1. Introduction

Accounting for 5% of anthropogenic greenhouse emissions, nitrous oxide (N₂O) is a potent greenhouse gas¹ with a warming potential 300 times greater than carbon dioxide. In addition to its climate change potential, as the primary source of stratospheric NO₃₋ surface N₂O emissions represent the dominant ozone-depleting emissions of the 21st century.¹,² Human actions such as manufacturing, fossil fuel use, and agriculture have given rise to increased emissions and N₂O concentrations are rising by 0.5–0.9 ppb per volume per year.³

Although unregulated by the Montreal Protocol,⁴ as a result of its negative environmental impact there is considerable interest in reducing N₂O emissions. One effective route to reducing emissions is via metal-catalysed N₂O reduction⁵,⁶ and this has been an active area of research in conventional heterogeneous catalysis and cluster science.⁷

At the very simplest level, the reactions of atomic metal cations and N₂O have been studied in detail by Böhme and coworkers,⁸ and the role of atomic and cluster ions as the ultimate single-site catalysts has been reviewed by Böhme and Schwarz.⁹ In terms of reactions of N₂O with metal ions, M⁺(N₂O) complexes represent model entrance-channel species in which the fundamental interactions can be studied in isolation.⁹ Metal atom–N₂O binding has been studied both theoretically¹⁰–¹² and experimentally,¹³,¹⁴ and the reactions of nitrous oxide with charged metal clusters have received much attention both under thermal and single-collision conditions.¹⁵–²³

We recently reported a spectroscopic study of M⁺(N₂O) (M = Cu, Ag, Au) complexes in which infrared photodissociation (IRPD) spectroscopy was combined with quantum chemical calculations to identify common structural binding motifs.²⁴ Spectroscopically distinct nitrogen- and oxygen-bound ligands were identified giving rise to a rich diversity of structural isomers. However, in practical N₂O-reduction catalysis, it is not the coinage metals which are typically used but the platinum group metals. Rhodium in particular plays a prominent role in the N₂O reduction in the automobile three-way catalytic converter. This in turn led to many fundamental studies of rhodium cluster reactions with nitrogen oxides,¹⁹,²⁵–³⁰ including infrared-driven cluster surface reactions.³¹–³³

Here, we report a combined experimental and quantum chemical study of group 9 ion –N₂O complexes, M⁺(N₂O) (M = Co, Rh, Ir) with the aim of investigating the fundamental interactions involved in the early stages of nitrous oxide reduction at heterogeneous catalysts. IRPD spectroscopy, using the Ar-tagging technique has been applied to determine the structures of the title complexes by comparison with the simulated spectra of energetically low-lying electronic and/or isomeric forms determined from density functional theory (DFT). This powerful approach has been employed by several groups, including our own, to provide reliable information on the structures of many gas-phase metal–ligand complexes.
complexes\textsuperscript{34–36} including, recently, those of metal–nitrosyl complexes \(\text{M}^+(\text{NO})_3\)\textsuperscript{37,38}

2. Experimental

The instrument and technique employed in these studies have been described previously\textsuperscript{24,39} and only brief details are given here. Gas-phase \(\text{M}^+(\text{N}_2\text{O})_n\) \((\text{M} = \text{Co}, \text{Rh}, \text{Ir})\) complexes and their argon-tagged counterparts are formed by entraining the products of focussed 532 nm pulsed laser ablation of a rotating metal disc in a 6 bar pulse of Argon carrier gas seeded with 0.6% \(\text{N}_2\text{O}\). As the gas expands into high vacuum weakly-bound complexes are formed in many-body collisions and subsequently cooled in the ensuing expansion. The resulting molecular beam is skimmed and the positively-charged species are detected by reflectron time-of-flight mass spectrometry.\textsuperscript{40} The cluster source and detection operates at 10 Hz.

Infrared spectra of the complexes of interest are recorded using the inert messenger technique\textsuperscript{41–46} – in this case using weakly-bound Ar atoms. Pulsed infrared radiation, tuneable in the region of the fundamental of the \(\nu_3\) asymmetric (\(\text{N}==\text{N}\)) stretch of nitrous oxide 2150–2400 \text{cm}^{-1}, is provided by an optical parametric oscillator/amplifier system (LaserVision). The infrared beam counter-propagates with the molecular beam and operates on a three pulse on/three pulse off duty cycle, allowing continuous IR on–off subtraction (total of 300 laser shots at each point). Absorption of an infrared photon results in heating of the complex and detachment of the weakly-bound Ar atom which thus provides a mass spectrometric signature. Monitoring the fractional depletion of the \(\nu_3\) stretch of nitrous oxide 2150–2400 \text{cm}^{-1} provides a mass spectrometric signature. The cluster source and detection operates at 10 Hz.

To aid in assigning and interpreting the experimental data, the structures and simulated infrared spectra of energetically low-lying isomers were calculated using density functional theory (DFT) employing the B3P86 hybrid density functional\textsuperscript{37} coupled with the Def2TZVP basis set.\textsuperscript{48,49} All calculations were carried out using the Gaussian09 suite of programs.\textsuperscript{50} To aid comparison with experimental spectra, the wavenumbers of infrared bands in the calculated spectra have been scaled by a factor 0.932, derived from the calculated \(\nu_3\) stretch of free \(\text{N}_2\text{O}\).\textsuperscript{51} Further details of the calculations, including structures of all isomers together with composite simulated spectra can be found in the ESL.\textsuperscript{†}

3. Results and discussion

3.1 \(\text{M}^+(\text{N}_2\text{O})_n\text{Ar}\) spectra

Fig. 1 shows the time-of-flight mass spectrum illustrating the production of \(\text{Co}^+(\text{N}_2\text{O})_n\) complexes generated following the ablation of a cobalt disc in the presence of an argon carrier gas seeded with 0.6% \(\text{N}_2\text{O}\). \(\text{Co}^+(\text{N}_2\text{O})_n\), \(\text{CoO}^+(\text{N}_2\text{O})_n\), and \(\text{Co}^+(\text{N}_2\text{O})_3\text{Ar}\) complexes can be identified clearly. The size distribution of complexes generated can be controlled crudely by varying the partial pressure of \(\text{N}_2\text{O}\) and/or the backing pressure behind the pulsed valve. The equivalent mass spectra obtained for \(\text{Rh}^+(\text{N}_2\text{O})_n\) and \(\text{Ir}^+(\text{N}_2\text{O})_n\) and are shown in the ESL.\textsuperscript{†} MO+ complexes are most prevalent in the cobalt mass spectrum and the Ir\textsuperscript{1} naked parent ion peak is almost undetectable suggesting highly efficient reaction and/or clustering in this case. Uniquely in the case of iridium ablation, \(\text{M}^+(\text{N}_2\text{O})_n\) complexes were also observed (see ESI). These observations are entirely consistent with the \(\text{M}^+ + \text{N}_2\text{O}\) reactivity reported by Böhme and coworkers\textsuperscript{8} and can be understood on the basis of the calculated reactive potential energy surfaces for the first reactive collision, \(\text{M}^+ + \text{N}_2\text{O}\), shown in Fig. 2.

Given the singlet ground states of both \(\text{N}_2\text{O}\) and \(\text{N}_2\), the O-atom transfer reaction

\[
\text{M}^+ + \text{N}_2\text{O} \rightarrow \text{MO}^+ + \text{N}_2
\]

is only formally spin-allowed for \(\text{M}^+\) and \(\text{MO}^+\) states of the same multiplicity.\textsuperscript{8} \(\text{Co}^+\) has a \((\text{d}^8)^{3\text{F}}\) ground state\textsuperscript{52} whilst the ground state of \(\text{CoO}^+\) is \(5\Delta\) (though Armentrout and Beauchamp invoked a low-lying \(\Sigma^-\) state in their reactivity study).\textsuperscript{53} Despite being exothermic, the \(\text{Co}^+ + \text{N}_2\text{O}\) reaction is both spin-forbidden and experiences a significant barrier on the ground state surface. Unsurprisingly, then, this reaction is very slow.\textsuperscript{5}

We find no evidence in any of our cobalt studies of the involvement of any excited electronic states. The \(\text{D}^1\) surface shown in Fig. 2 is the lowest energy excited state with the same \(\text{Co}^+\) \(\text{d}^8\) configuration as the ground state (there are lower \(\text{5F}\) and \(\text{3F}\) excited states at 0.4 eV and 1.2 eV, respectively, but these have \(\text{d}^{7}\text{(F)}\text{gs}\) configurations). As will become clear, in all the \(\text{M}^+(\text{N}_2\text{O})_n\) systems studied here, low-spin states are stabilised by successive ligation.

The \(\text{Rh}^+ + \text{N}_2\text{O}\) atom transfer reaction is the only one of the three systems here to be fully spin allowed, \(\text{RhO}^+\) having a \(\Sigma^-\) ground state. Despite being exothermic the reaction is very slow (\(k < 4 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}\)) as a result of the large 0.7 eV barrier on the ground state surface. The \(\text{d}^1\text{D}^1\) state is the lowest excited state of different multiplicity and the only excited state predicted at 5500 K by Böhme and coworkers\textsuperscript{8} in their modelling of their inductively coupled plasma source.
By contrast with the other two metal ions, the reaction of Ir\(^+\) with \(\text{N}_2\text{O}\) despite being spin-forbidden on the quintet ground state, is fast. We determine a small (0.19 eV) barrier to reaction on the ground electronic state. Lavrov et al.\(^8\) account for the anomalous reaction rate as arising from spin mixing in the formation of the metal oxide cation – i.e., in the exit channel.

Each potential energy surface shown in Fig. 2 shows two entrance-channel complexes corresponding to nitrous oxide bonding to the metal centre via the terminal N-atoms or the O-atom, respectively. In each case the N-bound isomer is the lower in energy. These structures form the basis for the understanding of the IRPD spectra to follow.

### 3.2.1 \(\text{Co}^{(\text{N}_2\text{O})n}\text{-Ar IRPD spectra}\)

Fig. 3a shows the IRPD spectra for the \(\text{Co}^{(\text{N}_2\text{O})n}\text{-Ar}\) \((n = 2–7)\) complexes. In each spectrum two distinct spectral features can be identified; one close to the \(\text{N}=\text{N}\) stretching frequency in free \(\text{N}_2\text{O}\) at \(2233.5\) \(\text{cm}^{-1}\) \(^{51}\) and a second significantly blue-shifted from the first by between 93 and 50 \(\text{cm}^{-1}\). The spectral feature near \(2240\) \(\text{cm}^{-1}\) is broad suggesting it is a blended feature of multiple vibrational bands and its integrated intensity drops with increasing complex size. A distinct feature at the free \(\text{N}_2\text{O}\) stretching frequency is apparent in the spectra for all complexes \(n > 2\) size, suggesting the presence of weakly-interacting ligands.

The second spectral feature undergoes a smooth red-shift (or decreasing blue-shift relative to the first band) with increasing ligand number from \(2316\) \(\text{cm}^{-1}\) for \(n = 2\) to \(2274\) \(\text{cm}^{-1}\) for \(n = 7\). In these regards, the trends in the spectra of the \(\text{Co}^{(\text{N}_2\text{O})n}\text{-Ar}\) complexes show close similarity with those reported previously for the coinage metal \(\text{N}_2\text{O}\) complexes\(^24\) and a similar rationale can be applied to their understanding.

Fig. 4 shows a representation of the calculated \(\text{Co}^{+}\)\(\text{N}_2\text{O}\) potential energy surface in the entrance channel. The line shows the calculated minimum energy as a function of \(\text{Co}^{+}\)–\(\text{N}_2\text{O}\) bond angle with \(\theta\) marking the linear \(\text{Co}^{+}\)–\(\text{NNO}\) structure (i.e., \(\eta^1\) via the N atom) which represents the lowest energy entrance-channel structure. A second, higher-lying, double-well minimum corresponding to the bent \(\text{Co}^{+}\text{ONN}\) structure (\(\eta^1\) via the O atom) is observed at \(155^\circ/205^\circ\). The N- and O-bound minima are separated by a large barrier to \(\text{N}_2\text{O}\) internal rotation of \(> 1\) eV. Rapid cooling within our free-jet expansion permits the formation of excited isomeric forms trapped behind such barriers, leading to the possibility of isomers with both N-bound and O-bound ligands. This ability of \(\text{N}_2\text{O}\) to bind in two distinct orientations with differing binding energies leads to complicated growth kinetics. For example, the binding of a ligand in an N-bound orientation can potentially displace an existing O-bound ligand but the reverse is less likely (indeed impossible without significant internal energy). For this reason, larger complexes will probably be richer in N-bound ligands.

It will be convenient in what follows to adopt a succinct notation \(\text{M}^{(\text{N}_2\text{O})n}\text{-Ar}\) for a particular structure in which \(x\) and \(y\) are integer values indicating the number of N- and O-bound ligands, respectively. Clearly \(x + y = n\). So, for example, \(\text{M}^{(\text{N}_2\text{O})1}\) represents a singlet state of a \(\text{M}^{(\text{N}_2\text{O})}\) isomer with two N-bound ligands and one O-bound ligand.

The \(\text{Co}^{(\text{N}_2\text{O})n}\text{-Ar}\) spectra can be understood qualitatively from DFT simulations of the \(\text{Co}^{(\text{N}_2\text{O})2}\text{-Ar}\) complex which shows the N- and O-bound ligands to be spectroscopically distinct isomers. Fig. 5 shows the experimental IRPD spectrum of \(\text{Co}^{(\text{N}_2\text{O})2}\)\text{-Ar} together with spectral simulations of the \(\text{Co}^{\text{N}}\text{O}, \text{Co}^{\text{N}}\text{O}^{1}\) and \(\text{Co}^{\text{O}}\text{O}^{1}\) isomers. Table S1 in the ESI\(^\dagger\) gives the relative energies of all calculated structures together with those of other electronic states. As discussed above, given clear that the evolution of the observed spectra with increased ligation, are markedly different for each of the three metal ions studied here. For this reason, the spectra for complexes of each metal ion are discussed separately.

### 3.2 \(\text{M}^{(\text{N}_2\text{O})n}\text{-Ar IRPD spectra}\)

The infrared spectra of \(\text{M}^{(\text{N}_2\text{O})n}\text{-Ar}\) complexes (\(M = \text{Co}, \text{Rh}, \text{Ir};\) \(n = 2–7\)) are presented in Fig. 3. Already from this overview it is
the relative energies of excited spin states only the triplet states are likely to contribute significantly to the spectra obtained.

The \(^{3}\text{Co}^{N_{2}}\) isomer is the lowest energy molecule-bound structure. It is clear from Fig. 5, however, that the \(^{3}\text{Co}^{N_{2}}\) structure alone cannot account for the two spectral bands observed experimentally and that O-bound ligands (in the form of \(^{3}\text{Co}^{N_{1}O_{1}}\) and \(^{3}\text{Co}^{O_{2}}\) isomers) must be present. The two bands observed experimentally can be assigned as follows: the lower wavenumber band at 2240 cm\(^{-1}\) is attributed to the N\(_{Q}\)N stretch in O-bound ligands. Such binding represents minimal perturbation to the N\(_{Q}\)N bond, leading to a fundamental band close to that in free N\(_{2}O\). The higher wavenumber feature (2316 cm\(^{-1}\)) arises from N-bound ligands. The binding mechanism for N-bound ligands is dominated by electron donation from the N\(_{2}O\) HOMO-1, 7\(\sigma\) orbital to the metal centre. As the 7\(\sigma\) orbital is antibonding with respect to the N\(_{Q}\)N bond, this results in a slightly stronger N\(_{Q}\)N bond reflected in a spectral blue-shift.\(^{13,14,24}\)

The two bands in the observed spectrum clearly indicate the presence of both O- and N-bound ligands. Given the relative energies of the different isomers, it is inconceivable that we generate a pure population of the \(^{3}\text{Co}^{N_{1}O_{1}}\) structure and we conclude that a mixture of isomers is present in our molecular beam.

The first two N\(_{2}O\) ligands bind to the Co\(^{+}\) centre tightly with M\(^{+}–L\) bond dissociation energies of 1.62 eV. Subsequent ligands are bound less strongly but can still influence the IRPD spectra. The lower wavenumber feature in the spectrum...
becomes broader with increasing ligation as not only O-bound ligands contribute in this region, but also less strongly interacting N-bound ligands. As a result, the interpretation of the spectra in this region becomes less clear cut.

As \( n \) increases further, the efficiency of \( \sigma \)-donation by N-bound core ligands drops leading to a smooth red-shift in the higher frequency vibrational band (see Fig. 3a). This red-shift appears to cease at \( n = 6 \), suggesting the completion of a coordination shell which is confirmed by DFT calculations and is consistent with the expected octahedral symmetry of a high-spin d\(^8\) complex.

### 3.2.2 Rh\(^+\)(N\(_2\)O\(_2\))\(_n\)–Ar spectra

The IRPD spectra for the Rh\(^+\)(N\(_2\)O\(_2\))\(_n\)–Ar \((n = 2–7)\) complexes are shown in Fig. 3b. Again, two distinct spectral features are observed which we can assign to N- and O-bound core and outer-ligands. It is clear, however, both from the presence of new spectral features and a contrasting trend in the band positions with \( n \) that the Rh\(^+\)(N\(_2\)O\(_2\)) complexes are more complicated than their Co\(^+\)(N\(_2\)O\(_2\)) counterparts.

Fig. 6 shows the IRPD spectrum of Rh\(^+\)(N\(_2\)O\(_2\))–Ar along with the simulated spectra for energetically low-lying singlet and triplet isomers in the region of the N\(_2\)O asymmetric (N–N) stretch. Simulated IR bands corresponding to N-bound and O-bound ligands are indicated in blue and red, respectively. Relative energies are given in eV. The vertical dashed line indicates the wavenumber of the \( v_{\nu N} (N\rightarrow N) \) mode in isolated N\(_2\)O at 2223.5 cm\(^{-1}\).\(^5\)

The IRPD spectra begin to get more complex with the Rh\(^+\)(N\(_2\)O\(_2\))–Ar species – see Fig. 7 which shows simulated spectra for a range of \(^{1\text{Rh}^+\text{N}^0\text{O}^0}\) isomers – as new bands appear. The signature of the core N- and O-bound ligands is clear in the intense feature at 2312 cm\(^{-1}\) and the broad feature 2225–2250 cm\(^{-1}\). A new band around 2280 cm\(^{-1}\) reflects the third ligand N-binding less strongly than the two core ligands. It has an increased M\(^+\)–NNO bond length of 2.23 Å compared with 2.07 Å for the core ligands and is clearly reproduced in the simulated spectra of the \(^3\text{Rh}^+\text{N}^1\), \(^3\text{Rh}^+\text{N}^2\text{O}^1\) and \(^3\text{Rh}^+\text{N}^2\text{O}^2\) isomers.

In the case of the rhodium complexes an additional complication rises due to low-lying electronically excited states. For the bare ion the d\(^8\) \(^1\text{D}\) state lies ca. 1.4 eV higher than the \(^3\text{F}\) ground state.\(^54,55\) However, upon complexation the singlet state is strongly stabilised such that by \( n = 3 \) the \(^1\text{Rh}^+\text{N}^1\) isomer is calculated to lie only 0.3 eV higher than the \(^3\text{Rh}^+\text{N}^1\) ground state. Fig. 8 shows the relative energies of the lowest isomeric forms of singlet, triplet and quintet states of M\(^+\)(N\(_2\)O\(_2\)) as a function of ligand number. Tables S1–S3 in the ESI\(^\dagger\) present the calculated relative energies of all M\(^+\)(N\(_2\)O\(_2\)) structural isomers identified in this study.

We believe the shoulder at 2330 cm\(^{-1}\) in Fig. 7 indicates the emergence of the singlet state in our spectrum. As shown in Fig. 8, the singlet state becomes comparable in energy with the triplet around \( n = 3 \) and becomes the ground state at larger \( n \). It seems likely that the observed spectrum of Rh\(^+\)(N\(_2\)O\(_2\))–Ar...
results from a complex combination of multiple isomers of two different electronic states.

The singlet and triplet states still have comparable energy in the $n = 4$ complexes although now the singlet state is the lower in energy, and this is reflected in an intensity alternation in the spectrum (see Fig. 3b). Fig. 9 shows the IRPD spectrum of the Rh$^+$(N$_2$O)$_n$–Ar complex, alongside simulated IR spectra from various calculated singlet and triplet isomers. Reflecting the low-spin d$^8$ configuration, a square-planar $^3$Rh$^+$/N$_4$ isomer is the calculated global minimum, with the $^3$Rh$^+$/N$^2$ counterpart 0.63 eV higher in energy.

It is not uncommon for the spin state of the global minimum to change upon increasing ligation.$^{56,57}$ For example, in the case of V$^+$(CO)$_n$ complexes, a lower (triplet) multiplicity state appears for $n \geq 4$. For Rh$^+$(N$_2$O)$_n$, the switch to the lower multiplicity, singlet state at $n = 4$ is consistent with the adoption of square-planar geometries which are known to be favoured by low-spin d$^8$ complexes. In such cases $n = 4$ represents a complete shell.$^{58}$

As in the $n = 3$ case, a combination of multiple isomers of both spin states provides a satisfactory understanding of the spectrum (see Fig. 9). The band at 2333 cm$^{-1}$ can be assigned to the now familiar N-bound ligand in a singlet isomer. This band lies markedly to the blue of the strongest feature in the $n = 3$ spectra (Fig. 7), reflecting the change in structure/spin state. The weaker 2302 cm$^{-1}$ band is most likely a strongly N-bound ligand in a triplet isomer (e.g., $^3$Rh$^+$/N$^3$O$^2$ or $^3$Rh$^+$/N$^3$O$^3$) but could be a weakly-interacting N-bound ligand in a singlet state isomer.

Once the singlet state is unambiguously the lowest energy state for $n > 4$, the spectra of the Rh$^+$(N$_2$O)$_n$–Ar complexes become simpler again. By contrast with Co$^+$(N$_2$O)$_n$ and the coinage metal complexes$^{24}$ the blue-shift in the N-bound band increases further with $n$ reflecting ever stronger σ-donation as captured in the calculated structures. $n = 4$ represents a complete coordination shell for the square-planar Rh$^+$(N$_2$O)$_n$ complexes. As further N$_2$O ligands add, the four metal–ligand (M–N) bond distances in the “core” shorten, increasing the σ-electron density donation leading to an increased spectral blue-shift in the band as observed in the experimental spectra (Fig. 10).

In the light of the above interpretations, it is possible to assign bands in the various spectra as arising from singlet and triplet isomers, accordingly as shown in Fig. 10. Once the spin configuration changes from triplet to singlet at $n = 4$, the singlet remains the lowest energy multiplicity predicted for the higher order complexes, $n = 5$–7 and dominate the spectra.

Finally, we cannot rule out the existence of inserted ORhN$_2$(N$_2$O)$_{n-1}$ structures in these spectra. In most cases these structures represents the true global minimum structure, albeit behind a significant barrier to reaction (see Fig. 2). The N$_2$ stretch, which is weakly IR-allowed in complexation to an ion, is predicted to lie in the same region. However, in most cases the overall O-atom transfer reaction (1) is strongly exothermic and it seems unlikely that an N$_2$ moiety could remain bound once significant energy is released upon formation of the MO$^+$ bond.

### 3.2.3 Ir$^+$(N$_2$O)$_n$–Ar spectra.

The IRPD spectra for the Ir$^+$(N$_2$O)$_n$–Ar ($n = 2$–7) complexes are shown in Fig. 3c and are
quite unlike those of any other M′(N₂O)ₙ system we have studied. Only a single, partially resolved feature is observed, slightly blue-shifted from the free N₂O vibration previously interpreted as arising from O-bound ligands (ca. 2260–2220 cm⁻¹/C₀₁).

The ground state of Ir⁺ is a 5d⁷(4F)6s⁵F state with a 5d⁸3F state ca. 0.25 eV higher. Complexation with even a single N₂O stabilises the 3F state of the ion relative to the 5F ground state and the 3Ir⁺N₂ isomer is clearly the lowest energy entrance-channel structure (see Fig. 8).

Fig. 11 shows a comparison of the Ir⁺(N₂O)₂ spectrum with calculated spectra of low-lying isomers. The simulated spectra for the 3Ir⁺N₂ and 3Ir⁺N'O₁ isomers agree very poorly with the observed spectrum in which there is no evidence of an "N-bound feature" around 2300 cm⁻¹. Given that the 4Ir⁺O₂ isomer lies 4 eV above the ground state it is inconceivable that a pure distribution of this species is formed.

Despite lying considerably higher in energy, the simulated spectra of the quintet states agree well with the experimental spectrum as no significant blue-shift is predicted even in the N-bound ligands. In the quintet, higher population of strongly antibonding orbitals (including a 6s–7s interaction) weakens the N-bound interaction and is reflected in non-linear structures (see Fig. 11). As a result, the predicted bands in all ligands appear in the region 2220–2400 cm⁻¹. The observed spectral band is notably broader than in the Co⁺(N₂O)₂–Ar and Rh⁺(N₂O)₂–Ar spectra and we thus assign this feature to a convolution of the three quintet isomers, 5Ir⁺N₂, 5Ir⁺N'O₁ and 5Ir⁺O₂.

One possible explanation for the absence of triplet states comes from the calculated M⁺ + N₂O reaction pathways shown in Fig. 2. On the triplet state surface the barrier to the O-atom transfer reaction is submerged and hence any reaction on the triplet surface can be assumed to proceed to completion resulting in the sequential production of IrO₉⁺. This is consistent with the single collision reaction results of Böhme and coworkers as well as the apparent complete loss of the parent Ir⁺ signal in our time of flight spectra (Fig. S51, ESI†).

In contrast, on the quintet surface, a small (0.19 eV) but real barrier to reaction exists (see Fig. 2c) and, under the rapid quenching conditions of our expansion, reactants might easily become trapped in the weakly-bound entrance channel structures. If such complexes then form seeds for subsequent clustering without inducing a change in spin state, then the only complexes observed would be quintet states with spectra as shown in Fig. 11 which agree well with the observed IRPD spectra. Such an interpretation would imply highly inefficient surface-crossings between quintet and triplet surfaces for all complexes studied here.

4. Discussion

One of the most striking findings of this study is the difference observed in the spectra of the three transition metal ions studied. In contrast, only subtle differences were observed in the structures and spectra of N₂O complexes with Cu⁺, Ag⁺ and Au⁺. The differences here appear to correlate with the importance of low-lying excited electronic states and, in particular, the differing effects successive ligation has on the ground and excited states of the metal ions (see Fig. 8).
In the simplest case of Co+, rather like in the coinage metal ions, a satisfactory understanding of the observed Co+(N₂O)_n spectra in terms of N- and O-bound ligands, is achieved by considering only the ground electronic state. The excited states all lie markedly higher in energy, at least up to n = 4. A smooth red-shift in the spectral band denoting N-bound ligands is observed with successive ligation as new ligands impair the efficiency of O-donation by the two core ligands.

The spectra of Rh+(N₂O)_n and Ir+(N₂O)_n complexes, and their variation with n, are qualitatively different to the other systems. Particularly in the case of Rh+(N₂O)_n, the IR spectra contain evidence for the role of excited electronic states with new bands appearing in the spectra around n = 3, 4 just as the singlet state is calculated to become the ground state. Such effects should not be surprising – it is exactly this abundance of low-lying electronic states which makes the platinum group metals so useful in catalysis.

It is worth emphasising that for all the metal–ligand cases studied here, a satisfactory understanding of the spectra observed is achieved by considering the calculated low-lying spin states and structures predicted by density functional theory. This contrasts with the naked metal clusters (M^{n+/0/}) of the same elements, the electronic and geometrical structures of which remain, in some cases, a matter of heated discussion.60–64

5. Conclusions

The structures of gas-phase M+(N₂O)_n complexes (M = Co, Rh, Ir; n = 2–7) have been studied using a combination of IRPD spectroscopy and density functional theory. The spectra of the complexes for the three transition metal ions are markedly different from one another and evolve in contrasting ways with increasing ligand number, n.

Spectral simulations based on calculated energetically low-lying structures provide clear explanations for the spectra observed in terms of isomers with spectroscopically distinguishable N- and O-bound ligands. In all cases, the N-bound structures represent the lower in energy but significant barriers to free internal rotation for the trapping of O-bound ligands. The IRPD spectra of the Rh+(N₂O)_n and Ir+(N₂O)_n complexes show additional evidence underlying the importance of low-lying excited electronic states including, in the case of the former, a switch in the spin multiplicity of the ground state at or around n = 4.

The combination of multiple binding motifs and low-lying electronic states gives rise to an unusually rich and diverse range of structures for these complexes. The fact that N- and O-bound core ligands are spectroscopically distinguishable gives rise to the tantalising possibility of addressing individual ligands with known binding motifs. In turn this offers the possibility of controllable infrared excitation for the study of intra-complex chemistry.
