface enhanced Raman spectroscopic (SERS) studies of ν_{O-O} have been instrumental in showing a $O_2^{\bullet-}$ intermediary reaction mechanism and the existence of lithium peroxide (Li₂O₂) as the primary battery discharge product.^{10–12}

Johnson *et al.*¹¹ in particular highlighted the effect of solvent choice in the determination of the ORR pathway *via* either surface or solution route. Using SERS they showed that low-donor number solvents, such as acetonitrile, lead to a surface reaction resulting in thin, insulating Li₂O₂ film growth. In contrast, in high-donor number solvents, such as dimethyl sulfoxide resulted in preferential Li₂O₂ particle growth in solution. High donor number solvents are thereby preferable in the context of Li– O_2 batteries as Li₂O₂ solution growth leads to higher capacities.

Creighton *et al.* first reported the ν_{O-O} stretch of $O_2^{\bullet-}$ with Raman spectroscopy of KO₂ and contaminated Na₂O₂ in 1964.¹³ This was corroborated and expanded upon with other group-1 alkali-metal cation complexes ($[M^+ \cdots O_2^{\bullet-}]$, where M = Li, Na, K, Rb or Cs) in the following decade at a variety of different temperatures.^{14–21} Sawyer *et al.* synthesised and spectroscopically characterised the first $O_2^{\bullet-}$ salt with an organic cation, in 1983, by substituting K⁺ with tetramethylammonium (TMA⁺).²² $[TMA^+ \cdots O_2^{\bullet-}]$ had a spectrum analogous to KO₂, though slightly red shifted ($\sim 22 \text{ cm}^{-1}$).²² Since then, the ν_{O-O} of many $O_2^{\bullet-}$ complexes $[C^+ \cdots O_2^{\bullet-}]$ have been detected in a variety of systems and phases. Such as: solid salts,^{13,22} doped into other salts,²³ as an organometallic complex,⁶ dissolved in organic solvents²⁴ or generated electrochemically at a SERS active electrode–electrolyte interface.^{10,11,25,26}

Understanding the reactivity and bonding environment of the $O_2^{\bullet-}$ intermediate is crucial in the development of more stable M– O_2 battery electrolytes and in particular, ambiguity around the existence and chemical character of the lithium superoxide (LiO₂) intermediary remains.^{27,28} Thus, a detailed look at the ν_{O-O} spectra of species produced during ORR/OERs is warranted to better understand in the reaction mechanisms in non-aqueous electrolytes in order to assist in the fundamental understanding of lithium–oxygen and in more general other M– O_2 batteries.

2. Experimental

2.1. Calculation of ion properties

Ionic volumes, ionic surface area, charge distributions and electrostatic potential surface distributions for a number of molecular ions were determined using a simple density functional theory (DFT, B3LYP functional, 6-31G* basis set) in Spartan 16. Ionic volumes and surface areas for atomic cations were calculated using a simple space-filling calotte (CPK) model.

3. Results and discussion

3.1. Meta-analysis of superoxide's Raman spectra

To investigate possible trends of $O_2^{\bullet-}$ bonding, relevant literature reports of > 50 species were collated and examined.^{10,11,13–18,25,26,29–60} See Table S1 (ESI†) for a catalogue of reported $[C^+ \cdots O_2^{\bullet-}]$ complexes.

Raman spectral band positions reflect molecular energy levels in a vibrating bond and are well known to be influenced by (1) the mass of the atoms in the bond, (2) the bond force constant and (3) lattice/symmetry effects. For $[C^+ \cdots O_2^{\bullet-}]$,

counter cations (or strongly coordinating solvents) attract O–O bond electron density at different rates which also influences the force constant of the vibration, resulting in $\nu_{\text{O-O}}$ band shifts, explained further below.⁶¹

The molecular mass-to-charge ratio ($M_r Q^{-1}$, units: $\text{mol g}^{-1} \text{C}^{-1}$) of an ion can dictate its Coulombic attractive strength towards counter-ions. Generally, ions with low $M_r Q^{-1}$ values are stronger Coulombic attractors than ions with high values. In a $[\text{C}^+ \cdots \text{O}_2^{\bullet-}]$ complex, where interactions between $\text{O}_2^{\bullet-}$ and the counter-cation (C^+) are weak: electron density is more concentrated on the $\text{O}_2^{\bullet-}$ anion, the effective nuclear charge experienced by O–O valence bonding electrons is lower and the bond is longer than when $\text{O}_2^{\bullet-}$ is strongly coordinated. This effect is visible spectroscopically, with weakly coordinated $\text{O}_2^{\bullet-}$ complexes having lower wavenumber $\nu_{\text{O-O}}$ values (e.g. tetrabutylammonium $[\text{TBA}^+ \cdots \text{O}_2^{\bullet-}]$: $< 1115 \text{ cm}^{-1}$)^{10,11,25,26,60} and strongly coordinated $\text{O}_2^{\bullet-}$ complexes having higher $\nu_{\text{O-O}}$ values (e.g. $[\text{Na}^+ \cdots \text{O}_2^{\bullet-}]$: $\geq 1155 \text{ cm}^{-1}$).^{15,17,47–52,62} The strength of the attraction between the coordinating cation and $\text{O}_2^{\bullet-}$ effects valence bond electron density and the O–O bond force constant, causing the observed difference in $\nu_{\text{O-O}}$ wavenumbers.

For monovalent $[\text{C}^+ \cdots \text{O}_2^{\bullet-}]$ complexes (independent of phase), plotting reported $\nu_{\text{O-O}}$ values against the $M_r Q^{-1}$ value of the coordinating cation (Fig. 2) shows an inverse trend ($R^2 = 0.757$). In Fig. 2, two further sub-trends are apparent for: (1) single atom cations (shown in blue) and (2) molecular

cations (shown in red). Single atom cations such as Rb^+ ($85.5 \text{ mol g}^{-1} \text{C}^{-1}$) and Cs^+ ($132.9 \text{ mol g}^{-1} \text{C}^{-1}$) have similar M_r values as TMA^+ ($74 \text{ mol g}^{-1} \text{C}^{-1}$) and tetraethylammonium (TEA^+) ($130.0 \text{ mol g}^{-1} \text{C}^{-1}$), respectively, but have higher wavenumber $\nu_{\text{O-O}}$ spectral bands ($> 15 \text{ cm}^{-1}$). This difference in the $\nu_{\text{O-O}}$ spectral bands can be accounted for by considering the size difference in these cations. Single atom alkali-metal cations are spatially smaller allowing them interact more closely with $\text{O}_2^{\bullet-}$ valence bond electron density than large molecular organic cations. Therefore, as a general rule: strong $\text{O}_2^{\bullet-}$ coordination has a higher wavenumber $\nu_{\text{O-O}}$ spectral band.

3.2. Ionic charge dispersion

The immediate coordinating environments ability to interact with $\text{O}_2^{\bullet-}$ also provides interesting information about the reactivity and basicity of $\text{O}_2^{\bullet-}$ in the complex which is reflected in the $\nu_{\text{O-O}}$ value. From Fig. 2, $[\text{C}^+ \cdots \text{O}_2^{\bullet-}]$ containing high M_r cations (e.g. TBA^+) have low $\nu_{\text{O-O}}$ values indicative of a more ionic ‘freer’ $\text{O}_2^{\bullet-}$ species. In these complexes, $\text{O}_2^{\bullet-}$ is a stronger Lewis base and can be expected to more readily donate electron density. Inversely, low M_r cation containing $[\text{C}^+ \cdots \text{O}_2^{\bullet-}]$ complexes such as (H^+) have stronger C^+ -to- $\text{O}_2^{\bullet-}$ interactions with slight covalent character, resulting in higher wavenumber $\nu_{\text{O-O}}$ bands indicative of a weaker Lewis base $\text{O}_2^{\bullet-}$ species. It was found that for cations coordinating O_2^x species, the: size, mass and charge influence the strength of coordination and in turn the O–O bond force constant which causes detectable changes in $\nu_{\text{O-O}}$. Thus, the physical parameters of one ion can indirectly influence the bond force constant and wavenumber of bonds present in the counter-ion. These values for ions can be simply quantified in terms of the M_r , ionic volume (i_v) and the charge on the ion (z). In O_2^x complexes; changes in the M_r and i_v of the coordinating counter-ions were found to be inversely proportional to changes in $\nu_{\text{O-O}}$ whilst changes in the charge of the counter-ion were proportional quantified by the term. Considering the effect the size of the cation has on the $\nu_{\text{O-O}}$ of $\text{O}_2^{\bullet-}$ complexes, this can be quantified by either the ionic volume (i_v) or the available ionic surface area ($i_{\text{s.a.}}$), measured in \AA^3 and \AA^2 , respectively. i_v and $i_{\text{s.a.}}$ values are known for most alkali-metal cations and can be calculated computationally using simple CPK or DFT models for larger molecular cations.

The $\nu_{\text{O-O}}$ of a $[\text{C}^+ \cdots \text{O}_2^{\bullet-}]$ complex changes proportionally with the charge (q) on the cation and inversely proportionally with the molecular mass (M_r) and i_v (and $i_{\text{s.a.}}$) of the coordinating cation (eqn (2)). Assuming a uniform charge distribution over the ion: multiplying the $M_r Q^{-1}$ and a spatial component (i_v or $i_{\text{s.a.}}$) gives a parameter (eqn (3)), hereon named the ‘ionic charge dispersion’ (\mathcal{H}_i).

$$\nu_{\text{O-O}} \propto \frac{Q^C}{M_r^C} \frac{1}{i_v^C} \text{ or } \frac{1}{i_{\text{s.a.}}^C} \quad (2)$$

$$\mathcal{H}_{i_v}^C = \frac{(i_v^C M_r^C)}{Q^C} \quad (3)$$

$$\nu_{\text{O-O}} \propto \frac{1}{\mathcal{H}_{i_v}^C} \quad (4)$$

Fig. 2 $\nu_{\text{O-O}}$ Raman bands for $[\text{C}^+ \cdots \text{O}_2^{\bullet-}]$ complexes plotted against the $M_r Q^{-1}$ value of the coordinating cation (listed data in Table S1, ESI†). An inverse trend is visible with heavier coordinating cations having lower wavenumber $\nu_{\text{O-O}}$ bands indicating a less energetic $\text{O}_2^{\bullet-}$ bond vibration and a ‘freer’ more Lewis basic species. A general fit produced R^2 values of 0.757 for the overall trend. Two sub-trends are apparent: (1) single atom and (2) molecular coordinating-cations. Lines of best fit for both trends (dashed lines) had R^2 values of 0.850 and 0.867 for single atom (blue) and molecular (red) coordinating cations, respectively. Circled bands (purple dashed line) are reports of LiO_2 related species. These do not match the expected trend for Li^+ , discussed later. Error bar refers to broad band between $1150\text{--}1200 \text{ cm}^{-1}$ reported as LiO_2 by Xia *et al.*³⁶

where: $\nu_{\text{O-O}} = \text{O}_2^{\bullet-}$ stretch (cm^{-1}), M_r^{C} = molecular mass of coordinating cation, Q^{C} = charge on cation, i_v^{C} = ionic volume of cation (\AA^3).

The \mathcal{K} value can be used to estimate the Coulombic attractive strength of an ion and the effect it will have on counter-ions. The Cyrillic symbol for \mathcal{Z} (\mathcal{K}) is used for ionic charge dispersion, subscripts i_v and $i_{\text{s.a.}}$ denote the use of ionic volume or ionic surface area, respectively, and superscripts A and C denote anion and cation, respectively. \mathcal{K} is an analogue of the charge density of an ion ($M_r Q^{-1} i_v^{-1}$). However, charge density does not account for the proportional relationship between: M_r , i_v and the Coulombic attractive strength of the ion. Thus, \mathcal{K} has been derived as a simple value to describe these ionic properties. \mathcal{K} is a measure the 'bulkiness' of the counter-ion, where, the higher the \mathcal{K} value the bulkier the ion is.

Excluding outliers, plotting the reported $\nu_{\text{O-O}}$ values of $[\text{C}^+ \cdots \text{O}_2^{\bullet-}]$ complexes from Table 1 against the calculated $\mathcal{K}_{i_v}^{\text{C}}$ (units: $\text{mol g}^{-1} \text{\AA}^3 \text{C}^{-1}$) or $\mathcal{K}_{i_{\text{s.a.}}}^{\text{C}}$ (units: $\text{mol g}^{-1} \text{\AA}^2 \text{C}^{-1}$) of each coordinating cation shows a clear inverse exponential relationship (Fig. 3 and Fig. S1, respectively, ESI†). \mathcal{K} provides a much better fit than using the M_r^{C} or i_v^{C} of the coordinating cation alone. The spatial components i_v^{C} or $i_{\text{s.a.}}^{\text{C}}$ are used to calculate \mathcal{K} but it appears to be unimportant which is used as they both change proportionally with one another between different cations. However, i_v^{C} gives a slightly better fit with a higher R^2 value of 0.952 (given the larger number of independent reports using different phases, systems and detection equipment spanning over > 50 years this is a fairly good fit) compared with 0.942 using $i_{\text{s.a.}}^{\text{C}}$ (Fig. S1, ESI†). Plotting on a logarithmic scale shows this correlation more clearly (Fig. 3). All reports of LiO_2 except for one³⁶ were excluded, this is discussed in Section 3.6.

When detecting the $\nu_{\text{O-O}}$ of $\text{O}_2^{\bullet-}$, the derived equation for the line of best-fit (eqn (5)) from Fig. 3 can be used to help estimate its ionic character and the coordination strength of the environment in terms of $\mathcal{K}_{i_v}^{\text{C}}$. With this knowledge, $\text{O}_2^{\bullet-}$ can be used as a diagnostic molecule to probe ion and even electrolyte interactions spectroscopically in environments where

Fig. 3 $\nu_{\text{O-O}}$ Raman band positions for $[\text{C}^+ \cdots \text{O}_2^{\bullet-}]$ complexes plotted versus the calculated $\log_{10} \mathcal{K}_{i_v}^{\text{C}}$ (see Table S1, ESI†) of the coordinating cation. Empirically derived equations for the lines of best fit and R^2 values for the fits are shown in bottom left-hand corner. \mathcal{K}^{C} was calculated using i_v^{C} which provides a better fit than using $i_{\text{s.a.}}^{\text{C}}$. i_v^{C} and $i_{\text{s.a.}}^{\text{C}}$ ionic volumes and surface areas were calculated in Spartan 15 using a CPK model for single atom cations (blue) and DFT (B3LYP, 6-31G*) for molecular cations (red). A single reference³⁶ of LiO_2 ($\nu_{\text{O-O}}$) has been considered due to the wide variation in wavenumber position reported, as discussed within the main text.

the coordination strength is unknown (e.g. novel electrolytes). This relationship between $\nu_{\text{O-O}}$ and $\mathcal{K}_{i_v}^{\text{C}}$ in Fig. 3 was found to hold in most cases. However, it can be manipulated by changing the symmetry, steric hindrance and charge of the coordinating cation, as well as the solvents Gutmann acceptor/donor numbers⁶³ and the potential at an electrode surface, where $\text{O}_2^{\bullet-}$ is generated electrochemically (to be discussed elsewhere).

$$\nu_{\text{O-O}} = -7.327 \log[\mathcal{K}_{i_v}^{\text{C}}] + 1192.9 \quad (5)$$

Considering these findings, hydrogen superoxide (HO_2) has a high $\nu_{\text{O-O}}$ value ($> 1165 \text{ cm}^{-1}$)^{26,29} and $\text{O}_2^{\bullet-}$ can be considered

Table 1 Table of calculated i_v^{C} , $i_{\text{s.a.}}^{\text{C}}$, $\mathcal{K}_{i_v}^{\text{C}}$ and $\mathcal{K}_{i_{\text{s.a.}}}^{\text{C}}$ values for some common cations and IL cations. Cations with smaller \mathcal{K} values are expected to be stronger Lewis acids

Fig. 4 Schematic depicting the strength of ion interactions in $[C^+ \cdots O_2^{\bullet-}]$ complexes. The size of the white arrows indicates the strength of the interaction between $O_2^{\bullet-}$ and the coordinate-cation. Small, light cations have concentrated charge with stronger electrostatic forces of attraction and may even be able to abstract $O_2^{\bullet-}$ electron density producing a covalent-like interaction, whilst the reverse is true for ions where the charge is dispersed over a large mass and area.

to have some covalent character, sharing part of its valence bonding electron with the cation. Whereas, tetrabutylammonium superoxide (TBAO₂) has a low ν_{O-O} value and can be considered to contain dissociated ions. Fig. 4 depicts this relationship between the cation, $O_2^{\bullet-}$ and ν_{O-O} schematically.

3.3. Ionic charge dispersion of other ions

The \mathcal{H}_i value estimates the dispersion of a formal charge on an ion by assuming the charge is delocalised (*i.e.* dispersed uniformly across the volume and molecular mass of the ion). \mathcal{H}_i is a simple value that can be calculated for any ion to approximate its coordination strength and/or propensity to interact with oppositely charged ions. Small \mathcal{H}_i values indicate ions that are strong: coordinators or Lewis acid/bases, whilst large values represent weak: coordinators or Lewis acid/bases. This can be further explained in terms of hard-soft acid-base

(HSAB) theory. Hard acids interact better with hard bases and soft acids with soft bases.⁶⁴ Ions with low \mathcal{H}_i values can be considered hard Lewis acid/bases and ions with high \mathcal{H}_i values can be considered soft Lewis acid/bases.

Tables 1 and 2 list calculated \mathcal{H}_i values for some common cations and anions, respectively. The \mathcal{H}_i value is a clear simplification of the charge on an ion, excluding many important contributions to inter-ion interactions such as: steric hindrance, charge density, the component molecules oxidation states and symmetry *etc.* However, as discussed, \mathcal{H}_i values give a good approximation for the influence of the cation on the ν_{O-O} of $O_2^{\bullet-}$ and are likely applicable to other systems too. Furthermore, additional quantifiable values for other ion properties (such as: symmetry *etc.*) could be added to refine the \mathcal{H}_i parameter further in future. When selecting ions for their attractive strength \mathcal{H}_i parameters (and possibly $\mathcal{H}_i^C : \mathcal{H}_i^A$ ratios) could be used to quickly screen some of the near infinite number of ions and combinations that can be selected. Also, \mathcal{H}_i parameters give a quick and cheap starting point when designing and tailoring novel IL electrolytes or salts. This is a good starting point compared with more precise computational or experimental techniques which are expensive, time consuming and would necessarily come later after first narrowing the field of search. Based on the \mathcal{H}_i^C value, the calculated Coulombic attractive strength of cations on anions is suggested to be similar for: Na⁺ and Ca²⁺ (233 and 301 g mol⁻¹ Å³ C⁻¹), Rb⁺ and Bi³⁺ (2272 and 2219 g mol⁻¹ Å³ C⁻¹) and TEA⁺ and Pyr₁₄⁺ (25 451 and 26 060 g mol⁻¹ Å³ C⁻¹, respectively).

Similarly, for the \mathcal{H}_i^A of anions, the Coulombic attractive strength of anions on cations is suggested to be similar for: F⁻ and OH⁻ (-276 and -296 g mol⁻¹ Å³, respectively), Cl⁻ and $O_2^{\bullet-}$ (-840 and 738 g mol⁻¹ Å³, respectively), whilst I⁻ is comparable with dicyanamide (DiCN⁻) and ClO₄⁻ (-4414, -4295 and -5384 g mol⁻¹ Å³, respectively).

3.4. Dioxygen spectra and important bond parameters

It is of great practical value to relate physical bond parameters with spectral measurements so they can be derived with ease experimentally. To that end, several efforts have been made, however, these methods remain empirical.⁶⁵ Key O_2^x bond

Table 2 Table of calculated \mathcal{H}_i^A , \mathcal{H}_i^C , \mathcal{H}_i^A and \mathcal{H}_i^C values for common anions and IL anions. Anions with smaller values are expected to be stronger Lewis bases

Table 3 Bond parameters of various O_2^x species and their outer $\pi^*(2p_{xy})$ valence orbital structures are listed. Raman spectral band $\nu_{O-O}^x/\nu_{O-O}^{\text{peroxide}}$ ratios show good approximations with B_O indicating that energy changes in the bond vibration are directly proportional to the addition or removal of a valence electron. Correlating these values allows ν_{O-O} to be used to approximate the B_O and other bond parameters

O–O bond parameters	O_2^{2-}	$O_2^{\bullet-}$	O_2	O_2^+	Ref.
$\pi^*(2p_{xy})$ MO outer valence structure	$\uparrow\downarrow \uparrow\downarrow$	$\uparrow\downarrow \uparrow$	$\uparrow \uparrow$	\uparrow	—
Bond length/ B_L (Å)	1.49	1.34	1.24	1.12	68

Bond order/ B_O	1	1.5	2	2.5	—
$\nu_{O-O}^x/\nu_{O-O}^{\text{peroxide}}$	1	1.49	2.10	2.53	—

Where: a = ν_{O-O} of (weakly coordinated) Cs_2O_2 salt, b = ν_{O-O} of TBAO₂ generated in dimethyl sulfoxide (DMSO), c = ν_{O-O} of gaseous dioxides.

parameters such as the bond order (B_O), bond dissociation enthalpy (B_H), bond force constant (B_k) and bond length (B_L) require various experimental procedures to derive, like X-ray crystallography (XRC). Bond parameter values for most O_2^x species exist and can be correlated well with empirically measured ν_{O-O} values. Table 3 lists these bond parameters for different O_2^x species. Correlating these O–O bond parameters allows for variations in each bond parameter to be estimated by only measuring the ν_{O-O} of the O_2^x species.

Considering the relationship between ν_{O-O} and the coordinating cation discussed in the previous section: $[C^+ \cdots O_2^{\bullet-}]$ complexes with strong coordinating cations can be considered to have partial-covalent character, *i.e.* the coordinating cation abstracts some amount of the $O_2^{\bullet-}$ valence bond electron density. This bond electron density abstraction interaction between the dioxide ion and its coordinator is here on referred to as secondary covalency. For different $O_2^{\bullet-}$ species, the amount of electron density abstracted by the cation can be estimated by considering the B_O of other O_2^x species. A change of 0.5 in the B_O corresponds to an electron being added or removed from the O–O bond. By assuming the B_O is variable, then a change of 0.25 indicates a valence bond electron being shared with the coordination environment, discussed later. A fully dissociated O_2^{2-} species has a B_O of 1 and there is an approximately linear relationship between the B_O and the bond force constant.^{66,67} As the bond force constant dictates the wavenumber of the ν_{O-O} , therefore, calculating the ratio between the ν_{O-O} of various O_2^x species and the ν_{O-O} of O_2^{2-} ($\nu_{O-O}^x/\nu_{O-O}^{\text{peroxide}}$) generates values that match well with the actual O–O B_O (Table 3) as observed by Livneh *et al.*⁹

Due to their high \mathcal{K}_v^C values; Cs^+ (4678 g mol⁻¹ Å³ C⁻¹) and TBA⁺ (78 656 g mol⁻¹ Å³ C⁻¹) are weak coordinating cations. Therefore, the B_O of Cs_2O_2 ^{9,15,53} and $[TBA^+ \cdots O_2^{\bullet-}]$ ^{25,26} can be assumed to be 1 and 1.5 and their Raman spectra used as ν_{O-O} values for dissociated O_2^{2-} and $O_2^{\bullet-}$, respectively. In reality, both oxides will have some slight covalent character, however, even without considering this, and also the contributions from anharmonicity in the O–O bond vibration (which are relatively small and decrease in magnitude from O_2^+ to O_2^{2-}),⁹ we see good agreement between the B_O and $\nu_{O-O}^x/\nu_{O-O}^{\text{peroxide}}$ ratios in Table 3. Fitting bond parameters in Fig. 5 with respect to known B_O values allows simple fits (eqn (6) and Table S2, ESI†)

for estimating O_2^x bond parameters to be derived. The trends are approximately linear, however, more accurate cubic fits where used. Therefore, provided the ν_{O-O} of a O_2^x is know, it is suggested that all other bond parameters can be estimated.

$$y = Ax^3 + Bx^2 + Cx + D \quad (6)$$

where B_O = bond order, n = number of bonding electrons, n^* = number of antibonding electrons.

To further qualify that the relationship between the ν_{O-O} of O_2^x and its bond parameters are approximately linear/cubic: it would be expected that a O_2^x species with secondary covalency (*i.e.* a O_2^x species with the outer valence electron partially shared with its coordinating environment) would have a B_O between that of two fully dissociated O_2^x species. For example, a O_2^x species with a B_O between that of O_2^{2-} ($B_O = 1$) and $O_2^{\bullet-}$ ($B_O = 1.5$) would be expected to have a B_O of ~ 1.25 , and would have a $\pi^*(2p)$ orbital structure between that of a O_2^{2-} , $[\uparrow\downarrow \uparrow\downarrow]$, and $O_2^{\bullet-}$, $[\uparrow\downarrow \uparrow]$, species. Thus, such a O_2^x species would have a

Fig. 5 Fitted plots of O_2^x bond parameters from Table 3 against the B_O . Colour-coordinated axis labels are shown above the graph. Cubic lines of best fits are shown by dashed lines. Fit values shown in Table 4.

detectable bond vibration and $\nu_{\text{O-O}}$ band somewhere between that of a strongly coordinated O_2^{2-} species (e.g. H_2O_2 ; 875 cm^{-1}) and a fully-dissociated $\text{O}_2^{\bullet-}$ (e.g. a $[\text{TBA}^+\cdots\text{O}_2^{\bullet-}]$; $\sim 1108\text{ cm}^{-1}$) species.⁶⁷ Therefore, $\nu_{\text{O-O}}$ values between those of these two species can be considered to have secondary covalent character, with valence bond electron density being shared by the O_2^x anion with its coordinating environment. Such a O_2^x species would be expected to have a partial dipole moment induced by the coordination interaction and the $\nu_{\text{O-O}}$ band would be both Raman and IR active.⁷³ Searching the literature this was indeed found to be the case for the $\nu_{\text{O-O}}$ of organic peroxy,^{74,75} transition metal superoxo-complexes,^{6,76,77} and metalloenzymes,⁷⁸ which all had Raman and/or IR values reported in the range between $875\text{--}1108\text{ cm}^{-1}$. Also, this trend in $\nu_{\text{O-O}}$ would be expected to be the same for O_2^x species with superoxo-oxyl and oxo-dioxygenyl character which was also observed to be the case and is discussed in detail below. To clarify language, the O_2^x valence electron is assumed to be partially shared with the coordinating species and:

- Peroxo-superoxyl refers to a coordinated O_2^x species with a $\pi^*(2p)$ valence orbital structure between $[1\downarrow 1\downarrow]-[1\downarrow 1]$, a B_{O} between 1–1.5 and a $\nu_{\text{O-O}}$ value between $875\text{--}1108\text{ cm}^{-1}$.
- Superoxo-oxyl refers to a coordinated O_2^x species with a $\pi^*(2p)$ valence orbital structure between $[1\downarrow 1]-[1\downarrow 1]$, a B_{O} between 1.5–2 and a $\nu_{\text{O-O}}$ value between $1179\text{--}1552\text{ cm}^{-1}$.
- Oxo-dioxygenyl refers to a coordinated O_2^x species with a $\pi^*(2p)$ valence orbital between $[1\downarrow 1]-[1]$, a B_{O} between 2–2.5 and a $\nu_{\text{O-O}}$ value between $1552\text{--}1825\text{ cm}^{-1}$.

3.5. Secondary covalent bonding

All the above discussed $\nu_{\text{O-O}}$ spectral bands for various O_2^x species (>200) have had their estimated bond properties calculated (using eqn (6) and Table 4) and have been plotted against their calculated B_{O} (Fig. 6). O_2^x species with B_{O} values divisible by 0.5 can be considered ionic or neutral whilst those with B_{O} values in-between can be considered to have some amount of electron donation occurring between O_2^x and its coordinating environment, *i.e.* secondary covalent bonding. Therefore, the B_{O} is assumed to be on a spectrum and to vary depending on how strongly coordinated the O_2^x diatom is (and therefore, how much of its valence electron it shares).

Experimental data on O–O bond parameters have been reported throughout the scientific literature for different O_2^x complexes. XRC or neutron diffraction techniques have been used to measure the B_{L} of many species, therefore, the estimated B_{O} and B_{L} values calculated from the $\nu_{\text{O-O}}$ value can be cross-compared with experimental results to gauge their accuracy. Where the information was available for some of these

Table 4 Cubic fit constants from Fig. 5 and eqn (6). In principle, all O_2^x parameters can be estimated by simply measuring $\nu_{\text{O-O}}$

x	y	A	B	C	D
B_{O}	$\nu_{\text{O-O}}$	592	−550	884	−184
B_{O}	l	−0.0933	0.52	−1.157	2.22
B_{O}	k	−2.607	15	−17.948	8.15
B_{O}	H	108	−632	1489	−816

Fig. 6 Fitted plots of estimated bond parameters for various O_2^x species calculated from the $\nu_{\text{O-O}}$ values reported in the literature (see Table S2 for values, ESI†). Light green shaded regions signify O_2^x species that are ionic or neutral with valence bond electrons concentrated in the $\pi_{2p_{xy}}^*$ orbitals. Light orange regions signify O_2^x species with secondary covalent interactions with the coordinate environment and where the outermost valence electron is shared with the coordinator. Colour coordinated axis labels are shown above the graph.

cross-comparisons are listed in Table S2 (ESI†) with the difference between the measured and calculated B_{L} values shown as a percentage (the literature is exhaustive and largely disorganised, *i.e.* individual bond parameters and $\nu_{\text{O-O}}$ values tend to be reported in different chemical, crystallographic, spectroscopic journals, and could warrant further compilation in future). Overall, the experimentally reported B_{L} and the estimated B_{L} values match well (generally <4% difference), supporting the correlation well. This relationship is useful for analysing O–O properties from experimental $\nu_{\text{O-O}}$ results.

$$\%e^- \text{ donation} = \frac{(B_{\text{O,c}} - B_{\text{O,i}})}{0.25} \times 100 \quad (7)$$

where: $B_{\text{O,c}}$ = calculated bond order, $B_{\text{O,i}}$ = nearest B_{O} to the $B_{\text{O,c}}$ divisible by 0.5 (if the nearest bond order is less than $B_{\text{O,c}}$ then the species is covalent in the opposite direction). A change in bond order of 0.5 is equivalent to adding/removing an electron from O_2^x . A change in bond order of 0.25 is equivalent to adding/removing 1/2 an electron (*i.e.* secondary covalent bond). An electron donation value of 100% indicates half the O_2^x valence electron is being shared with the coordinate environment, *i.e.* a fully covalent interaction.

Considering the change in the estimated B_{O} value of O_2^x species (calculated using the measured $\nu_{\text{O-O}}$ values) between strong and weak coordination, the secondary covalent character (*i.e.* amount of electron donation/abstraction between O_2^x and its coordinating environment) can be roughly estimated (eqn (7)). This is another useful, low-cost, method for estimating the

interaction between a O_2^x species and its environment based solely on its experimental ν_{O-O} bond vibration (see examples below). Thus, a value for the amount of electron donation/abstraction for a O_2^x can be teased out of the ν_{O-O} literature. One side note, these values are not suggested to be precise; as contributions from anharmonicity are excluded *etc.*, rather they are useful tools for quickly calculating approximate values for O_2^x bond parameters, which confirm and enhance the understanding of its vibrational spectra. This is particularly useful for helping to understand dynamic systems that are in flux such as at an electrode surface where countless thermodynamic, kinetic and charge transfer processes are occurring simultaneously, allowing for a general understanding of reaction processes to be rationalised with respect to O_2^x in terms of its ν_{O-O} . This also enables O_2^x species to be used as diagnostic molecules to probe the coordination strength of its environment by measuring the generated ν_{O-O} band.

Some examples calculations are given: NaO_2 (1156 cm^{-1}), $TBAO_2$ ($\sim 1108\text{ cm}^{-1}$), $Cu:O_2$ complex A (1033 cm^{-1}),⁶ have calculated B_O values of 1.549, 1.5, and 1.409 and electron donation values of 19.5, 0 and -36.4% , respectively. Values greater than $\pm 50\%$ can be considered to have significant secondary covalent character. In NaO_2 , Na^+ can be thought of as abstracting $\sim 20\%$ of an electron from the outer electron bond density of $O_2^{\bullet-}$, which has slight oxygen character, relative to $TBAO_2$. While in $Cu:O_2$ complex A, the Cu-centred ligand can be thought of as donating $\sim 36\%$ of an electron to $O_2^{\bullet-}$ giving it slight peroxide character, relative to $TBAO_2$.

Therefore:

$$\%e^- \text{ donation to } Na^+ = \left(\frac{(1.549 - 1.5)}{0.25} \right) \times 100 = 19.5\% \quad (NaO_2)$$

$$\%e^- \text{ donation to } TBA^+ = \left(\frac{(1.5 - 1.5)}{0.25} \right) \times 100 = 0\% \quad (TBAO_2)$$

$$\begin{aligned} \%e^- \text{ donation to } Cu \text{ complex A} &= \left(\frac{(1.409 - 1.5)}{0.25} \right) \times 100 \\ &= -36.4\% \quad (Cu : O_2 \text{ A}) \end{aligned}$$

It should be emphasised this method is not meant to be precise, rather to be used as a tool for approximating O–O bond properties, at a glance, using empirically derived ν_{O-O} values for O_2^x species' with complex structures or coordinate environments. This approach of deriving bond properties from spectral bond vibration values in different coordination environments could deliver comparable results for other homonuclear bonds and provide similar quick approximations, though this would require further work.

3.6. The trouble with lithium superoxide

Meta-analysis of reported Raman bands of LiO_2 shows that it sticks out like a sore-thumb in terms of both a wide range of reported values and that these values, are in the main, fall outside the trend of all other measured superoxide species (Fig. 2 and 3).²⁸ Raman spectral bands in the $O_2^{\bullet-}$ region ($1100\text{--}1200\text{ cm}^{-1}$) have

Fig. 7 Plot of ν_{O-O} spectral bands attributed to LiO_2 in the non-aqueous $Li-O_2$ battery literature (see Table S1, ESI[†]). The expected ν_{O-O} for LiO_2 based on the meta-analysis would be $1167 \pm 10\text{ cm}^{-1}$, with this range highlighted by the red box.

been reported as being either chemically stable LiO_2 or from polyvinylidene fluoride (PVDF) binder degradation during cycling of non-aqueous $Li-O_2$ cells (Fig. 7).^{27,38,79} Fundamental *in situ* SERS studies also report the presence of LiO_2 as an intermediate produced during ORR at the roughened Au (rAu) electrode surface.^{10,11,26} LiO_2 has long been believed to be both thermodynamically and kinetically unstable at temperatures above 25 K ^{10,50,80–85} and it is still unclear whether this observed intermediary species is a pure LiO_2 phase or a partially electrolyte/electrode stabilised $[Li^+ \cdots O_2^{\bullet-}]$ complex.^{86,87} This has led to some uncertainty over whether LiO_2 can exist as a stable discharge product, reaction intermediate, or at all. In light of the trend in ν_{O-O} of $O_2^{\bullet-}$ discussed previously, looking at the ν_{O-O} spectra of these reports can add to the debate.

Variation in reported bands comes down to the following: (1) $O_2^{\bullet-}$ is reacting with PVDF abstracting a proton and forming an alkene bond that causes a concomitant shift in the G-band with a serendipitously similar bond vibration to $O_2^{\bullet-}$ observed *in situ*. (2) δ^+ proton sites in the structure of PVDF ($[-CH_2-CF_2-]_n$) binder are stabilising $O_2^{\bullet-}$ and Li^+ interactions allowing a stabilised $[(Li^+)_x \cdots O_2^{\bullet-}]$ complex to deposit and grow on the cathode/binder. This could explain the accompanying distorted carbon G-band ($\sim 1505\text{ cm}^{-1}$). (3) Due to similarities in the wavenumber of their spectral bands, a $Li_2O_2 \cdot 2H_2O$ species, similar to the $Na_2O_2 \cdot 2H_2O$ species ($\sim 1135\text{ cm}^{-1}$)⁴⁸ observed in non-aqueous $Na-O_2$ batteries, is being formed when H_2O is present in the electrolyte. (4) A thermodynamically irregular or amorphous LiO_2 phase or a weakly coordinated $[Li^+ \cdots O_2^{\bullet-}]$ complex is formed. (5) A partially intercalated $O_2^{\bullet-}$ species in the carbon cathode that allows Li^+ to bind but inhibits disproportionation to Li_2O_2 is formed. The interaction between $O_2^{\bullet-}$ and the graphitic layers could produce the observed G-band ($\sim 1505\text{ cm}^{-1}$) shift.

From the derived \mathcal{K}_i^C relationship, the expected ν_{O-O} for LiO_2 was estimated to be $1167 \pm 10\text{ cm}^{-1}$, with this range shown *via* a red box in Fig. 7. Region (A) ν_{O-O} values would fit with the expected value of a LiO_2 species. Only one value

matched this and it was reported by Xia *et al.* who observed a broad $\nu_{\text{O-O}}$ band (1150–1200 cm^{-1}) after discharging a non-aqueous Li–O₂ battery.³⁶ Region (B) $\nu_{\text{O-O}}$ values would be expected to be partially stabilised [$\text{Li}^+ \cdots \text{O}_2^{\bullet-}$] species' or incorrectly assigned bands. Other reports of $\nu_{\text{O-O}}$ in a variety of different systems (Table S1, ESI†) are likely surface/solution stabilised [$\text{Li}^+ \cdots \text{O}_2^{\bullet-}$] species or possibly PVDF degradation products.^{27,42,88}

In summary, it is suggested that many of the $\nu_{\text{O-O}}$ values reported as LiO₂ are too low and instead environmental influences (electrolyte and electrode) are helping to stabilise a [$(\text{Li}^+)_x \cdots \text{O}_2^{\bullet-}$] complex (where $x < 1$). Current evidence suggests; that for species generated on cathodes with PVDF binder (1) is the most probable cause of these reported ' $\nu_{\text{O-O}}$ ' spectral bands. However, (2) and (5) are other possibilities, but again are not a pure LiO₂ product. In addition, during *in situ* spectroelectrochemical investigations of the interface partially electrolyte stabilised [$\text{Li}^+ \cdots \text{O}_2^{\bullet-}$] complexes are being detected. Though, the report by Xia *et al.* suggests that it may still be feasible to produce a pure LiO₂ phase during discharge if the conditions are right though the presence of toroid discharge product morphologies (associated with water containing electrolytes)^{89,90} may suggest HO₂ was being detected rather than LiO₂.

4. Conclusions

Superoxide ($\text{O}_2^{\bullet-}$) vibrational spectral bands reported in the literature were collated (> 50 species) and trends in their coordinating environment were observed and described. The \mathcal{K} parameter based on the mass-to-charge ratio and ionic volume of the coordinating ion was derived, which gave an excellent approximation of the collated results. The \mathcal{K} parameter can be calculated with relative ease for most ions and is analogous to charge density and gives a simple low-cost method of quantifying an ions Coulombic attractive strength over oppositely charged species. It was determined that $\text{O}_2^{\bullet-}$ can be used as a diagnostic molecule to probe the coordination strength of its immediate environment, by observing its vibrational spectrum. Furthermore, dioxygen vibrational spectral bands reported in the literature were collated (> 200 species). The trends due to the changes in the coordinating environment were observed, where changes in the O–O vibrational spectral band were shown to be a result of electron abstraction/donation from/into the O–O bond *via* a 'secondary covalent' bonding interaction between the dioxygen species and its coordinating environment. A simple cubic approximation was drawn that enabled the bond order, bond dissociation enthalpy, bond length and bond force constants to be estimated solely using experimentally measured O–O spectral bond vibrations. For the bond length this approximation gave estimated values that matched extremely well with reported values (0.5–5%) measured experimentally using X-ray crystallography. It was shown by estimating the bond order allowed for the level of e^- abstraction by the environment (*i.e.* the strength of the secondary covalent interaction) can also be estimated for any dioxygen species based solely on its vibrational spectra.

Raman spectrum of LiO₂ was analysed and most reported bands were found to be too low to be a pure LiO₂ phase, suggesting that coordinate [$\text{Li}^+ \cdots \text{O}_2^{\bullet-}$] complexes or degradation products are the most likely cause of these spectral reports in the non-aqueous Li–O₂ battery literature.

Nomenclature

O_2^+	Dioxygen cation
O_2	Dioxygen
$\text{O}_2^{\bullet-}$	Superoxide anion
O_2^{2-}	Peroxide anion
ROS	Reactive oxide species
O_2^x	Dioxide species, where $x = -2, -1, 0, +1$
$\nu_{\text{O-O}}$	O-O symmetric stretching vibration
$[\text{M}^+ \cdots \text{O}_2^{\bullet-}]$	Alkali-metal superoxide complex
$[\text{C}^+ \cdots \text{O}_2^{\bullet-}]$	Cation coordinated superoxide complex
C^+	Coordinate cation
$M_r Q^{-1}$	Molecular mass-to-charge ratio
M_r	Relative molecular mass (mol g^{-1})
$[(\text{Li}^+)_x \cdots \text{O}_2^{\bullet-}]$	Superoxide rich lithium coordinate complex
XRC	X-ray crystallography
i_v	Ionic volume
$i_{\text{s.a.}}$	Ionic surface area
B_{O}	Bond order
B_{L}	Bond length
B_{k}	Bond force constant
B_{H}	Bond dissociation enthalpy
C	Cation
A	Anion
\mathcal{K}	'Ionic charge dispersion'
q	No. of bonding electrons
q^*	No. of anti-bonding electrons
Q	Charge on an ion (C)
