## New insights into the dissociation dynamics of methylated anilines<sup>†</sup>

Neil C. Cole-Filipiak and Vasilios G. Stavros \*

Aniline, an important model system for biological chromophores, undergoes ultrafast H-atom loss upon absorption of an ultraviolet photon. By varying the number and position of methyl substituents on both the aromatic ring and amine functional group, we explore the ultrafast production of photofragments as a function of molecular structure. Both *N*-methyl aniline and 3,5-dimethyl aniline show altered H-atom loss behaviour compared to aniline, while no evidence for  $\text{CH}_3$  loss was found from either *N*-methyl aniline or *N,N*-dimethyl aniline. With the addition of time-resolved photoelectron spectroscopy, the photofragment appearance times are matched to excited state relaxation pathways. Evidence for a sequential excited state relaxation mechanism, potentially involving a valence-to-Rydberg decay mechanism, will be presented. Such a global, bottom-up approach to molecular photochemistry is crucial to understanding the dissociative pathways and excited state decay mechanisms of biomolecule photoprotection in nature.

### 1. Introduction

By investigating the basic building blocks of aromatic biomolecules, chemists and biologists may develop a fundamental understanding of the structure–dynamics–function relationship governing molecular biology. Towards that goal, the ultraviolet (UV) photochemistry of phenols, pyrroles, *etc.* have been studied for some time as both simple biomolecule model and as the basic chromophore of many biopolymers.<sup>1–3</sup> Of particular importance was the revelation that these molecules have a weakly bound,  $\pi\sigma^*$  electronic excited state which becomes dissociative at extended O–X or N–X distances (X = H,  $\text{CH}_3$ , *etc.*), eventually intersecting the ground electronic state; a schematic potential energy cut is shown in Fig. 1.<sup>4</sup> Evolution of excited state population along this dissociative coordinate affords an opportunity for rapid, non-radiative transfer to the ground state, a key clue to photoprotection in nature.<sup>4,5</sup> As such, these heteroaromatic systems have attracted considerable interest from spectroscopists (see ref. 1, 2 and references therein). Modifications to these fundamental chromophores

alters their photochemistry and, in addition to increasing complexity, is a powerful tool to explore and explain fundamental behaviour.<sup>6,7</sup> Through such investigations, we ultimately seek to develop a complete, bottom-up understanding of biomolecule photochemistry.

The photochemistry of aniline, the simplest aromatic amine and a model subunit of many biomolecules, has been extensively studied both experimentally and theoretically. The first excited state of aniline is a bound, valence  $^1\pi\pi^*$  state<sup>8,9</sup> (labelled  $^1\pi\pi^*$ , see Fig. 1), photoexcitation to which results in an extended excited state lifetime<sup>9–14</sup> and high fluorescence quantum yield;<sup>15</sup> photoexcitation to this state does not result in N–H bond dissociation.<sup>16,17</sup> In the Franck–Condon (FC) region, the  $^1\pi\sigma^*$  state is largely Rydberg in character (N 3s) and weakly bound<sup>18</sup> while, at elongated N–H bond lengths, the state takes on increasing  $\sigma^*$  character.<sup>1,8,9</sup> From the  $^1\pi\sigma^*$  state, photoexcited population may relax *via* two, competing pathways: dissociation or internal conversion (IC). H-atom loss from the  $^1\pi\sigma^*$  state, due to N–H bond fission, results in high kinetic energy (KE) H-atoms<sup>16</sup> dissociating on a sub-ps timescale.<sup>17</sup> Alternatively, IC to the  $^1\pi\pi^*$  state results in ‘trapped’ population which again persists for an extended excited state lifetime.<sup>10,12,14,19</sup>

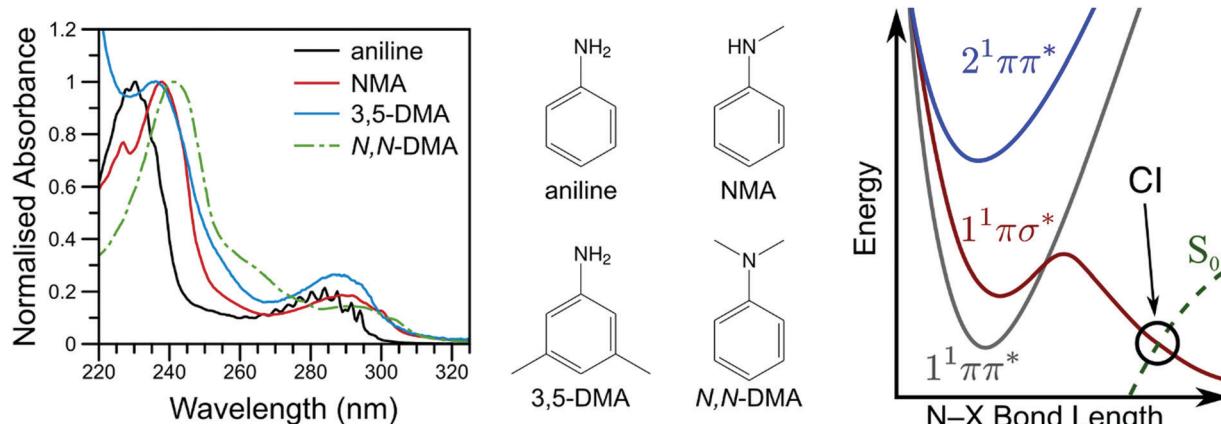

While several computational investigations have found several other low-lying Rydberg excited states in aniline,<sup>8,9,19</sup> these states have received little experimental attention. Indeed, most of the recent experimental work on aniline photodynamics has focused on excitation to a second, higher lying  $^1\pi\pi^*$  state at *ca.* 240 nm. Relaxation from this state, henceforth referred to as  $^2\pi\pi^*$ , has been observed to occur in  $\leq 50$  fs<sup>14</sup> and may decay

† Electronic supplementary information (ESI) available: Description of the new ion detector, example  $\text{Xe}^+$  transient, details of the instrument response function and kinetic models, computational results, and additional experimental results (including TR-PES fit residuals; additional  $\text{H}^+$  TKER;  $m/z = 15$  TKER and transients; and the results from aniline and *N,N*-DMA) may be found. See DOI: 10.1039/c8cp07061j

‡ Present address: Combustion Research Facility, Mail Stop 9055, Sandia National Laboratories, Livermore, CA 94551-0969, USA.

**Fig. 1** The vapour phase spectra of aniline (black line), NMA (red line), 3,5-DMA (blue line), and *N,N*-DMA (green, dot-dashed line) are shown on the left with the corresponding structures shown in the middle panel. A schematic potential energy cut along the aniline N-X reaction coordinate is shown on the right (adapted from ref. 16).

through the aforementioned Rydberg states.<sup>9,20</sup> Though a consensus on the exact decay pathways remains elusive (namely the degree to which  $2^1\pi\pi^*$  state population decays to the  $1^1\pi\sigma^*$  and  $1^1\pi\pi^*$  states, *cf.* ref. 11, 12, 14 and 17), photoexcitation at 240 nm results in high KE H-atoms<sup>16</sup> with an appearance lifetime of 155 fs.<sup>17</sup> Theoretical explorations have found several conical intersections (CIs) between the  $2^1\pi\pi^*$ ,  $1^1\pi\sigma^*$ ,  $1^1\pi\pi^*$ , and  $S_0$  states,<sup>17,21</sup> including an apparent  $2^1\pi\pi^*/1^1\pi\sigma^*/1^1\pi\pi^*$  three-state CI which lies along the minimum energy  $2^1\pi\pi^* \rightarrow S_0$  relaxation pathway.<sup>21</sup> Recent time-resolved photoelectron spectroscopy (TR-PES) by Fielding and co-workers<sup>14</sup> has yielded considerable insight into the  $2^1\pi\pi^*$  decay mechanisms, concluding that photoexcitation at 238 nm populates the  $2^1\pi\pi^*$  which decays almost exclusively to  $S_0$  with some IC to both the  $1^1\pi\sigma^*$  and  $1^1\pi\pi^*$  states *via* the aforementioned multi-state CI.<sup>21</sup> The latter process is clearly revealed through a delayed rise in photoelectron signal due to the sequential population of the  $1^1\pi\pi^*$  state.<sup>11,12</sup>

To help elucidate and explore the relaxation mechanisms of photoexcited aniline, recent TR-PES work by Townsend and co-workers<sup>19,22</sup> has explored the excited state dynamics of *N,N*-dimethylaniline (N,N-DMA) and 3,5-dimethylaniline (3,5-DMA) at 250 and 240 nm. The  $1^1\pi\sigma^*$  state dynamics (as prepared by a 250 nm photon) of both species show remarkably similar behaviour to that of bare aniline,<sup>19</sup> though N-H dissociation appears to be more favourable than direct  $1^1\pi\sigma^* \rightarrow 1^1\pi\pi^*$  IC in 3,5-DMA than in aniline (as inferred by TR-PES results alone). At 240 nm,<sup>22</sup> the ultrafast decay of PES features attributed to the  $2^1\pi\pi^*$  and  $3s/\pi\sigma^*$  states (the latter nomenclature explicitly denoting the mixed N 3s and  $1^1\pi\sigma^*$  nature of the first dissociative excited state), was followed by a rapid rise and slow decay of a low eKE feature attributed to the  $1^1\pi\pi^*$  state. Fits to these results suggested population transfer from the mixed  $3s/\pi\sigma^*$  state to the  $1^1\pi\pi^*$  state in competition with rapid N-X bond fission, as supported by theoretical potential energy cuts (PECs) along the N-X stretch coordinate. Contrary to aniline,<sup>14</sup> no direct evidence for population transfer from the  $2^1\pi\pi^*$  to the lower lying excited states was found; the authors<sup>22</sup> instead

concluded that the observed TR-PES behaviour must be due to population of the  $3s/\pi\sigma^*$  state in the initial photoexcitation which subsequently decays to the lower lying  $1^1\pi\pi^*$  state. Photoelectron angular distributions (PAD) in N,N-DMA also revealed evidence for the initial population of a high-lying, N 3p Rydberg state. Of particular interest from the work on 3,5-DMA and N,N-DMA at 240 nm is the insensitivity of the TR-PES lifetimes to methylation of either the amine or aromatic ring,<sup>22</sup> a surprising find given the large amine geometry changes required to access previously reported CIs.<sup>17,21</sup> To explain these results, Townsend and co-workers<sup>22</sup> echoed previous speculation on the dynamics of aniline<sup>9,20</sup> and suggested that one or more N centred Rydberg states may play a role in the  $2^1\pi\pi^*$  state decay dynamics.

In the present work, we seek to measure the H-atom or CH<sub>3</sub> appearance lifetime from *N*-methylaniline (NMA), *N,N*-DMA, and 3,5-DMA (structures shown in Fig. 1) to explore how simple alkyl substituents affect the dissociation dynamics of aniline. By correlating photofragment appearance lifetimes to excited state decays, as observed *via* TR-PES, we unveil both Rydberg-to-valence and valence-to-Rydberg dynamics in our attempt to develop a more complete picture of the excited state dynamics following photoexcitation to the  $2^1\pi\pi^*$  state. We note that while previous investigations have referred to the mixed  $3s/\pi\sigma^*$  state using a variety of labels, in the present work we use  $1^1\pi\sigma^*$  to refer to the entire state and N 3s to refer to the bound, Rydberg-like local minimum near the Franck-Condon region.

## 2. Experimental

Aniline (Acros Organics, 99.8%), NMA (Aldrich, 98%), *N,N*-DMA (Acros Organics, 99%), and 3,5-DMA (Acros Organics, 98%) were used without further purification. Room temperature vapour phase UV spectra (Fig. 1) were recorded on a Cary 60 spectrophotometer by placing a drop of sample into an empty quartz cuvette.

The experimental apparatus used in the present work has been previously described in detail<sup>23–25</sup> with a summary

provided herein. The molecule of interest is gently heated (35 °C for aniline, NMA, and *N,N*-DMA; 55 °C for 3,5-DMA) and seeded in a molecular beam of ~3 bar He. This gas mixture is then expanded into vacuum by an Even-Lavie pulsed solenoid valve<sup>26</sup> operating at 125 Hz. The molecular beam then passes through a skimmer which separates the source and interaction chambers. Two, temporally delayed, ultraviolet laser beams—the ‘pump’ and ‘probe’—intersect the molecular beam: the former initiates photochemistry while the latter ionises either the photoexcited molecules or the resulting photoproducts. A set of ion optics designed for velocity map ion imaging<sup>27</sup> (VMI) accelerate and focus the photoions or photoelectrons onto a position sensitive detector at the end of a time-of-flight tube such that scattered particles with the same initial velocity are projected onto the same point on the detector. The detector itself consists of two microchannel plates (MCP) coupled to a phosphor screen (Photek VID-240) and imaged by a CCD camera (Basler A-312f) interfaced with a computer. Images are recorded as a function of pump–probe time delay ( $\Delta t$ ), thus producing time-resolved ion image (TR-VMI) or photoelectron spectroscopy (TR-PES) transients. Similarly, the total ion yield (TR-IY) transient of a particular *m/z* value may be measured using a recently installed MCP/metal anode detector that can rotate into the ion flight path, as shown in Section S1 of the ESI.† Ion signal, gated in flight time, is recorded as a function of time delay on an oscilloscope (LeCroy LT372 Waverunner) connected to a computer.

To generate the pump and probe laser beams, the pulsed (~40 fs duration) 800 nm output of a commercial oscillator and regenerative amplifier (Spectra Physics Tsunami and Spitfire XP) operating at 1 kHz is split into three 1 W beams. The first two beams each pass through a tuneable UV optical parametric amplifier (Light Conversion TOPAS-C) to generate the pump and probe pulses of approximately 500 cm<sup>-1</sup> full width at half maximum. The pulses are temporally delayed by a hollow corner gold retroreflector mounted on a motorised delay stage in the pump beam path prior to the TOPAS for a maximum  $\Delta t$  = 1.2 ns. The pump pulses ( $\lambda_{\text{pu}}$ ) were, unless noted otherwise, centred at 238 nm. For TR-VMI, the probe wavelengths were centred at  $\lambda_{\text{pr}} = 333$  or 243 nm to provide 2 + 1 resonance enhanced multiphoton ionisation (REMPI) of the CH<sub>3</sub> or H-atom photofragments, respectively. TR-VMI experiments were also performed with the probe pulse tuned away from the REMPI wavelength while maintaining a similar photon energy (*i.e.*  $\lambda_{\text{pr}} = 245$  nm while monitoring *m/z* = 1 and  $\lambda_{\text{pr}} = 307$  nm while monitoring *m/z* = 15); these conditions will henceforth be described as an off-resonant or non-resonant probe. For TR-PES, the probe pulse wavelength was centred around 305 nm to minimise probe-initiated photodynamics (see Fig. 1), observe dynamics from multiple excited states, and for consistency with previous investigations.<sup>11,12,14,22</sup> For TR-VMI the pump electric field vector was parallel to the plane of the detector (the probe polarisation is irrelevant); for TR-PES the probe pulse electric field vector was also held parallel to the plane of the detector. The laser beams are then focused to intersect the molecular beam within the ion optics. The instrument response function (IRF)

was characterized by the non-resonant TR-IY of Xe<sup>+</sup> at the temporal overlap of the pump and probe pulses ( $\Delta t = 0$ ). The Xe<sup>+</sup> transient was fit to a Gaussian distribution with a typical full width at half maximum (FWHM) of ~100 fs; see Section S2 of the ESI.† Laser power studies were also performed to ensure single photon photochemistry.

Quantum chemical calculations were performed using the GAMESS computational package.<sup>28,29</sup> The geometry of NMA was optimised on the ground electronic states of the neutral (S<sub>0</sub>) and cationic (D<sub>0</sub><sup>+</sup>) surfaces at the CAM-B3LYP<sup>30</sup>/aug-cc-pVDZ<sup>31</sup> level of theory,<sup>32–34</sup> using the restricted Hartree–Fock<sup>35</sup> or restricted open-shell Hartree–Fock<sup>36</sup> methods respectively. Excitation energies and transition dipole moments were calculated from the S<sub>0</sub> equilibrium geometry using the time-dependent version of the above level of theory; excited state character was determined by the component atomic orbital amplitudes and visual inspection of the three dimensional orbitals using the wxMacMolPlt program.<sup>37</sup> Normal mode analysis was used to calculate the zero-point energies of the D<sub>0</sub><sup>+</sup> state at the equilibrium and Franck–Condon (*i.e.* S<sub>0</sub> equilibrium) geometries. All computational results are presented in Section S3 of the ESI.†

### 3. Results and analysis

The velocity map ion images were deconvoluted to produce the one-dimensional velocity distribution using the polar onion peeling (POP) method.<sup>38</sup> The velocity distributions were converted to total kinetic energy release (TKER) distributions by calibrating to the known dissociation energies of HBr<sup>39</sup> and an appropriate mass weighting factor:

$$\text{TKER} = (m_{\text{AB}}/m_{\text{B}})\text{KE}_{\text{A}} \quad (1)$$

where  $m_{\text{AB}}$  is the mass of the parent molecule,  $m_{\text{B}}$  is the mass of the counter-fragment, and KE<sub>A</sub> is the kinetic energy of the measured photofragment (*i.e.* CH<sub>3</sub> or H-atom). A TKER distribution reveals information about energy partitioning during a photodissociation event by the following relationship:

$$hc/\lambda_{\text{pu}} + E_0 - \text{BDE(A-B)} = \text{TKER} + E_{\text{int}} \quad (2)$$

where  $hc/\lambda_{\text{pu}}$  is the pump photon energy,  $E_0$  is the energy of the molecule prior to photoexcitation, BDE(A–B) is the asymptotic A–B bond dissociation energy, and  $E_{\text{int}}$  is the internal energy of the photofragments. In the limit of cold molecules and photoproducts (*i.e.*  $E_0 = E_{\text{int}} = 0$ ) the maximum TKER is given by  $\text{TKER}_{\text{max}} = hc/\lambda_{\text{pu}} - \text{BDE(A-B)}$ .

POP deconvolution also produces the one-dimensional angular distributions of the photofragments. These are then fit to the known functional form<sup>40</sup> to yield the anisotropy parameter  $\beta$  which, for the rapid fragmentation of polyatomic molecules, provides a measure of the alignment of the laser electric field vector and the dissociating bond. In the limiting cases,  $\beta$  may take a value of 2 or -1 corresponding to a parallel or perpendicular dissociation event, respectively; an isotropic distribution will result in  $\beta = 0$ .

Similar to the photofragment analysis, the photoelectron images were processed *via* POP deconvolution. The resulting

photoelectron velocity distributions are converted to electron kinetic energy (eKE) by calibrating to the 2 + 1 REMPI of Xe.<sup>41</sup> Similar to eqn (2), the photoelectron spectra unveil the excited state dynamics by:

$$hc/\lambda_{\text{pu}} + hc/\lambda_{\text{pr}} + E_0 - \text{IE} = \text{eKE} + E_{\text{int}}^+ \quad (3)$$

where  $hc/\lambda_{\text{pr}}$  is the probe photon energy, IE is the ionisation energy, and  $E_{\text{int}}^+$  is the internal energy of the cation (which includes information about the excited state populations prior to ionisation). Again, POP deconvolution will fit the PAD to the known functional form,<sup>40</sup> resulting in the anisotropy parameters  $\beta_2$  and  $\beta_4$ .

The two-dimensional TKER transients are then analysed by following the behaviour of a particular feature over  $\Delta t$  and fitting with a one-dimensional, parallel dynamics model consisting of a sum of exponential decay and rise functions convoluted with a Gaussian IRF; see Section S2 of the ESI<sup>†</sup> for further details of the kinetic model. Non-resonant production of  $\text{H}^+$  (*i.e.* dissociative ionisation) was similarly modelled using a sum of exponential decays convoluted with a Gaussian IRF. Conversely, the two-dimensional TR-PES results are analysed using global lifetime analysis<sup>42,43</sup> to monitor changes to the entire spectrum as a function of time delay using the Glotaran software package.<sup>44</sup> All TR-PES results were fit with two exponential decay models: one assuming sequential dynamics and, for comparison with previously reported results,<sup>11,12,14,22</sup> a model assuming parallel (branched) dynamics. The evolution associated spectra (EAS) that are obtained from the sequential dynamics fit to the experimental data highlight the spectral feature changes associated with each step in the sequential model while, for the parallel model, the extracted decay associated spectra (DAS) are the wavelength dependent amplitudes for each exponential decay lifetime.<sup>42</sup> Further details pertaining to how EAS and DAS are extracted from the experimental data using the aforementioned kinetic models, as well as details regarding the interpretation of these spectra, may be found in ref. 42–44. TR-PES lifetimes will be reported as  $\tau_n$ , where increasing  $n$  denotes increasing lifetime. Similarly, H-atom appearance lifetimes will be reported as  $\tau_n^{\text{H}}$ . Photoelectron

anisotropy parameters will be reported as  $\beta_2$  and  $\beta_4$  while a photofragment anisotropy parameter will be given as  $\beta_A$  where A indicates the dissociated fragment (*e.g.*  $\beta_{\text{H}}$  for N-H bond fission).

### (a) N-Methylaniline

**(i) TR-PES.** At  $\lambda_{\text{pu}} = 238$  nm, the NMA TR-PES results (shown in Fig. 2b and Section S4.1 of the ESI<sup>†</sup>) bear a strong resemblance to previous aniline and substituted aniline results.<sup>11,12,14,22</sup> Near  $\Delta t = 0$ , a high eKE feature around  $10\ 000\text{--}12\ 000\ \text{cm}^{-1}$ , largely attributable to ionisation from the  $2^1\pi\pi^*$  state, is initially populated. Next, the sharper feature at  $\sim 8000\ \text{cm}^{-1}$  is indicative of ionisation out of a Rydberg state and is consistent with ionisation out of the N 3s state observed in other aniline derivatives.<sup>11,12,14,22</sup> Finally, a broad, low eKE feature is rapidly populated before narrowing and decaying (see Fig. S4 in the ESI<sup>†</sup>). This low eKE feature has previously been assigned to ionisation from the  $1^1\pi\pi^*$  state, though ionisation of any long-lived  $2^1\pi\pi^*$  state population to the first electronic excited state of the cation ( $\text{D}_1^+$ ) may contribute to the TR-PES signal around  $4000\ \text{cm}^{-1}$ .<sup>45</sup> Similar to aniline,<sup>11,12</sup> a clear temporal delay of *ca.* 50 fs is evident between the initial rise of the high eKE feature ( $10\ 000\text{--}12\ 000\ \text{cm}^{-1}$ ) and all lower eKE features. Such an offset suggests sequential decay behaviour in NMA and, as such, results from the TR-PES fits using a sequential kinetic model will be presented here in the manuscript while the results of a parallel dynamics model fit are presented in the ESI.<sup>†</sup> Overall, a total of five lifetimes are needed to satisfactorily fit these data; time constants are given in Table 1, EAS for each time constant are shown in Fig. 3, and DAS and all fit residuals may be found in Fig. S4 of the ESI.<sup>†</sup>

The  $\beta_2$  values as a function of eKE near  $\Delta t = 0$  are also shown in Fig. 3. Of particular interest are the two modest rises in  $\beta_2$  at  $\sim 8000$  and  $\sim 13\ 000\ \text{cm}^{-1}$ . As has been previously outlined,<sup>15</sup> such  $\beta_2$  features are typically due to ionisation from Rydberg orbitals with well-defined energies and orbital angular momenta; the  $\beta_2$  feature at  $8000\ \text{cm}^{-1}$  is consistent with the assignment of the corresponding TR-PES feature to the N 3s state. The previous TR-PES investigation of *N,N*-DMA<sup>22</sup> found a sharp rise in both  $\beta_2$

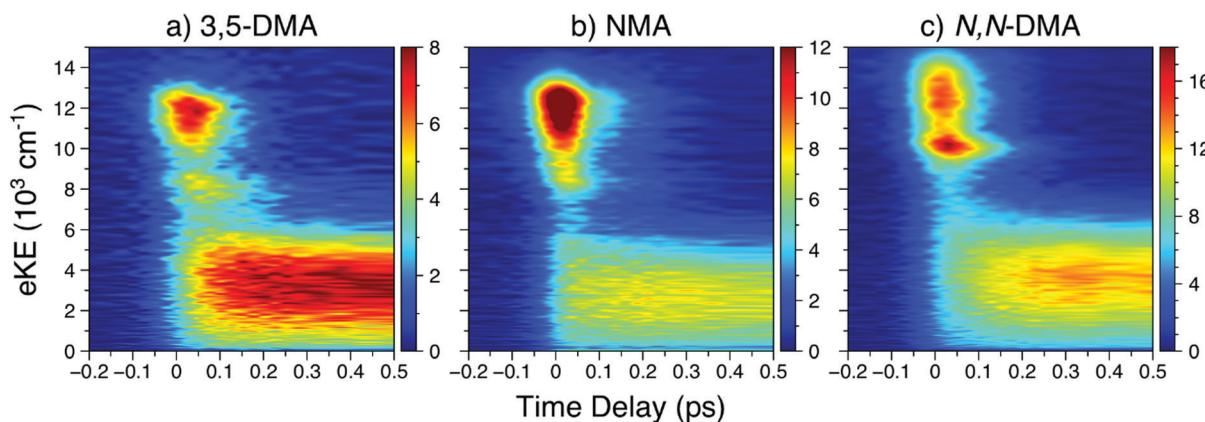

Fig. 2 In order of increasing amine substitution, the short time delay TR-PES results at  $\lambda_{\text{pu}} = 238$  nm and  $\lambda_{\text{pr}} = 305$  nm from (a) 3,5-DMA, (b) NMA, and (c) *N,N*-DMA.

<sup>a</sup> Ref. 14. <sup>b</sup> Ref. 17.

**Fig. 3** TR-PES results for NMA at 238 nm with (a) EAS and (b) the photoelectron signal (black line) and  $\beta_2$  values (blue circles) near  $\Delta t = 0$ . The short-time TR-PES transient for NMA may be found in Fig. 2; a full transient is shown in Fig. S4 of the ESI.† The EAS have been smoothed using a 3 point moving average; the  $\tau_1$  EAS intensity has been scaled for visual clarity.

and  $\beta_4$  at the highest eKE, which the authors attributed to ionisation from a high lying N 3p state. In NMA, the  $\beta_2$  feature at  $\sim 13\,000\text{ cm}^{-1}$  may also be due to ionisation from a N 3p state which yields only minimal TR-PES intensity. Unfortunately, large oscillations in the  $\beta_4$  distribution at these high eKE, shown in Fig. S5 of the ESI,† limit our confidence in this anisotropy parameter at the highest eKE and we cannot firmly assign the  $\sim 13\,000\text{ cm}^{-1}$   $\beta_2$  feature to a N 3p state. Furthermore, the excited state calculations on NMA, presented in Section S3.1 of the ESI† and discussed below, reveal two candidate Rydberg states lying near the  $2^1\pi\pi^*$  state energy. Thus, while the highest eKE edge of the  $2^1\pi\pi^*$  TR-PES feature contains information about the dynamical behaviour of a Rydberg state, it is at present unclear from which Rydberg state these photoelectrons originate, whether the Rydberg state is populated in the initial

photoexcitation, and how population of a Rydberg state affects the photodynamics of NMA.

Using the quantum defect value of  $\delta = 0.912$  from the aniline N 3s state<sup>18</sup> as a qualitative estimate for NMA (as methylation of the amine will shift the value of  $\delta$ ), we can estimate the energy of the 3s state in NMA using

$$E_{3s} = \text{IE} - \frac{R}{(n - \delta)^2} \quad (4)$$

where  $R$  is the Rydberg constant and  $n$  is the principal quantum number of the state. From eqn (4), the N 3s state in NMA should appear at  $\sim 34\,100\text{ cm}^{-1}$  ( $\sim 293\text{ nm}$ ).<sup>45</sup> Although the absorption spectrum of NMA in Fig. 1 does show additional intensity near 290 nm, there is not an obvious, additional feature when compared to aniline. Furthermore, similar spectral shifts are observed for the other substituted anilines suggesting that this behaviour is due to methyl group stabilisation of the  $1^1\pi\pi^*$  state. Examining eqn (3) and (4) we may also estimate the eKE at which the N 3s state will appear using  $\text{eKE} = E_{3s} + hc/\lambda_{\text{pr}} - \text{IE}$ . The resulting estimated eKE value of  $7600\text{ cm}^{-1}$  is in remarkably good agreement with the experimental photoelectron spectra, further supporting the assignment of the  $\sim 8000\text{ cm}^{-1}$  TR-PES feature to the N 3s state in NMA.

**(ii) Photodissociation.** A strong  $\text{H}^+$  signal appears centred at a TKER of  $\sim 6000\text{ cm}^{-1}$  (see Fig. 4). The  $\text{H}^+$  signal promptly appears ( $< 2\text{ ps}$ ) and, as time delay is increased, shows a marked increase in intensity along the lower KE side. The TKER spectrum at  $\Delta t = 1\text{ ps}$  shows additional signal at the high TKER edge due to time-dependent, non-resonant dissociative ionisation; an example TKER acquired with a non-resonant probe at  $\Delta t = 1\text{ ps}$  is also shown in Fig. 4. Using a published N-H bond dissociation energy for NMA,<sup>46</sup> a  $\text{TKER}_{\text{max}} = 12\,376\text{ cm}^{-1}$  is in relatively good agreement with the high TKER edge of the spectra, though the same publication reports an aniline BDE(N-H) approximately  $1400\text{ cm}^{-1}$  smaller than Ashfold and co-workers.<sup>16</sup> As also shown in Fig. 4, non-resonant production of  $\text{H}^+$  (independently detected using a non-resonant probe) contributes a small amount to the TKER signal at all kinetic energies and  $\Delta t$ . Fig. S6 of the ESI† reveals a nearly constant  $\beta_{\text{H}} \approx -0.3$  across the entire main feature of the TKER spectrum; this value of  $\beta_{\text{H}}$  is also conserved at all values of  $\Delta t$ . This value of  $\beta_{\text{H}}$  is consistent with a perpendicular dissociation occurring before significant rotational randomisation of the

Fig. 4 (a) H<sup>+</sup> TKER spectra at several time delays and  $\lambda_{pu} = 238$  nm; spectra have been smoothed using a 10 point moving average. The expected TKER<sub>max</sub> at this wavelength is shown as a purple arrow.<sup>46</sup> The dashed, grey line shows an example H<sup>+</sup> TKER acquired with an off-resonant probe. (b) H<sup>+</sup> transient for the main TKER feature at 238 nm (black circles) and the corresponding fit (black line). The two rises are due to the production of neutral H-atoms with appearance lifetimes assigned to each rise. The red circles are probe or multiphoton initiated H-atom loss dynamics and, for simplicity, have been excluded from the overall fit. Inset: The time-dependent, dissociative ionisation production of H<sup>+</sup> is also shown (blue diamonds) along with the accompanying fit (blue line). The exponential decay lifetime from the inset transient ( $\tau_{decay}$ ) was included in the fit to the main transient; see eqn (S1) (ESI†) for further details.

photoexcited NMA. Due to rotational randomisation, we would expect the H<sup>+</sup> appearing at later time delays to have an isotropic ( $\beta_H = 0$ ) distribution. The preservation of  $\beta_H \approx -0.3$  at all time delays is likely due to the dominance of the initial, ultrafast H-atom loss mechanism to the total TKER spectral intensity. Thus, the absence of any significant change with increasing time delay is unsurprising given the small TKER contribution from H-atoms dissociating with lifetime  $\tau_2^H$  (after rotational randomisation). The similarity of the TKER spectra to those taken at  $\lambda_{pu} = 252$  nm (see Fig. S7 of the ESI†) where dissociation occurs above the  $1^1\pi\sigma^*$  barrier in aniline,<sup>7</sup> suggests that the N-H bond fission is occurring from the same excited state (namely the  $1^1\pi\sigma^*$  state) for both pump wavelengths.

Integration of the main TKER feature (*ca.* 2500–8000 cm<sup>-1</sup>) yields the transient also shown in Fig. 4. These transients show a clear, ultrafast rise in H<sup>+</sup> intensity followed by an additional rise of *ca.* 100 ps. To account for the time-dependent dissociative ionisation captured in the integration of the main TKER feature, a separate H<sup>+</sup> transient was produced by integrating

TKER  $> 11\,000$  cm<sup>-1</sup> (Fig. 4b inset) and was fit using the exponential decay model described in Section S2.3 of the ESI.† The resulting H<sup>+</sup> decay lifetime was included in the fit to the transient at lower TKER (*i.e.* Fig. 4b), yielding the two neutral H-atom appearance lifetimes given in Table 1. Further details on fitting and kinetic models may be found in Section S2 of the ESI.† It is interesting to note that the H-atom appearance lifetimes are similar to the TR-PES  $\tau_2$  and  $\tau_4$ .

CH<sub>3</sub> loss was also investigated at  $\lambda_{pu} = 238$  nm; example transients and TKER distributions at *m/z* = 15 may be found in Fig. S7 of the ESI.† TKER distributions at several time delays show no features other than a sharp rise in intensity near zero kinetic energy, consistent with dissociative ionisation.<sup>47</sup> The transients largely show a decay in signal, again due to dissociative ionisation of photoexcited NMA to *m/z* = 15. The transient appears to plateau at large  $\Delta t$ , in agreement with the behaviour observed in the TR-PES results at low eKE. The *m/z* = 15 transient also reveals an apparent exponential rise (with an estimated lifetime of 2 ps) superimposed on the overall decay that is not observed with an off-resonant probe, suggesting that this rise reports on the production of neutral CH<sub>3</sub>. However, a pump laser power study revealed that these neutral CH<sub>3</sub> photofragments appear to be due to multiphoton pump photoexcitation, likely to a region of a cationic potential energy surface which, with a few picosecond lifetime, undergoes dissociation along the N-CH<sub>3</sub> coordinate. Attempts to investigate single pump photon production of CH<sub>3</sub> (*i.e.* by decreasing the pump laser power) were unsuccessful, as no time-dependent signal could be observed. Thus, no evidence was found for single pump photon initiated photodissociation to produce neutral CH<sub>3</sub> photoproducts from NMA.

(iii)  $\lambda_{pu} = 245$  nm. While the highest lying Rydberg feature observed in Fig. 3b appears  $\sim 1500$  cm<sup>-1</sup> above the centre of the  $2^1\pi\pi^*$  TR-PES feature, quantum chemical calculations predict two possible Rydberg states lying near the  $2^1\pi\pi^*$  state energy (see Section S3.1 of the ESI†). Indeed, other theoretical investigations of aniline-based systems have predicted several Rydberg orbitals in close proximity to the  $2^1\pi\pi^*$  state.<sup>8,9,19,22</sup> To help determine which candidate Rydberg state is excited, and explore the effects of said state on the observed NMA photodynamics, TR-PES and H-atom transients were also acquired at  $\lambda_{pu} = 245$  nm (shown in Fig. S9–S11 of the ESI†). At this pump wavelength, the high KE  $\beta_2$  distribution near  $\Delta t = 0$  no longer shows a slight rise, the highest eKE portion of the  $\beta_2$  distribution instead drops towards zero within the  $2^1\pi\pi^*$  feature. Thus, following photoexcitation at  $\lambda_{pu} = 245$  nm, the absence of a second rise in  $\beta_2$  at the highest eKE (*i.e.* eKE  $\geq 10\,000$  cm<sup>-1</sup>) is consistent with population of a Rydberg state lying above the  $2^1\pi\pi^*$  state at  $\lambda_{pu} = 238$  nm. Apart from the change in  $\beta_2$  behaviour, the TR-PES and H-atom results are very similar to those recorded at 238 nm, though with a noticeable increase in both  $\tau_4$  and  $\tau_2^H$ ; all time constants are given in Table 1. We note that while  $\tau_1^H$  also increases with increasing pump wavelength, the time-dependent dissociative ionisation at both wavelengths reduces our confidence in the first H-atom appearance lifetime.

### (b) Aniline, 3,5-dimethylaniline, and *N,N*-dimethylaniline

The short time TR-PES results from 3,5-DMA and *N,N*-DMA are shown in Fig. 2; full results are in Section S4.2 of the ESI† and lifetimes are given in Table 1. Similar to NMA, TR-PES results from 3,5-DMA and *N,N*-DMA reveal five decay lifetimes. While the previous study by Townsend and co-workers<sup>22</sup> used four decay time constants, the new time constant is only apparent at  $\Delta t > 100$  ps (larger time delays than the previous investigation). The additional time constant results in a slight contraction of the  $\tau_2$  and  $\tau_3$  lifetimes relative to their published values.<sup>22</sup> Close examination of the *N,N*-DMA results shown in Fig. 2 show slightly different behaviour of the N 3s feature (the sharp rise in TR-PES intensity near  $10\,000\text{ cm}^{-1}$  and  $\Delta t = 0$ ) from the other two anilines studied herein: the feature has shifted to a higher eKE and now appears concurrently with the  $2^1\pi\pi^*$  state rather than at a later time-delay.

The H-atom TKER spectrum from aniline at  $\lambda_{\text{pu}} = 238$  nm was re-investigated to explicitly verify only one, sub-ns N–H bond dissociation process.<sup>17</sup> As shown in Fig. S12 of the ESI,† TKER spectra at  $\Delta t = 1$  ps and 1.2 ns are identical; the  $\text{H}^+$  transient was not re-investigated. Similar to aniline,  $\text{H}^+$  TKER spectra from 3,5-DMA (shown in Fig. 5) taken at  $\Delta t = 1$  ps and 1.2 ns show no appreciable differences; both feature a clear peak at  $\sim 6000\text{ cm}^{-1}$  which sits upon a structureless dissociative ionisation ‘baseline.’ Integration of the main TKER feature results in a  $\text{H}^+$  transient which reveals rapid H-atom loss with an appearance lifetime of  $\sim 70$  fs (also shown in Fig. 5).

To complement the previous TR-PES investigation of *N,N*-DMA,<sup>22</sup> which speculated that rapid N–CH<sub>3</sub> bond fission was occurring, CH<sub>3</sub> loss from *N,N*-DMA was investigated in the present work; the results may be found in Fig. S15 of the ESI.†

However, the TKER distributions and  $m/z = 15$  transient are strikingly similar to the results from NMA, suggesting that the production of  $m/z = 15$  photoions is dominated by dissociative ionisation of the parent cation. We note however that, unlike NMA, a pump laser power study suggests that the rise in the *N,N*-DMA  $m/z = 15$  transient is from single pump photon photoexcitation. Given the absence of a TKER feature obviously attributable to neutral N–CH<sub>3</sub> bond fission, we speculate that the rise in CH<sub>3</sub><sup>+</sup> intensity is due to neutral excited state evolution resulting in enhanced Franck–Condon factors for dissociative ionisation. Thus, while we cannot rule out CH<sub>3</sub> loss from *N,N*-DMA, there is no clear evidence for single photon initiated N–CH<sub>3</sub> bond dissociation.

## 4. Discussion

The above results raise several pertinent questions regarding the excited state dynamics of aniline-based systems. For the present discussion, we will focus on the nature of the initial photoexcitation, the excited state population leading to the second H-atom appearance in NMA, and the absence of CH<sub>3</sub> loss from NMA and *N,N*-DMA in an attempt to synthesise a global relaxation mechanism and elucidate the structure–dynamics relationships underpinning these results. Before the discussion of an excited state decay mechanism, two important points must be made. First, the following discussion will focus on the relaxation of the  $2^1\pi\pi^*$  state to the other electronic excited states. Previous investigations have either found no evidence for  $2^1\pi\pi^*$  state population transfer to the  $1^1\pi\sigma^*$  or  $1^1\pi\pi^*$  states<sup>22</sup> or concluded that a barrierless  $2^1\pi\pi^* \rightarrow S_0$  excited state pathway was dominant.<sup>11,12,14</sup> While we are unable to directly probe repopulation of  $S_0$ , the former conclusion (exclusive  $2^1\pi\pi^* \rightarrow S_0$  population transfer) is in apparent conflict with our present results. As a quantitative determination of the excited state branching ratios is difficult,<sup>48</sup> we instead accept the second conclusion that relaxation of the  $2^1\pi\pi^*$  state to the lower lying singlet excited states may only be a minor decay pathway. However, the importance of each pathway remains a key question in the photodynamics of these aniline-based systems; excited state trajectory calculations to elucidate the initial, ultrafast branching ratios would be of considerable interest. The second point is a caveat regarding TR-PES assignments: the strong similarity of TR-PES results across molecules does not guarantee that the NMA assignments are transferrable to other anilines. However, as the H-atom results provide compelling evidence for overlapping TR-PES assignments in NMA and 3,5-DMA, we follow previous examples<sup>19,22</sup> and will assume (unless otherwise noted) that the global dynamics of these anilines may be discussed across species. As a final aside, Fig. 6 shows a proposed decay mechanism along a schematic cut through the potential energy surfaces important to the dynamics. This mechanism is presented first as a reference point and will be explored throughout the following text.

### (a) Photoexcitation

The first, and perhaps most fundamental, task is to determine which excited states the pump photon populates. From Fig. 1,

Fig. 5 H<sup>+</sup> transient from 3,5-DMA at  $\lambda_{\text{pu}} = 238$  nm; data are shown as open circles while the black line is the fit. Inset: Example TKER spectra at  $\lambda_{\text{pu}} = 238$  nm; the spectra have been smoothed using a 30 point moving average. Both the transient and TKER reveal that 3,5-DMA has only one ultrafast (i.e. within 1.2 ns) H-atom loss mechanism. The peak at  $\Delta t = 0$  is due to multiphoton dissociative ionisation within the cross-correlation of the two laser pulses.

**Fig. 6** Schematic diagram showing the proposed  $2^1\pi\pi^*$  de-excitation pathways. Photoexcitation (purple arrow) to the  $2^1\pi\pi^*$  state undergoes IC to the N 3p state, which couples through the N 3s region of the  $1^1\pi\sigma^*$  state (a) where it immediately scatters to dissociate. Simultaneously, the  $2^1\pi\pi^*$  state undergoes IC onto  $1^1\pi\pi^*$  (b) and undergoes IVR. From the  $1^1\pi\pi^*$  state, population can either sample the  $1^1\pi\sigma^*$  state via a Cl<sup>17,21</sup> and dissociate (c), undergo IC to the ground state (d), or fluoresce (e and blue arrow). Dashed green arrows indicate dissociative mechanisms while solid green arrows represent non-dissociative mechanisms. In the case of *N,N*-DMA, the initial photoexcitation may be to both the  $2^1\pi\pi^*$  and N 3s states. Not shown are any possible direct  $2^1\pi\pi^* \rightarrow 1^1\pi\sigma^*$  population transfer or intersystem crossing(s) to the triplet manifold.

it is clear that photoexcitation at 238 nm will principally populate the strongly absorbing  $2^1\pi\pi^*$  state. However, as previous work has concluded that other excited states must also be photoprepared in the dimethyl anilines,<sup>22</sup> we explore that possibility herein. The DAS for each species, particularly 3,5-DMA, show clear evidence for delayed population of the lower-lying excited states; see Fig. S4, S9, S13, and S14 in the ESI.† For NMA and 3,5-DMA, the N 3s and  $1^1\pi\pi^*$  TR-PES features show a clear time delay offset from the appearance of the  $2^1\pi\pi^*$  feature (see further discussion below) and we thus conclude that the corresponding states are not populated by the pump laser pulse.

Based on the PAD results from NMA at 238 nm, and supported by the previous investigation of *N,N*-DMA,<sup>22</sup> a high-lying Rydberg orbital is populated at or near  $\Delta t = 0$  and the initial photoexcitation may thus populate both the  $2^1\pi\pi^*$  and a nearby Rydberg state (though not the N 3s state, see above). While direct excitation to a Rydberg state is generally less favourable than a valence-to-valence transition, as evidenced by the weak oscillator strengths calculated for other anilines,<sup>9,22</sup> the oscillator strengths for the two Rydberg orbitals closest to the  $2^1\pi\pi^*$  state in NMA are only a factor of two and four smaller than for excitation to the  $2^1\pi\pi^*$  state (see Table S1 in the ESI†). At  $\lambda_{pu} = 245$  nm, the absence of the highest eKE Rydberg-like  $\beta_2$  feature suggests that the 238 nm pump photon populates a Rydberg state lying above the  $2^1\pi\pi^*$  state energy. The carbon-centred Rydberg state, described in Table S1 in the ESI† is the most likely source of the highest eKE  $\beta_2$  feature as this state's energy – calculated to lie  $\sim 400$  cm<sup>-1</sup> above the  $2^1\pi\pi^*$  state – is within

the pump laser bandwidth of the  $2^1\pi\pi^*$  state. In contrast, the energy difference (from both electronic structure and quantum defect calculations<sup>45</sup>) between the  $2^1\pi\pi^*$  and lower-lying N 3p states is greater than the pump laser bandwidth. Thus, the results from NMA at  $\lambda_{pu} = 238$  nm support the photoexcitation of a high-lying, carbon-centred Rydberg orbital, though the otherwise strong similarity of the NMA TR-PES and H-atom temporal behaviour at both pump wavelengths suggests that this Rydberg state does not play a significant role in the observed photodynamics.

### (b) Initial TR-PES and lifetime assignments

The TR-PES results from NMA reveal similar dynamics to the overall behaviour previously observed in aniline, *N,N*-DMA, and 3,5-DMA.<sup>11,12,14,22</sup> The length of the newly observed ns lifetime ( $\tau_5$ ) suggests that this process is the fluorescent decay of the  $1^1\pi\pi^*$  state<sup>15</sup> and supports the assignment of the low eKE TR-PES feature to this state; measurement of the fluorescence lifetimes and quantum yields following photoexcitation to the higher lying states of aniline would help confirm the assignment of  $\tau_5$  and add insight to the other decay dynamics. As mentioned above, it is possible that  $2^1\pi\pi^*$  state dynamics are appearing in the low eKE feature. Indeed, excited state dynamics calculations of aniline using a model Hamiltonian suggested that the  $2^1\pi\pi^*$  state lives for  $> 300$  fs.<sup>9</sup> However, given that we can neither support nor eliminate this possibility, we accept previous assignments<sup>11–14,19,22</sup> that the low eKE TR-PES feature itself is principally due to ionisation from the  $1^1\pi\pi^*$  state.

While  $\tau_1$  is still clearly dominated by decay of the  $2^1\pi\pi^*$  TR-PES feature within the IRF, some of the  $2^1\pi\pi^*$  feature persists to decay along with the N 3s state ( $\tau_2$ ). The  $\tau_2$  EAS also involves population of the lowest eKE feature, suggesting a sequential decay mechanism from the  $2^1\pi\pi^*$  or N 3s states. Indeed, the  $\tau_2$  DAS for all species (see Fig. S4, S9, S13, and S14 in the ESI†) show negative amplitude for the lowest TR-PES feature, indicative of population transfer from the higher lying states. Such a sequential mechanism is supported by the delayed rise of the  $1^1\pi\pi^*$  TR-PES feature, as shown in Fig. 2. As discussed below, the time constants of  $\tau_2$  and  $\tau_4$  are in good agreement with the H-atom appearance times in NMA and (for  $\tau_2$  only) 3,5-DMA. It thus seems reasonable to conclude that these time constants are related to population sampling the  $1^1\pi\sigma^*$  state.

The dynamics described by  $\tau_3$  are not simple to assign, as altering the methyl substitution and pump wavelength both substantially change the best-fit value of this lifetime (see Table 1). For 3,5-DMA and *N,N*-DMA,<sup>19,22</sup> the equivalents of  $\tau_3$  and  $\tau_4$  have been assigned to IVR on and decay of the  $1^1\pi\pi^*$  state. The assignment of  $\tau_4$  to  $1^1\pi\pi^*$  relaxation is reasonable, further analysis of this lifetime may be found along with the second H-atom loss discussion below. While energy redistribution seems to be supported by the negative DAS amplitudes associated with  $\tau_3$  (see Fig. S14 of the ESI† for a clear example), the assignment of  $\tau_3$  to IVR is at odds with the increased lifetime observed upon methyl substitution (see Table 1).

The possibility of a  $N\ 3s \rightarrow 1^1\pi\pi^*$  population transfer was a proposed explanation for the low eKE PAD change on a similar timescale in *N,N*-DMA and 3,5-DMA,<sup>22</sup> however we find no evidence for the  $N\ 3s$  TR-PES feature on this timescale. The equivalent aniline lifetime to  $\tau_3$  has been assigned to population dynamics on the  $1^1\pi\sigma^*$  state located away from the Franck-Condon region.<sup>14</sup> Such dynamics may contribute to the lowest eKE TR-PES signal, as previous work on alkyl substituted amines has revealed a broad, structureless  $\sigma^*$  feature at low eKE (see, for example, ref. 22 and 49). Indeed, the second H-atom appearance from NMA suggests that the  $1^1\pi\sigma^*$  state must be populated or remain accessible for several 10s of ps, though we attribute that dissociative population to  $1^1\pi\pi^* \rightarrow 1^1\pi\sigma^*$  IC with lifetime  $\tau_4$  (see below). Diffusion of the excited state wavepacket, particularly along a relatively flat potential energy surface, has been observed to occur with a  $\sim 1$  ps lifetime in the related system 2-hydroxypyridine<sup>50</sup> and may also contribute to the present TR-PES changes described by  $\tau_3$ . Thus, while dynamics on both the  $1^1\pi\pi^*$  and  $1^1\pi\sigma^*$  states are possible, and some form of population redistribution must be occurring, the excited state processes described by  $\tau_3$  may be both highly mixed and strongly dependent upon molecular structure. As such, we are hesitant to assign one mechanism across all aniline species to the changes described by  $\tau_3$ .

### (c) The $N\ 3s$ feature

The energetic and temporal behaviour of the  $N\ 3s$  TR-PES feature is worth discussing in some greater detail. While previous TR-PES experiments have observed this Rydberg state,<sup>11–14,19,22</sup> the feature has not received a close, comparative analysis as a function of chemical modification. First, as seen in Fig. 2 and previous investigations,<sup>11–14,19,22</sup> the  $N\ 3s$  feature (in aniline, 3,5-DMA, and NMA) is separated from the low eKE feature by  $\sim 5000$ – $6000$   $\text{cm}^{-1}$ . As the separation of the  $1^1\pi\pi^*$  and  $1^1\pi\sigma^*$  states in aniline is only  $\sim 3700$   $\text{cm}^{-1}$ ,<sup>18</sup> the remaining eKE difference is likely due to the projection of the vibrationally excited  $1^1\pi\pi^*$  state onto the vibrationally excited  $D_0^+$  state while the  $N\ 3s$  state projects closer to the  $\nu = 0$  level of the ground cationic state (see Section S3.3 of the ESI†). The  $3s$  feature clearly shifts to higher eKE with increasing alkylation of the amine, possibly due to the Rydberg state becoming more ‘atom-like’ (less dependent upon molecular geometry) and able to project closer to the vibrationally cold, electronic ground state of the cation.

There is also a clear shift in the temporal behaviour of the  $N\ 3s$  feature with increasing amine alkylation: the rise in 3,5-DMA is noticeably offset to later  $\Delta t$  from the  $2^1\pi\pi^*$  onset, while in *N,N*-DMA the two features seem to appear simultaneously. The appearance of the  $N\ 3s$  peak in NMA is less clear due to overlap with the  $2^1\pi\pi^*$  peak along the energy axis, though a slight shift to later time delays with decreasing eKE is evident. In the case of *N,N*-DMA, the  $1^1\pi\sigma^*$  absorption itself may have shifted to higher energies and may therefore be prepared by the initial photoexcitation, however this interpretation is inconsistent with both published electronic structure calculations<sup>22</sup> and expectations using quantum defect arguments.<sup>45</sup> As the  $N\ 3s$

feature appears most intense after the peak intensity of the  $2^1\pi\pi^*$  feature, we will continue with our conclusion that for all of the anilines studied herein the  $N\ 3s$  state is not populated by the initial photoexcitation.

### (d) Decay of $N\ 3s$ and rapid H-atom loss

Due to the strong similarity in TKER distributions and H-atom appearance lifetimes, the first H-atom appearance in NMA and 3,5-DMA appears to be dissociation along a similar  $1^1\pi\sigma^*$  state as in aniline.<sup>17</sup> While photoexcitation to the  $N\ 3p$ ,  $2^1\pi\pi^*$ , or carbon-centred Rydberg states could reproduce the observed H-atom angular distribution of  $\beta_H \approx -0.3$  from NMA photo-dissociation (see Section S3.2 of the ESI†), as discussed above direct photoexcitation to the  $N\ 3p$  state seems unlikely. Furthermore, the similarity of the NMA H-atom results at  $\lambda_{pu} = 238$  and 245 nm (*i.e.* with and without the carbon-centred Rydberg state) suggests that the observed H-atom signal is due to photoexcitation of the  $2^1\pi\pi^*$  state. Thus the observed H-atom anisotropy, along with the delayed appearance of the  $N\ 3s$  TR-PES feature, reinforces the conclusion that H-atom loss from NMA and 3,5-DMA is due to rapid population transfer from the  $2^1\pi\pi^*$  state onto the dissociative  $1^1\pi\sigma^*$  state.

In NMA, the elongation of  $\tau_1^H$  (relative to aniline) is likely due to the heavier  $\text{CH}_3$  group retarding any amine geometry change prior to or during the dissociation. One such motion was proposed<sup>21</sup> as a three state  $2^1\pi\pi^*/1^1\pi\sigma^*/1^1\pi\pi^*$  CI where the  $\text{H}_2\text{N}-\text{C}$  bond is approximately perpendicular to the plane of the ring. While motion through the three state CI would explain the increase in  $\tau_1^H$  for NMA, such a motion should also retard the population of the lower lying states. However, the appearance  $\Delta t$  of the lower lying TR-PES features appears to remain constant upon methylation of the amine, *e.g.* comparing 3,5-DMA (Fig. 2a) to NMA (Fig. 2b). The increased  $\tau_1^H$  in NMA is thus most likely due to the dissociation coordinate involving larger changes to the amine geometry (such as planarisation towards the anilino radical equilibrium geometry<sup>16</sup>) in addition to the N–H stretch.

Thus, either the decay of the  $2^1\pi\pi^*$  state is due to the aforementioned CI<sup>21</sup> with the expected changes to the  $2^1\pi\pi^*$  and  $1^1\pi\sigma^*$  lifetimes obscured by the IRF or population transfers to the  $N\ 3s$  state by another mechanism, such as sequential transfer through the  $N\ 3p$  state (see ref. 49 and 51–53 for related examples). This latter mechanism would explain the absence of any evidence for direct  $2^1\pi\pi^* \rightarrow 1^1\pi\sigma^*$  transfer from previous TR-PES work<sup>11,12,14,22</sup> and is qualitatively supported by (i) the highly mixed nature of the  $2^1\pi\pi^*$  transition (which includes contributions from nearby N- and C-centred Rydberg orbitals; see Table S1 in the ESI†) and (ii) visual inspection of the molecular orbitals shown in Fig. S3 of the ESI† which suggest good overlap between the  $N\ 3s$  and lowest-lying  $N\ 3p$  Rydberg orbitals. Unfortunately, we are unable to further support or disprove either mechanism in NMA at this point: the temporal resolution of our experiment limits the information we can obtain near  $\Delta t = 0$  and we would expect any  $N\ 3p$  state population to yield little or no discernible TR-PES structure.<sup>22,48</sup> Regardless of the mechanism, population transferred into the  $N\ 3s$  state in

3,5-DMA and NMA rapidly escapes the ionisation window towards dissociation (shown schematically in Fig. 6 as the dashed green arrow). We note that the previously reported 3,5-DMA DAS,<sup>22</sup> which do not show the same ‘sequential’ behaviour as is shown in Fig. S13 in the ESI,<sup>†</sup> are reproducible with the previously published kinetic model of four exponential decays.

### (e) $1^1\pi\pi^*$ , $\tau_4$ , and the second H-atom loss mechanism

With a small decrease in TKER, *i.e.* an increase in  $E_{\text{int}}$ , the second H-atom appearance lifetime in NMA is most likely due to dissociation following excited state IVR. Building on the possible mechanisms discussed above, a  $2^1\pi\pi^* \rightarrow 1^1\pi\pi^*$  transition (likely also described by  $\tau_2$ , see DAS in Fig. S4 of the ESI<sup>†</sup>) will result in a highly vibrationally excited  $1^1\pi\pi^*$  state. The excellent agreement between  $\tau_2^{\text{H}}$  and  $\tau_4$  thus implies that some of the vibrationally excited  $1^1\pi\pi^*$  population must sample a  $1^1\pi\sigma^*/1^1\pi\pi^*$  CI<sup>17,21</sup> and transiently populate the  $1^1\pi\sigma^*$  state, ultimately accessing the repulsive portion of the potential (shown schematically in Fig. 6c). The absence of any obvious, long-lived  $1^1\pi\sigma^*$  TR-PES features and the modest growth in  $\text{H}^+$  signal with  $\tau_2^{\text{H}}$  (see Fig. 4) suggest that a relatively small amount of  $1^1\pi\pi^*$  population relaxes *via* dissociation on the  $1^1\pi\sigma^*$  state. Furthermore, the increase in both  $\tau_2^{\text{H}}$  and  $\tau_4$  with increasing pump wavelength suggest that non-dissociative mechanisms (*e.g.* IC) control the excited state relaxation time  $\tau_4$  and thus the H-atom appearance lifetime  $\tau_2^{\text{H}}$ ; similar behaviour has been observed in the excited state dissociation of 1,3-dihydroxybenzene.<sup>54</sup> Thus,  $\tau_4$  is likely describing the majority of the  $1^1\pi\pi^*$  state population undergoing IC to the  $S_0$  state (*via* CIs such as the prefulvenic geometries previously reported<sup>17,21</sup>) or intersystem crossing to the triplet manifold,<sup>15,55</sup> though some population appears to remain in the  $1^1\pi\pi^*$  state and likely fluoresces<sup>15</sup> with lifetime  $\tau_5$  as discussed above.

Assuming the  $1^1\pi\pi^* \rightarrow 1^1\pi\sigma^*$  pathway outlined above ultimately leads to N–H fission with lifetime  $\tau_2^{\text{H}}$ , there are several possible explanations for the absence of this second H-atom loss mechanism in aniline and 3,5-DMA. First, IC back out of the  $1^1\pi\sigma^*$  state (to either the  $1^1\pi\pi^*$  state or  $S_0$ ) may be more facile than dissociation for aniline and 3,5-DMA; methylation of the amine may shift a relevant CI. Alternatively, and not exclusively, dissociative tunnelling out of the  $1^1\pi\sigma^*$  state minimum is likely mediated by particular vibrational modes<sup>13,16</sup> which are sensitive to methylation. In this case, amine methylation would apparently enhance the rate of tunnelling while methylation of the ring would disrupt a mode-specific mechanism (in contrast, alkylation of the pyrrole ring reduces the contribution of tunnelling mechanisms to dissociation<sup>25,56,57</sup>). The higher symmetry of aniline and 3,5-DMA *versus* NMA may also play a role in the disappearance of  $\tau_2^{\text{H}}$ , as both the number and positions of substituents have been shown to play a crucial role in H-atom loss dynamics (see, for examples, ref. 7, 58 and 59). Ultimately, further study of the second H-atom loss pathway – such as high-resolution photofragment translational spectroscopy<sup>60</sup> – will be needed to fully elucidate the excited state dynamics at work.

### (f) Absence of $\text{CH}_3$ loss

The apparent absence of  $\text{CH}_3$  loss from both NMA and *N,N*-DMA may be understood by comparison to the related system

*N*-methylpyrrole. In a previous study of *N*-methylpyrrole, Ashfold and co-workers<sup>61</sup> only observed excited state  $\text{N}-\text{CH}_3$  bond fission over a narrow range of pump photon energies above the  $\text{N}-\text{CH}_3$  stretch barrier. This behaviour was attributed to the heavier and slower  $\text{CH}_3$  group helping facilitate efficient  $1^1\pi\sigma^*/S_0$  coupling at the CI at extended  $\text{N}-\text{CH}_3$  bond lengths (see the schematic potential energy cut in Fig. 1). In these substituted anilines, the  $1^1\pi\sigma^*/1^1\pi\pi^*$  CI is accessed faster in *N,N*-DMA than in 3,5-DMA,<sup>22</sup> thus reducing the relative importance of the dissociative coordinate in the relaxation dynamics of *N,N*-DMA. However, as the same investigation<sup>22</sup> concluded that *N,N*-DMA photoexcited at 240 nm (above the  $1^1\pi\sigma^*$  state barrier) must undergo some ultrafast  $\text{N}-\text{CH}_3$  bond cleavage, our present results would thus indicate that this dissociative population returns to the ground state *via* the  $1^1\pi\sigma^*/S_0$  CI. Thus, while our present results do not support ultrafast  $\text{CH}_3$  loss as a competitive dissociation product from photoexcited NMA or *N,N*-DMA, neither do our results disprove this relaxation pathway. Indeed, the qualitative agreement between our results and the absence of ‘fast’  $\text{CH}_3$  loss from *N*-methylpyrrole at short pump wavelengths<sup>61</sup> suggests that  $\text{CH}_3$  loss from these anilines may occur near the  $1^1\pi\sigma^*$  absorption onset; further study of these systems would substantially contribute to the understanding of non-hydride  $\pi\sigma^*$  states.

### (g) Remaining questions

From the above discussion, it is evident that relaxation of these substituted anilines following photoexcitation at 238 nm involves competing population and decay of the lower lying  $1^1\pi\sigma^*$  and  $1^1\pi\pi^*$  states. The correlation between excited state decay times and photofragment appearance times strongly supports the assignment of several PES features and dynamics to loss of population *via* dissociation on the  $1^1\pi\sigma^*$  excited state. While the mechanisms discussed provide a reasonable picture for the dynamics, some lingering questions remain. First, the apparent acceleration of  $\tau_1^{\text{H}}$  upon methylation of the ring (aniline *versus* 3,5-DMA) seems at odds with preparation of a N 3s Rydberg orbital. However, the previously reported TR-PES results from aniline at 238 nm show the  $2^1\pi\pi^*$  and  $1^1\pi\sigma^*$  features appearing simultaneously,<sup>11,12,14</sup> suggesting that direct population of and dissociation from the  $1^1\pi\sigma^*$  state may overlap with and obscure dynamics from the  $2^1\pi\pi^*$  state of aniline. TR-PES and H-atom appearance measurements from aniline following photoexcitation at  $\sim 225$  nm (the peak of the aniline  $2^1\pi\pi^*$  state absorption shown in Fig. 1) could be of significant interest, though aniline photoexcitation at both 200 and 240 nm results in a similar H-atom appearance time.<sup>17</sup> Similarly, a more systematic study of N–H bond dissociation time as a function of ring substitution would add considerable insight to the connections between ring substituents and ultrafast dissociation from a mixed valence/Rydberg state.

Another dynamical question is the nature of the N 3s state preparation in these substituted anilines. Principally, is population of the N 3s Rydberg state due to direct ultrafast transfer from the  $2^1\pi\pi^*$  state? Or does population flow through a more complicated pathway, such as through the N 3p state?

As discussed above, the initial photoexcitation appears to be dominated by the  $2^1\pi\pi^*$  state; the EAS/DAS for all of the substituted anilines studied at  $\lambda_{pu} = 238$  nm show loss of the highest eKE signal (*i.e.* from the most internally excited  $2^1\pi\pi^*$  state) with lifetime  $\tau_1$  followed by a slightly longer decay of the remaining  $2^1\pi\pi^*$  feature with lifetime  $\tau_2$ . Indeed, the 3,5-DMA  $\tau_1$  DAS (shown in Fig. S13 of the ESI<sup>†</sup>) shows negative amplitude in the N 3s eKE region, indicative of sequential dynamics from the highest eKE feature into the N 3s state. While direct population from the  $2^1\pi\pi^*$  state is the simplest explanation consistent with the observed dynamics, the previously reported  $2^1\pi\pi^*/1^1\pi\pi^*$  and  $2^1\pi\pi^*/1^1\pi\sigma^*$  CIs show considerable out-of-plane motion of the amine,<sup>17,21</sup> which neither previous<sup>22</sup> nor the present work can find evidence to support. However the current results may also be interpreted using a valence-to-Rydberg decay mechanism, *i.e.*  $2^1\pi\pi^* \rightarrow \text{N } 3\text{p}$ , a pathway which has only been experimentally identified in a few small molecules (see, for examples, ref. 53 and 62–65) and was previously alluded to play a role in the dynamics of *N,N*-DMA.<sup>22</sup> While such a  $2^1\pi\pi^* \rightarrow \text{N } 3\text{p}$  transition would also have to be within the IRF, and thus cannot be confirmed in the present work, the possibility further reinforces the conclusion that Rydberg states play a vital and complicated role in the relaxation dynamics of many systems.

## 5. Conclusions

In the present work we have investigated the ultrafast dissociation dynamics of several substituted anilines. By correlating the photoproduct appearance times to TR-PES decay lifetimes, we are able to assign some of the observed lifetimes to specific excited states. Our results strongly support a sequential mechanism whereby population first moves from the photoprepared  $2^1\pi\pi^*$  state to the  $1^1\pi\sigma^*$  state, where the wavepacket scatters to produce photoproducts. Concurrently, the  $2^1\pi\pi^*$  state relaxes to the lower lying  $1^1\pi\pi^*$  state where, for NMA, population samples the  $1^1\pi\pi^*/1^1\pi\sigma^*$  CI, resulting in a second H-atom loss pathway. While population of these states have been previously reported,<sup>10–14,19,22</sup> our experiments are the first to clearly match specific TR-PES features and lifetimes to dissociative processes. Ultimately, the work presented herein further highlights the rapid depopulation of higher-lying, potentially reactive excited states in these model biomolecules. While ultrafast dissociation is observed along the N–H bond, the absence of a  $\text{CH}_3$  loss channel may indicate efficient  $1^1\pi\sigma^*/\text{S}_0$  coupling in these anilines, reinforcing the role of these states as central to photo-protection in molecular biology. Despite the substantial insight afforded by these two techniques, important dynamical questions remain including the nature of the  $1^1\pi\sigma^*$  excited state population (direct *versus* valence-to-Rydberg population transfer from the  $2^1\pi\pi^*$  state) and the exact structure–dynamics relationship underlying the second H-atom loss channel. Furthermore, the decay of the  $2^1\pi\pi^*$  state appears to be largely insensitive to molecular geometry; as this study is one of several that is unable to firmly identify the cause, *ab initio* quantum dynamics calculations would be of considerable interest.

## Data availability

Data underpinning the present work are available through the Zenodo data repository at doi: 10.5281/zenodo.1488380; a detailed description of the archive may be found in the ESI.<sup>†</sup>

## Conflicts of interest

The authors declare no conflicts of interest.

## Acknowledgements

The authors would like to thank N. d. N. Rodrigues, S. Trouton, G. Thornton, and K. Krokidi for laboratory assistance; Dr M. Staniforth for many helpful discussions; and the Warwick Centre for Ultrafast Spectroscopy for the use of the Cary 60 spectrophotometer. N. C. C. F. thanks the Leverhulme Trust for post-doctoral funding (RPG-2015-190) and V. G. S. thanks the EPSRC for an equipment grant (EP/J007153) and the Royal Society and Leverhulme Trust for a Royal Society Leverhulme Trust Senior Research Fellowship.
