# Intracuster proton transfer in protonated benzonitrile–(H<sub>2</sub>O)<sub>n≤6</sub> nanoclusters: hydrated hydronium core for $n \geq 2$ †

 Kuntal Chatterjee  and Otto Dopfer \*

Protonation and hydration of aromatic hydrocarbon molecules and their derivatives play a key role in many biological and chemical processes. The recent detection of benzonitrile (BN, cyanobenzene, C<sub>6</sub>H<sub>5</sub>CN) in the interstellar medium suggests the existence of its protonated form (H<sup>+</sup>BN) in both the gas phase and in or on ice grains. Herein, we analyze the vibrational signatures of size-selected protonated clusters composed of BN and water (W, H<sub>2</sub>O), H<sup>+</sup>(BN–W<sub>n=1–6</sub>), in the XH stretch range (X = C, N, O) with the aid of dispersion-corrected density functional theory calculations (B3LYP-D3/ aug-cc-pVTZ). The size-dependent frequency shifts provide detailed insight about the site of protonation and the structure of the hydration shell. For  $n = 1$ , the proton is attached to the N atom of the CN group in BN, and W acts as a proton acceptor in an NH...O ionic hydrogen bond (H-bond) of a H<sup>+</sup>BN–W type structure with cation–dipole configuration. For  $n \geq 2$ , the proton is transferred to the H-bonded hydration network, consistent with thermochemical arguments arising from both the relative proton affinities of BN and W<sub>n</sub> and the solvation energies. In these proton-transferred BN–H<sup>+</sup>W<sub>n</sub> structures, the excess proton is more or less localized at a H<sub>3</sub>O<sup>+</sup> hydronium core solvated by neutral W and BN ligands. At least for the considered cluster size ( $n \leq 6$ ), the BN impurity molecule is located in the first solvation shell of the H<sub>3</sub>O<sup>+</sup> ion, consistent with the larger electric dipole moment and proton affinity of BN as compared to W. However, the energy gap between these structures and surface isomers with BN solvated further away from the charge decreases with cluster size, suggesting that BN is located at the surface in large BN–H<sup>+</sup>W<sub>n</sub> clusters. While for smaller clusters ( $n \leq 4$ ) the hydration network prefers branched structures at  $T = 0$  K, in larger clusters ( $n \geq 5$ ) cyclic configurations with four- or five-membered H<sup>+</sup>W<sub>n</sub> rings are most stable because they feature more H-bonds than the branched structures. Comparison with bare H<sup>+</sup>W<sub>n</sub> clusters reveals the substantial effects of the perturbation by the BN impurity on the structure of the hydration network.

## 1. Introduction

Protonation and subsequent hydration of aromatic molecules are fundamental processes in chemistry and biology. For example, protonated arenes often appear as reactive intermediates (Wheland intermediates,  $\sigma$  complexes) in chemical reaction mechanisms.<sup>1</sup> Furthermore, many biomolecules including proteins occur in their protonated state at physiological pH values.<sup>2–4</sup> Hydration of these biomolecules is also crucial for their structure, stability, dynamics, reactivity, and function. As a result, “interfacial” or “biological” water is now considered as an integral part of these bioactive molecules.<sup>5–9</sup> The hydration

shell also acts as a proton transport (or proton pump) medium through the formation of a hydrogen-bonded (H-bonded) hydration network.<sup>10–12</sup> Microhydrated aromatic cluster ions, both protonated closed-shell clusters and open-shell radical cations, isolated in the gas phase are suitable model systems to study the protonation and hydration process of arenes at the molecular level. Depending on the proton affinity (PA) and the solvation energy of the aromatic compound and the water cluster, the proton sticks to the arene or to the solvent. Because the proton affinity of water clusters, (H<sub>2</sub>O)<sub>n</sub> or W<sub>n</sub>, increases substantially and monotonically with cluster size  $n$  (e.g., PA = 691 kJ mol<sup>–1</sup> for  $n = 1$  and 908 kJ mol<sup>–1</sup> for  $n = 6$ ),<sup>13–17</sup> the location of the excess proton may strongly depend on the cluster size. Because the PA of most aromatic molecules (A), in particular heterocyclic arenes or arenes with functional groups containing N or O atoms, is substantially higher than that of W, the monohydrated protonated cluster has the form H<sup>+</sup>A–W.

Upon further hydration, the PA of the  $W_n$  solvent cluster increases, and intracuster proton transfer from  $AH^+$  to  $W_n$  may occur at a critical cluster size ( $n_c$ ), leading to the proton-transferred structure,  $A-H^+W_n$ . In case of open-shell aromatic radical cations, such proton transfer to solvent has been observed, for example, for benzene ( $A$  = phenyl) at a critical size of  $n_c = 4$ ,<sup>16,18,19</sup> and for phenol ( $A$  = phenoxy) at  $n_c = 3$ .<sup>20,21</sup> For closed-shell protonated aromatic ions, examples include naphthalene ( $n_c = 2$ )<sup>22</sup> and benzaldehyde ( $n_c = 3$ ).<sup>23</sup> Interestingly, although benzene has a significantly larger PA than  $W$  (750 vs. 691 kJ mol<sup>-1</sup>),<sup>24</sup> the most stable structure of the protonated dimer is benzene- $H_3O^+$  (*i.e.*,  $n_c = 1$ ),<sup>25,26</sup> even though the higher-energy  $C_6H_7^+-H_2O$  isomer has also been detected.<sup>27</sup> The latter example clearly emphasizes that, in addition to the relative PA values of  $A$  and  $W_n$ , the (sometimes substantial) difference in the solvation energies in  $H^+A-W_n$  and  $A-H^+W_n$  has to be taken into account as well to determine the position of the excess proton.<sup>28,29</sup>

In this work, we apply infrared photodissociation (IRPD) spectroscopy to microhydrated clusters of protonated benzonitrile,  $H^+(BN-W_n)$ , in the size range  $n = 1-6$ , and analyse these with the aid of dispersion-corrected density functional theory (DFT) calculations. This cluster system has been chosen for the following reasons. (1) BN has been the first aromatic molecule detected recently in the taurus molecular cloud (TMC-1) by radioastronomy,<sup>30</sup> and this observation supports the long-standing hypothesis that (polycyclic) aromatic molecules are present in the interstellar medium (ISM).<sup>31</sup> Because of the large abundance of  $H_3^+$  in the ISM,<sup>32</sup> many molecules occur in these environments also in their protonated form.<sup>31,33-35</sup> To this end, laboratory spectra of protonated aromatic molecules are highly requested.<sup>36-43</sup> In addition to the isolated aromatic ion, also the structure and spectroscopy of microhydrated clusters<sup>16,18,19,22,26,44,45</sup> are interesting in the context of their reactivity in ice grains and on ice surfaces.<sup>22,45-48</sup> (2) Triggered by the astronomical detection of BN, we recently characterized  $BN^+-L_n$  clusters with nonpolar ( $L = Ar$ ,  $n \leq 2$ ), quadrupolar ( $L = N_2$ ,  $n \leq 4$ ), and dipolar ligands ( $L = H_2O$ ,  $n = 1$ ) by IRPD spectroscopy and DFT calculations.<sup>49</sup> As a major result, the preferred binding site changes from  $\pi$ -bonding for  $L = Ar$  and  $N_2$  to bifurcated  $CH \cdots O$  H-bonding for  $L = W$ , illustrating the differences in the interaction potential as a function of the polarity of the ligand. Significantly, the excess positive charge present in  $BN^+-W$  changes the preferred binding motif from in-plane H-bonding ( $OH \cdots N$  and  $CH \cdots O$ ) in neutral  $BN-W$ <sup>50-54</sup> to bifurcated  $CH \cdots O$  bonding in  $BN^+-W$  because of the dominant charge-dipole forces.<sup>49</sup> The current work explores the effect of protonation of  $BN-W_n$  on the preferred hydration motif. Neutral  $BN-W_n$  clusters with  $n = 1-3$  have cyclic structures, in which the linear  $W_n$  unit connects the *ortho* CH proton ( $CH \cdots O$ ) with the CN group at the N end ( $OH \cdots N$ ),<sup>52,53</sup> and we expect a big change in geometry and binding energy upon protonation. (3) The information available about the structure, reactivity, and spectroscopy of  $H^+BN$  and its clusters is rather limited. Substituted (or heterocyclic) arenes may protonate at the aromatic ring (carbenium ions) or the functional group (or heteroatom).<sup>55-63</sup> The early low-resolution electronic ultraviolet photodissociation

spectrum of  $H^+BN$  does not unravel the protonation site.<sup>64,65</sup> Mass spectrometric studies using isotopic labelling conclude N-protonation at the CN group,<sup>66</sup> with a recommended PA of 812 kJ mol<sup>-1</sup>,<sup>13</sup> in line with previous low-level quantum chemical calculations.<sup>67</sup> In our recent combined IRPD and high-level DFT study of  $H^+BN-L_n$  clusters with  $L = Ar$  and  $N_2$  ( $n \leq 4$ ), we confirmed for the first time with spectroscopic tools that N-protonation is strongly preferred over C-protonation.<sup>68</sup> Analysis of the IRPD spectra recorded in the CH and NH stretch range yields vibrational frequencies relevant for astronomical purposes and information about the acidity of the N-H and aromatic C-H bonds. The hydrophobic  $Ar$  and  $N_2$  ligands prefer H-bonding to the acidic NH proton of  $H^+BN$  *via* linear  $NH \cdots L$  bonds to  $\pi$ -bonding at the aromatic ring, illustrating the large impact of protonation on the interaction potential. Herein, we extend these studies to  $H^+(BN-W_n)$  clusters with  $n = 1-6$  to probe for the first time the solvation of  $H^+BN$  by hydrophilic protic dipolar ligands. As the recommended PA of BN (812 kJ mol<sup>-1</sup>)<sup>13</sup> is in the range of the PAs of small  $W_n$  clusters (PA = 691, 808, 862, 900, 904, and 908 kJ mol<sup>-1</sup> for  $n = 1-6$ ),<sup>13-17</sup> we expect intracuster proton transfer from  $H^+BN$  to the  $W_n$  solvent cluster at the cluster size  $n_c \sim 2$ . Thus, larger  $H^+(BN-W_n)$  clusters with  $n \geq 2$  are predicted to be of the type  $BN-H^+W_n$ , and it is interesting to explore the effects of the BN impurity or dopant molecule on the structure, energetics, and bonding of the well-characterized bare  $H^+W_{n+1}$  clusters.<sup>69-80</sup> While BN has a larger electric dipole moment and PA than  $W$ ,  $W$  can be better integrated in a H-bonded network because it can be involved in a larger number of strong  $\sigma$ -type H-bonds (up to four) than BN (only one).

## 2. Experimental and computational methods

### 2.1 Experimental methods

IRPD spectra of mass-selected  $H^+(BN-W_n)$  clusters ( $n \leq 6$ ) are measured in a quadrupole tandem mass spectrometer coupled to an electron ionization (EI) source and an octopole ion guide.<sup>81,82</sup> Briefly,  $H^+(BN-W_n)$  clusters are produced in a pulsed supersonic plasma expansion by electron/chemical ionization of BN and subsequent three-body hydration reactions in the high-pressure region of expansion. A carrier gas mixture of  $Ar$  and 5%  $H_2/He$  in a ratio 5 : 1 (10 bar) is bubbled through a reservoir containing liquid BN (Sigma-Aldrich, >99%, heated to 60 °C). To generate hydrated clusters, a few drops of water are added to the gas line just before entering the BN sample reservoir. Protonation of BN is achieved by proton transfer from  $H_3^+$  or  $H^+W_n$  clusters generated by chemical ionization of  $H_2$  and  $W_n$ . The addition of  $H_2$  substantially increases the  $H^+BN/BN^+$  ratio in the ion source, indicating that  $H_3^+$  is an efficient proton donor toward BN under the employed plasma conditions.<sup>68</sup> Clusters of the type  $BN-H^+W_n$  may also be produced by simple three-body aggregation of  $H^+W_n$  and BN or by bimolecular  $W \rightarrow BN$  ligand exchange reactions. The desired  $H^+(BN-W_n)$  parent clusters are filtered by the first quadrupole

and irradiated in the adjacent octupole with a tuneable IR laser pulse ( $\nu_{\text{IR}}$ ) emitted from an optical parametric oscillator pumped by a nanosecond Q-switched Nd:YAG laser. The IR laser is characterized by a pulse energy of 2–5 mJ in the XH stretch range, a repetition rate of 10 Hz, and a bandwidth of 1  $\text{cm}^{-1}$ . Calibration of  $\nu_{\text{IR}}$  to better than 1  $\text{cm}^{-1}$  is achieved by a wavemeter. Resonant vibrational excitation of  $\text{H}^+(\text{BN}-\text{W}_n)$  is followed by intracluster vibrational energy redistribution and subsequent evaporation of a single neutral W ligand. Only the loss of W is observed because its binding energy is lower than that of BN. This observation is consistent with the smaller dipole moment and PA of W as compared to BN. The resulting  $\text{H}^+(\text{BN}-\text{W}_{n-1})$  daughter ions are size-selected by the second quadrupole mass spectrometer and recorded with a Daly detector as a function of  $\nu_{\text{IR}}$  to derive the IRPD spectrum of the parent cluster. The separation of the laser-induced dissociation signal from metastable decay is achieved by (i) triggering the ion source at twice the laser repetition rate and (ii) subtracting the fragment signals from alternating triggers. The reported IRPD yield is normalized for laser intensity variations measured with a pyroelectric detector. The widths of the peaks observed in the IRPD spectra are mainly due to unresolved rotational structure of the vibrational transitions, sequence hot bands involving inter- and low-frequency intramolecular modes, lifetime broadening, and possibly contributions from different structural isomers.

## 2.2 Computational methods

Quantum chemical calculations are performed for  $\text{H}^+(\text{BN}-\text{W}_n)$  clusters and their subunits at the B3LYP-D3/aug-cc-pVTZ level to determine their structural, energetic, and vibrational properties.<sup>83</sup> The employed dispersion-corrected functional accounts well for the electrostatic, induction, and dispersion forces of the investigated clusters, and reproduces their experimental binding energies and IR spectra to satisfactory accuracy.<sup>45,49,68,84–91</sup> For example, the binding energy computed for  $\text{W}_2$  ( $D_0 = 1103 \text{ cm}^{-1}$ ) is in excellent agreement with the measured value ( $D_0 = 1105 \pm 10 \text{ cm}^{-1}$ ),<sup>92</sup> indicating that the H-bond interactions in the hydration networks are modeled accurately by this computational approach. All coordinates are allowed to relax during the search for stationary points, and their nature as minima or transition states are verified by harmonic frequency analysis. For energy optimization, the tight convergence criterion with ultrafine integration grid is employed. We manually generate a substantial number of conceivable starting structures, guided by the dimer potentials, experimental spectra, sequential cluster growth, and the comparison with well-known  $\text{H}^+\text{W}_n$  structures. Throughout this paper, the lowest energy structure found is denoted “global minimum”. For the cluster sizes  $n = 1$ –4, we are confident that these structures are indeed the true global minima. For  $n = 5$  and 6, global optimization techniques (not used here) would be required to ensure the reliable determination of the true global minima. Cartesian coordinates of all relevant structures and their energies are available in the ESI.† Harmonic intramolecular vibrational XH stretch frequencies are subjected to a linear scaling factor of 0.9586,<sup>68</sup> derived previously from fitting

the calculated harmonic CH stretch frequencies of neutral BN to available experimental values.<sup>93</sup> Intramolecular frequencies below 2500  $\text{cm}^{-1}$  are scaled by 0.98, while intermolecular frequencies remain unscaled. Computed scaled IR stick spectra are convoluted with a Gaussian line profile (fwhm = 10  $\text{cm}^{-1}$ ) to facilitate convenient comparison with the experimental IRPD spectra. All relative energies ( $E_0$ ) and dissociation energies ( $D_0$ ) are corrected for harmonic zero-point vibrational energy. Relative free energies ( $G$ ) are obtained for  $T = 298.15 \text{ K}$ . If not stated otherwise, the total intermolecular dissociation energies are determined with respect to the molecular  $\text{H}^+\text{BN}$  and W monomer fragments (also for the proton-transferred isomers of  $\text{BN}-\text{H}^+\text{W}_n$ ). Previous experience with the employed DFT level demonstrates that basis set superposition errors are less than 1%,<sup>45,90</sup> and thus they are not considered further here. Natural bond orbital (NBO) analysis is employed to evaluate the effects of protonation and hydration on the atomic charge distribution.<sup>94</sup> Second-order perturbation energies ( $E^{(2)}$ ) of the interaction between donor and acceptor NBOs involved in the H-bonds are used to quantify their relative strengths.<sup>95</sup> Regarding the strength of these H-bonds, noncovalent interaction (NCI) calculations are performed by evaluating the reduced gradient of the electron density  $\rho$ ,  $s(\rho) \sim |\text{grad}(\rho)|/\rho^{4/3}$ , as a function of  $\rho$  oriented by the sign of second eigenvalue ( $\lambda_2$ ) of the Hessian,  $\rho^* = \rho \cdot \text{sign}(\lambda_2)$ .<sup>96,97</sup> The strength of the intermolecular H-bonds is related to the absolute value of their negative  $\rho^*$  values.

## 3. Results and discussion

Fig. 1 compares the experimental IRPD spectra of  $\text{H}^+(\text{BN}-\text{W}_n)$  with  $n = 1$ –6 recorded between 2650 and 3850  $\text{cm}^{-1}$  in the single W loss channel. The positions and widths of the transitions observed (A–E) are listed in Table 1, along with the suggested vibrational and isomer assignments. Significantly, the spectra show a large variation with cluster size  $n$ , because the investigated spectral range encompasses the OH ( $\nu_{\text{OH}}$ ), NH ( $\nu_{\text{NH}}$ ), and CH ( $\nu_{\text{CH}}$ ) stretch fundamentals, which are highly sensitive to the position of the excess proton and the structure of the H-bonded solvent network. The predicted IR intensities of the  $\nu_{\text{CH}}$  modes are, however, much weaker than those of  $\nu_{\text{OH}}$  and  $\nu_{\text{NH}}$  (by 2–4 orders of magnitude,  $I_{\text{CH}} < 10 \text{ km mol}^{-1}$  for BN and  $\text{H}^+\text{BN}$ )<sup>68</sup> and thus not observed at the current experimental sensitivity (Table S1 in the ESI†). As will be shown below, the bands A–C arise from free OH stretch modes, while transitions D and E are attributed to bound OH and NH stretch vibrations, respectively. In the following, we first discuss the calculated structures of the BN,  $\text{H}^+\text{BN}$ , and W monomers and then compare the IR spectra predicted for the lowest-energy isomers of  $\text{H}^+(\text{BN}-\text{W}_n)$  with the measured IRPD spectra to determine the observed cluster structures. For completeness, we also include a comparison of the  $\text{H}^+\text{BN}-\text{W}$  monohydrate with previous results obtained for  $\text{H}^+\text{BN}-\text{L}$  with  $\text{L} = \text{Ar}$  and  $\text{N}_2$ ,<sup>68</sup> to discuss similarities and differences of the microsolvation of  $\text{H}^+\text{BN}$  with ligands of different polarity.

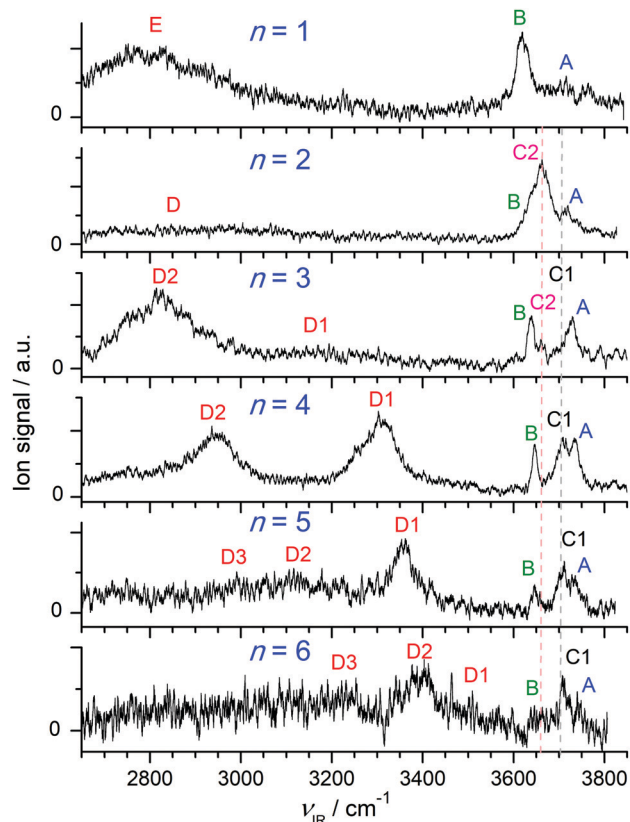

Fig. 1 IRPD spectra of  $\text{H}^+(\text{BN}-\text{W}_n)$  with  $n = 1-6$  recorded in the single W loss channel. The positions, widths, and vibrational and isomer assignments of the transitions observed (A–E) are listed in Table 1.

### 3.1 BN, $\text{H}^+\text{BN}$ , and W monomers

The structural and vibrational properties of both BN and  $\text{H}^+\text{BN}$  calculated at the B3LYP-D3/aug-cc-pVTZ level are discussed in detail in our previous reports.<sup>49,68</sup> Briefly, the computed structural, rotational, and vibrational data of the planar BN molecule ( $C_{2v}$ ,  $^2\text{A}_1$ ) are in good agreement with available experimental data (Table S2 in the ESI<sup>†</sup>),<sup>49,68,93,98,99</sup> and the calculated dipole moment is close to the measured one ( $\mu = 4.71$  vs.  $4.51$  D).<sup>100</sup> Protonation of BN occurs preferentially at the terminal N atom of the CN group, leading to a planar structure with  $C_{2v}$  symmetry in the  $^1\text{A}_1$  ground electronic state.<sup>68</sup> Protonation at the aromatic C atoms is highly unfavourable ( $E_0 > 115$  kJ mol<sup>-1</sup>) and thus not observed (Fig. S1 in the ESI<sup>†</sup>).<sup>68</sup> Interestingly, N-protonation contracts both the  $\text{C}\equiv\text{N}$  ( $\Delta r_{\text{CN}} = -5.2$  mÅ) and the adjacent aliphatic C–C bond ( $\Delta r_{\text{CC}} = -35.6$  mÅ). The frequency of the most intense IR-active fundamental,  $\nu_{\text{NH}} = 3560$  cm<sup>-1</sup> (1221 km mol<sup>-1</sup>), is close to its measured value ( $3555 \pm 3$  cm<sup>-1</sup>).<sup>68</sup> Concerning W, the O–H bond parameters in its  $^1\text{A}_1$  ground state ( $r_{\text{OH}} = 0.9619$  Å,  $\nu_{1/3} = 3639/3738$  cm<sup>-1</sup>) agree reasonably well with the experimental data ( $0.9578$  Å,  $3657/3756$  cm<sup>-1</sup>).<sup>101,102</sup> The computed  $\nu_{1/3}$  frequencies are systematically lower by 18 cm<sup>-1</sup>, because the  $\nu_{\text{OH}}$  modes are not accounted for in the evaluation of the single scaling factor in the XH stretch range, which however fits well the  $\nu_{\text{CH}}$  and  $\nu_{\text{NH}}$  frequencies of ( $\text{H}^+$ )BN.<sup>68</sup> Similar to BN, the

calculated dipole moment of W agrees well with the experimental value ( $\mu = 1.847$  vs.  $1.855$  D). In addition, the proton affinities computed for BN and W ( $\text{PA} = 827$  and  $681$  kJ mol<sup>-1</sup>) are close to the measured values ( $\text{PA} = 812$  and  $691$  kJ mol<sup>-1</sup>),<sup>13</sup> indicating that the electrostatic intermolecular interactions between  $\text{H}^+\text{BN}/\text{BN}$  and  $\text{W}/\text{H}^+\text{W}$  are well described at this level of theory.

### 3.2 $\text{H}^+\text{BN}-\text{Ar}$ , $\text{H}^+\text{BN}-\text{N}_2$ , and $\text{H}^+\text{BN}-\text{W}$ dimers

The global minimum on the  $\text{H}^+(\text{BN}-\text{L})$  dimer potential is for all three considered ligands L the planar H-bonded  $\text{H}^+\text{BN}-\text{L}(\text{H})$  structure with  $C_{2v}$  symmetry, in which L forms a linear  $\text{NH}\cdots\text{L}$  ionic H-bond to N-protonated  $\text{H}^+\text{BN}$  (Fig. 2). The binding energy increases as  $D_0 = 874 < 1792 < 6924$  cm<sup>-1</sup> along the series  $\text{Ar} < \text{N}_2 < \text{W}$ , in line with their proton affinities ( $\text{PA} = 369.2 < 493.8 < 691$  kJ mol<sup>-1</sup>).<sup>13</sup> The H-bond length contracts accordingly ( $R = 2.31 > 1.89 > 1.49$  Å). The charge transfer from  $\text{H}^+\text{BN}$  to L ( $\Delta q = 27 < 46 < 109$  me, Fig. S2 in the ESI<sup>†</sup>) upon formation of the  $\text{NH}\cdots\text{L}$  ionic H-bond, the corresponding NBO orbital interaction energies ( $E^{(2)} = 28.9 < 74.7 < 329.9$  kJ mol<sup>-1</sup>, Fig. S3 in the ESI<sup>†</sup>), and the NCI analysis ( $-\rho^* = 0.015 < 0.029 < 0.075$  a.u., Fig. S4 in the ESI<sup>†</sup>) confirm this trend. The formation of the H-bond causes an elongation of the N–H proton donor bond ( $\Delta r_{\text{NH}} = 7.2 < 18.1 < 74.1$  mÅ), accompanied by a reduction in the NH stretch frequency ( $-\Delta\nu_{\text{NH}} = 145 < 331 < 1055$  cm<sup>-1</sup>) and an enhancement in its IR activity ( $\Delta I_{\text{NH}} = 1325 < 2362 < 4025$  km mol<sup>-1</sup>, Fig. 3 and Table S3 in the ESI<sup>†</sup>). In the  $\text{NH}\cdots\text{L}$  H-bonded dimers, the NH proton attacks the  $2p_z$  lone pairs of  $\text{N}_2$  (N atom) and  $\text{H}_2\text{O}$  (O atom), leading to a linear ionic H-bond. The anisotropy of the electrostatic charge–quadrupole ( $\text{L} = \text{N}_2$ ) and charge–dipole ( $\text{L} = \text{W}$ ) interaction favours such a linear approach. For  $\text{H}^+\text{BN}-\text{W}(\text{H})$ , the partial charge transfer from  $\text{H}^+\text{BN}$  to W elongates the O–H bonds (by 2.1 mÅ), and thus reduces the OH stretch frequencies by  $-\Delta\nu_{1/3} = 18/30$  cm<sup>-1</sup>, accompanied by an intensity enhancement, in particular for  $\nu_1$  (Table 1). The barrier for internal rotation of W around its  $C_2$  axis at the planar transition state is relatively low ( $V_b = 65$  cm<sup>-1</sup>, Fig. S5 in the ESI<sup>†</sup>), in particular in view of the low harmonic torsional frequency ( $\tau = 58$  cm<sup>-1</sup>). Actually, optimization of  $\text{H}^+\text{BN}-\text{W}(\text{H})$  yields a structure with a tiny deviation from  $C_{2v}$  symmetry due to a slightly nonlinear  $\text{NH}\cdots\text{W}$  bond ( $\theta = 177.6^\circ$ ). The  $C_{2v}$ -symmetric transition state corresponds to a very small barrier ( $V_b = 7$  cm<sup>-1</sup>) for the in-plane bending motion with low imaginary frequency ( $128i$  cm<sup>-1</sup>), so that the zero-point energy level lies above the barrier leading to a vibrationally-averaged ground state structure with  $C_{2v}$  symmetry.

In addition to the NH-bonded  $\text{H}^+\text{BN}-\text{L}(\text{H})$  global minima, less stable  $\pi$ -bonded local minima exist for  $\text{L} = \text{Ar}$  and  $\text{N}_2$  (Fig. 2), in which the ligand is attached to the aromatic  $\pi$ -electron system mostly by dispersion and induction forces with  $D_0 = 489$  and  $581$  cm<sup>-1</sup>, respectively.<sup>68</sup> In these  $\text{H}^+\text{BN}-\text{L}(\pi)$  isomers, the ligands have a negligible influence on the structural and vibrational properties of  $\text{H}^+\text{BN}$ . As a result,  $\nu_{\text{NH}}$  remains almost unshifted ( $\Delta\nu_{\text{NH}} \leq 2$  cm<sup>-1</sup>) from the value in bare  $\text{H}^+\text{BN}$  ( $\nu_{\text{NH}} = 3560$  cm<sup>-1</sup>), with nearly unchanged IR intensities.

**Table 1** Positions, widths (fwhm in parentheses), and suggested vibrational and isomer assignments of the transitions observed in the IRPD spectra of  $\text{H}^+(\text{BN}-W_n)$  clusters compared to frequencies calculated at the B3LYP-D3/aug-cc-pVTZ level. All values are given in  $\text{cm}^{-1}$ . For comparison, spectral data of W are provided. For  $n = 5$  and 6, the given isomer assignments are tentative

	Exp. <sup>a</sup>	Mode	Calc. <sup>b</sup>	Isomer

<sup>a</sup> The notation (b) indicates broad bands for which it is difficult to extract the widths. <sup>b</sup> Vibrational symmetry species and IR intensities (in  $\text{km mol}^{-1}$ ) are listed in parentheses. <sup>c</sup> Ref. 102. <sup>d</sup> Ref. 68. <sup>e</sup> The notations A, W, and D are abbreviations for 'acceptor', 'water', and 'donor', respectively.

All attempts to locate a  $\pi$ -bonded  $\text{H}^+\text{BN}-W(\pi)$  minimum fail and converge to H-bonded isomers. On the other hand, two further nonequivalent in-plane minima exist on the  $\text{H}^+\text{BN}-W$  potential, in which the W ligand forms a bifurcated  $\text{CH}\cdots\text{O}$  H-bond to two adjacent CH protons of the aromatic ring

(Fig. S6 in the ESI<sup>†</sup>). The resulting isomers,  $\text{H}^+\text{BN}-W(\text{o/m})$  and  $\text{H}^+\text{BN}-W(\text{p/m})$ , are much less stable ( $D_0 = 2332$  and  $2188 \text{ cm}^{-1}$ ) than the NH-bonded global minimum (by  $\Delta E_0 \geq 4592 \text{ cm}^{-1}$  or  $54.9 \text{ kJ mol}^{-1}$ ). Similar to the  $\pi$ -bonded  $\text{H}^+\text{BN}-L(\pi)$  local minima, their IR spectra have an unperturbed

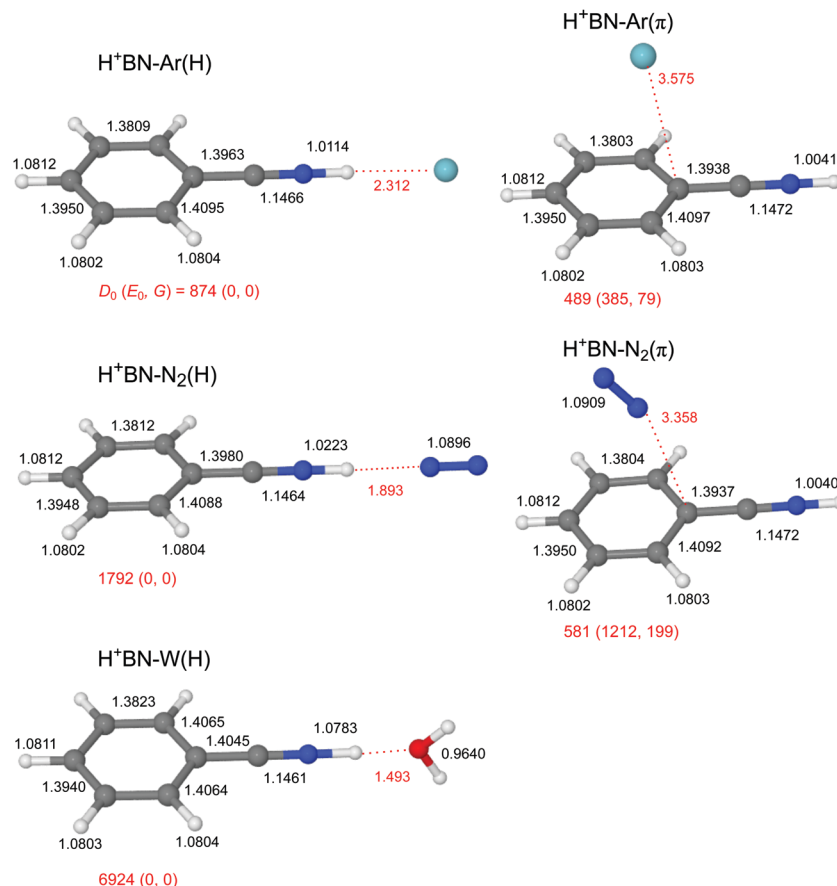

Fig. 2 Optimized structures of  $\text{H}^+\text{BN-L}$  with  $\text{L} = \text{Ar}$ ,  $\text{N}_2$ , and  $\text{W}$  calculated at the B3LYP-D3/aug-cc-pVTZ level. Binding energies ( $D_0$ ) and bond lengths are given in  $\text{cm}^{-1}$  and Å, respectively. Numbers in parentheses correspond to relative energies and free energies in  $\text{cm}^{-1}$  ( $E_0$ ,  $G$ ).

free  $\nu_{\text{NH}}$  band near  $3570 \text{ cm}^{-1}$  (Fig. S7 in the ESI†). However, the aromatic  $\nu_{\text{CH}}$  modes exhibit a slight intensity enhancement due to the formation of the bifurcated  $\text{CH} \cdots \text{O}$  H-bond. The barriers between the CH-bonded minima are relatively low (e.g.,  $V_b = 225 \text{ cm}^{-1}$  for the transition state between two equivalent  $\text{H}^+\text{BN-W(p/m)}$  minima, Fig. S8 in the ESI†).

Because the PA of BN ( $812 \text{ kJ mol}^{-1}$ ) is much higher than those of any of the three ligands (by more than  $120 \text{ kJ mol}^{-1}$ ), and this energy difference is much larger than any of the solvation energies, the excess proton in  $\text{H}^+(\text{BN-L})$  remains with BN, justifying the notation of  $\text{H}^+\text{BN-L}$  for all ligands. All attempts to locate  $\text{H}_3\text{O}^+\text{-BN}$  minima with either an  $\text{OH} \cdots \pi$  or an  $\text{OH} \cdots \text{N}$  H-bond fail. This is in contrast to clusters of  $\text{H}_3\text{O}^+\text{-A}$  with  $\text{A} = \text{benzene}$  or  $\text{naphthalene}$ , for which  $\pi$ -bonded structures of  $\text{H}_3\text{O}^+$  with the aromatic ring are the global or at least local minima.<sup>22,25,26</sup> This difference is due to the lower PA of benzene and naphthalene ( $\text{PA} = 750.4$  and  $802.9 \text{ kJ mol}^{-1}$ )<sup>13</sup> and the lack of a dipole moment. The large dipole moment of BN along the CN axis does not favour a cation- $\pi$  interaction with an  $\text{OH} \cdots \pi$  ionic H-bond of  $\text{H}_3\text{O}^+$  and the aromatic  $\pi$  electron system of BN. At this point, we note that a peak at  $m/z$  122 observed in very recent electron impact mass spectra of a BN/ $\text{H}_2\text{O}$  mixture has wrongly been assigned to  $\text{H}_3\text{O}^+\text{-BN}$  (rather than  $\text{H}^+\text{BN-H}_2\text{O}$ ),<sup>103</sup> illustrating that mass spectrometry

is not sensitive to determine the position of the excess proton in clusters.

The IRPD spectra of the  $\text{H}^+\text{BN-L}$  dimers are compared in Fig. 3 to linear IR absorption spectra computed for the most stable isomers with the  $\text{NH} \cdots \text{L}$  ionic H-bond. The spectra for  $\text{L} = \text{Ar}$  and  $\text{N}_2$  have been discussed previously<sup>68</sup> and are included here only for comparison with  $\text{L} = \text{W}$ . The weak and symmetric band F at  $3556 \text{ cm}^{-1}$  in the spectrum of  $\text{H}^+\text{BN-Ar}$  is assigned to the free  $\nu_{\text{NH}}^f$  mode of  $\text{H}^+\text{BN-Ar}(\pi)$  computed as  $3561 \text{ cm}^{-1}$ . It provides a good approximation for  $\nu_{\text{NH}}$  of bare  $\text{H}^+\text{BN}$  as  $3555 \pm 3 \text{ cm}^{-1}$ ,<sup>68</sup> which is taken as reference point herein to evaluate  $\Delta\nu_{\text{NH}}$  shifts upon cluster formation. This band is missing in the  $\text{H}^+\text{BN-L}$  spectra with  $\text{L} = \text{N}_2$  and  $\text{W}$ , indicating that in the observed clusters with these ligands the NH group is solvated by L. That means, only the NH-bonded global minima  $\text{H}^+\text{BN-N}_2(\text{H})$  and  $\text{H}^+\text{BN-W(H)}$  are detected, and other isomers are below the detection limit (Fig. 3 and Fig. S7 in the ESI†). For  $\text{L} = \text{Ar}$ , the abundance ratio of 1 : 5 estimated for the  $\pi$  and NH isomers is ascribed to their small energy difference of only  $400 \text{ cm}^{-1}$ . For  $\text{L} = \text{N}_2$  and  $\text{W}$ , the less stable  $\pi$  and CH isomers are much higher in energy, which explains their complete absence in the IRPD spectra. Following this isomer assignment, the intense bands E at  $3414$ ,  $3221$ , and  $2750 \text{ cm}^{-1}$  are readily assigned to the H-bonded  $\nu_{\text{NH}}^b$  mode of  $\text{H}^+\text{BN-L(H)}$  with  $\text{L} = \text{Ar}$ ,

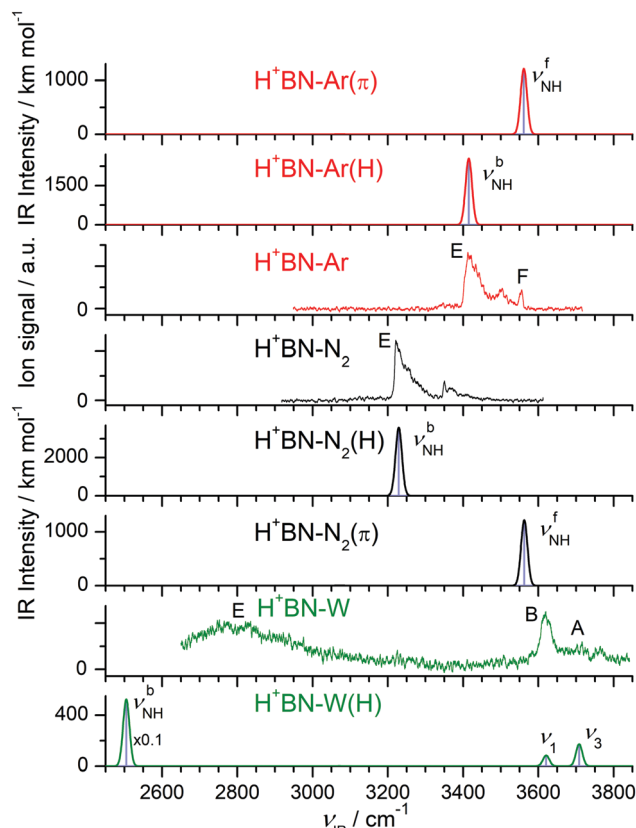

Fig. 3 Comparison of experimental IRPD spectra of  $\text{H}^+\text{BN-L}$  ( $\text{L} = \text{Ar}, \text{N}_2, \text{W}$ ) with linear IR absorption spectra of the most stable isomers calculated at the B3LYP-D3/aug-cc-pVTZ level. High computed IR intensities are multiplied with a factor of 0.1 to display the weak features.

$\text{N}_2$ , and  $\text{W}$ , respectively, in good agreement with the predicted values of 3415, 3229, and  $2505\text{ cm}^{-1}$ , respectively. These proton donor stretch bands are broader and typically exhibit a sharp rise on the red side (P branch head) and a long tail toward the blue side.<sup>82,104,105</sup> The latter is attributed to absorption of clusters with initial internal energy, giving rise to sequence hot bands of the type  $\nu_{\text{NH}}^b + \nu_x \leftarrow \nu_x$ , where  $\nu_x$  are low-frequency inter- and intramolecular modes. Cold  $\text{H}^+\text{BN-L(H)}$  clusters with  $\text{L} = \text{Ar}$  and  $\text{N}_2$  can be dissociated from the ground vibrational state under the employed single-photon absorption conditions, and their  $\nu_{\text{NH}}^b$  bands display indeed such a blue-shaded contour. In contrast, the high calculated binding energy of  $\text{H}^+\text{BN-W(H)}$ ,  $D_0 = 6924\text{ cm}^{-1}$ , implies that only clusters with an internal energy of more than  $\sim 4000\text{ cm}^{-1}$  can be fragmented upon single-photon IRPD. This may explain that the  $\nu_{\text{NH}}^b$  band of these internally hot  $\text{H}^+\text{BN-W(H)}$  clusters is substantially blue-shifted from its predicted value ( $+245\text{ cm}^{-1}$ ), while those measured for  $\text{L} = \text{Ar}$  and  $\text{N}_2$  are computed well (to within  $\pm 10\text{ cm}^{-1}$ ). The free OH stretch modes of  $\text{H}^+\text{BN-W(H)}$  are observed as sharper bands at  $\nu_1 = 3620$  and  $\nu_3 = 3708\text{ cm}^{-1}$ , respectively, and their red shifts from the values of bare  $\text{W}$  ( $-\Delta\nu_{1/3} = 37/46\text{ cm}^{-1}$ ) are in accordance with the computed ones ( $-\Delta\nu_{1/3} = 18/30\text{ cm}^{-1}$ ). Interestingly, the observed relative intensities of  $\nu_{1/3}$  appear to be reversed from the predictions.

This may be related to the high effective temperature of the clusters and/or the much larger width of the  $\nu_3$  band. Finally, the remaining bands in the spectra of  $\text{L} = \text{Ar}$  and  $\text{N}_2$  at 3500 and  $3351\text{ cm}^{-1}$  are attributed to combination bands  $\nu_{\text{NH}}^b + \nu_s$ , where  $\nu_s$  is the intermolecular stretch frequency in the  $\nu_{\text{NH}}^b$  excited state ( $86$  and  $130\text{ cm}^{-1}$ ). This mode is not included in harmonic calculations. It is also absent in the IRPD spectrum with  $\text{L} = \text{W}$ , for which  $\nu_s$  is computed as  $255\text{ cm}^{-1}$  (and thus  $\nu_{\text{NH}}^b + \nu_s$  is expected near  $3060\text{ cm}^{-1}$ ). Clearly, the IRPD spectrum measured for  $\text{H}^+(\text{BN-W})$  lacks any signature of the free OH stretch bands of the  $\text{H}_3\text{O}^+$  ion expected near  $3500\text{--}3550\text{ cm}^{-1}$  for a  $\text{H}_3\text{O}^+\text{-BN}$  cluster (with either an  $\text{OH}\cdots\text{N}$  or  $\text{OH}\cdots\pi$  H-bond).<sup>26</sup> Thus, we can safely exclude any detectable contributions from a  $\text{H}_3\text{O}^+\text{-BN}$  type isomer to the  $\text{H}^+(\text{BN-W})$  ion population in the plasma beam, which thus is assigned completely to the  $\text{H}^+\text{BN-W(H)}$  isomer. This experimental conclusion is in line with the failure of locating any  $\text{H}_3\text{O}^+\text{-BN}$  minimum on the  $\text{H}^+(\text{BN-W})$  potential by the B3LYP-D3 calculations.

### 3.3 $\text{H}^+(\text{BN-W}_2)$

Our search on the potential energy surface of the  $n = 2$  cluster results in three low-energy structural isomers (Fig. 4 and Fig. S9 in the ESI<sup>†</sup>), which are obtained by adding a second  $\text{W}$  ligand to

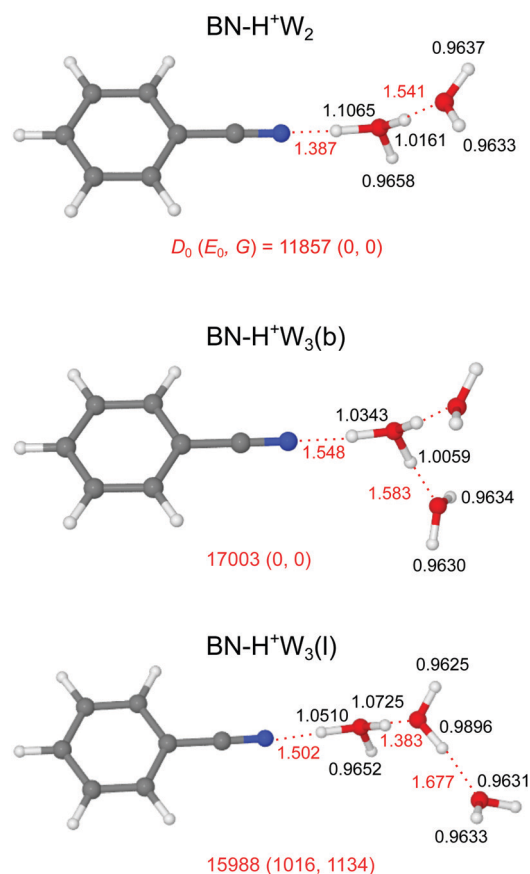

Fig. 4 Optimized structures of  $\text{BN-H}^+\text{W}_2$  and two isomers of  $\text{BN-H}^+\text{W}_3$  calculated at the B3LYP-D3/aug-cc-pVTZ level. Binding energies ( $D_0$ ) and bond lengths are given in  $\text{cm}^{-1}$  and Å, respectively. Numbers in parenthesis correspond to relative energies and free energies in  $\text{cm}^{-1}$  ( $E_0, G$ ).

the clearly most stable  $\text{H}^+\text{BN}-\text{W}(\text{H})$  dimer either at the W or the CH binding sites, resulting in  $\text{BN}-\text{H}^+\text{W}_2$ ,  $\text{H}^+\text{BN}-\text{W}_2(\text{o}/\text{m})$ , and  $\text{H}^+\text{BN}-\text{W}_2(\text{m}/\text{p})$ . The by far most stable structure is the proton-transferred  $\text{BN}-\text{H}^+\text{W}_2$  isomer with a total dissociation energy of  $D_0 = 11\,857\text{ cm}^{-1}$ , in which the neutral W and BN ligands individually bind to a central  $\text{H}_3\text{O}^+$  cation core *via*  $\text{OH}\cdots\text{O}$  and  $\text{OH}\cdots\text{N}$  ionic H-bonds. This means that we observe an intracluster proton transfer from  $\text{H}^+\text{BN}$  to the solvent cluster upon attachment of the second W ligand. This result is in accordance with the similar PA values of BN and  $\text{W}_2$  (812 and  $808\text{ kJ mol}^{-1}$ ),<sup>13,14</sup> when taking into account that the solvation energy of the  $\text{H}_3\text{O}^+$  ion is larger than that of  $\text{H}^+\text{BN}$ . Because this proton transfer is barrierless, we can not optimize a  $\text{H}^+\text{BN}-\text{W}_2$  local minimum, in which a neutral  $\text{W}_2$  dimer binds to the NH proton of  $\text{H}^+\text{BN}$  *via* an  $\text{NH}\cdots\text{O}$  H-bond. The  $\text{OH}\cdots\text{N}$  bond of  $\text{H}_3\text{O}^+$  to BN ( $R = 1.387\text{ \AA}$ ,  $D_0 = 11\,955\text{ cm}^{-1}$ ) is much stronger and shorter than the  $\text{OH}\cdots\text{O}$  bond to W ( $R = 1.541\text{ \AA}$ ,  $D_0 = 4933\text{ cm}^{-1}$ ), because both the PA and  $\mu$  of BN are larger than those of W so that BN is the better proton acceptor. This result is supported by the larger charge transfer from  $\text{H}_3\text{O}^+$  to BN as compared to W ( $\Delta q = 199$  vs.  $80\text{ me}$ , Fig. S2 in the ESI†), the larger  $E^{(2)}$  energy ( $757.3$  vs.  $249.9\text{ kJ mol}^{-1}$ , Fig. S3 in the ESI†), and the NCI data ( $-\rho^* = 0.111$  vs.  $0.066\text{ a.u.}$ , Fig. S4 in the ESI†). As a result of the substantially stronger H-bond, the O–H donor bond in the  $\text{OH}\cdots\text{N}$  bond is more elongated than that in the  $\text{OH}\cdots\text{O}$  bond (by  $90.4\text{ m\AA}$ ), resulting in a much lower  $\nu_{\text{OH}}^b$  frequency ( $1361$  vs.  $2760\text{ cm}^{-1}$ ). The predicted free OH stretch frequencies of the W ligand ( $\nu_{1/3} = 3626/3714\text{ cm}^{-1}$ ) are slightly blue-shifted compared to the  $n = 1$  cluster because the  $\text{OH}\cdots\text{O}$  H-bond to the W ligand in  $n = 2$  is weaker than the  $\text{NH}\cdots\text{O}$  H-bond in  $n = 1$  ( $D_0 = 4933$  vs.  $6924\text{ cm}^{-1}$ ), as also demonstrated by the smaller charge transfer ( $\Delta q = 80$  vs.  $108\text{ me}$ ), the lower  $E^{(2)}$  energy ( $249.9$  vs.  $329.9\text{ kJ mol}^{-1}$ ), and the smaller  $-\rho^*$  value ( $0.066$  vs.  $0.075\text{ a.u.}$ ). The free OH stretch frequency of the  $\text{H}_3\text{O}^+$  core ion occurs between  $\nu_1$  and  $\nu_3$  at  $\nu_f = 3643\text{ cm}^{-1}$  (Fig. 5). Finally, we note that the  $\text{BN}-\text{H}^+\text{W}_2$  structure is formally derived from the most stable symmetric  $\text{H}^+\text{W}_3$  isomer ( $\text{H}_2\text{O}_3^+$ ,  $\text{W}-\text{H}_3\text{O}^+-\text{W}$ , Fig. S10 in the ESI†)<sup>69</sup> by simple substitution of one W ligand by BN.  $\text{H}_2\text{O}_3^+$  has a large total binding energy of  $D_0 = 19\,767\text{ cm}^{-1}$  (*i.e.*,  $9884\text{ cm}^{-1}$  per W) and relatively short  $\text{OH}\cdots\text{O}$  H-bonds ( $R = 1.456\text{ \AA}$ ). Hence, replacing one W ligand by BN substantially destabilizes the remaining  $\text{OH}\cdots\text{O}$  H-bond to W, because of the much stronger  $\text{OH}\cdots\text{N}$  H-bond to BN.

In the  $\text{H}^+\text{BN}-\text{W}_2(\text{o}/\text{m})$  and  $\text{H}^+\text{BN}-\text{W}_2(\text{m}/\text{p})$  isomers, the two W ligands bind separately to the  $\text{H}^+\text{BN}$  core *via*  $\text{NH}\cdots\text{O}$  and bifurcated  $\text{CH}\cdots\text{O}$  H-bonds (Fig. S9 in the ESI†). Their total binding energies of  $D_0 = 8925$  and  $8825\text{ cm}^{-1}$  are far lower than that of the proton-transferred global minimum. Moreover, because of noncooperative three-body effects involved in interior ion solvation, the total binding energy is somewhat smaller than the sum of the binding energies of the individual H-bonds in the  $\text{H}^+\text{BN}-\text{W}$  dimer of  $9256$  and  $9112\text{ cm}^{-1}$  (corresponding to a noncooperativity in energy of  $331$  and  $287\text{ cm}^{-1}$  or  $3.6$  and  $4.2\%$ , respectively). Thus, the H-bonds in these  $\text{H}^+\text{BN}-\text{W}_2$  trimers are somewhat weaker and longer than in the corresponding  $\text{H}^+\text{BN}-\text{W}$  dimer isomers. As a consequence, the proton remains

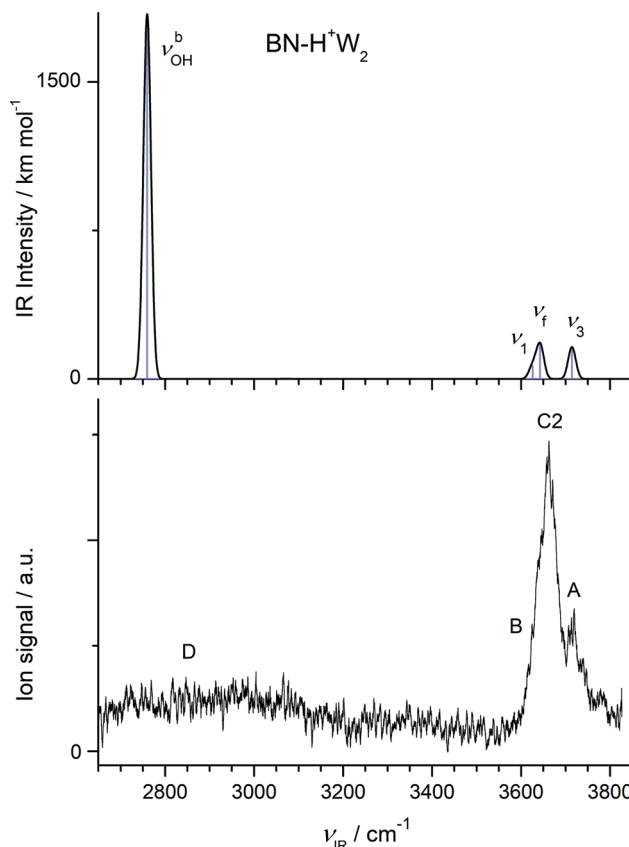

Fig. 5 Comparison of experimental IRPD spectrum of  $\text{H}^+(\text{BN}-\text{W}_2)$  with linear IR absorption spectrum of the most stable  $\text{BN}-\text{H}^+\text{W}_2$  isomer calculated at the B3LYP-D3/aug-cc-pVTZ level.

with BN in these clusters, because the CH-bonded W ligand decreases the acidity of the NH proton. The IR spectra predicted for these isomers are more or less a superposition of the IR spectra of the respective dimers (Fig. S11 in the ESI†). Significantly, in the considered spectral range, the appearance of the IR spectra predicted for these  $\text{H}^+\text{BN}-\text{W}_2$  isomers of  $n = 2$  is quite similar to the one of the  $\text{H}^+\text{BN}-\text{W}(\text{H})$  isomer of  $n = 1$ , with a modest blue shift of around  $50\text{ cm}^{-1}$  for the intense  $\nu_{\text{NH}}^b$  band upon adding the CH-bonded W ligand.

In Fig. 5, we compare the IRPD spectrum of  $\text{H}^+(\text{BN}-\text{W}_2)$  recorded in the W loss channel with the IR spectrum predicted for the most stable  $\text{BN}-\text{H}^+\text{W}_2$  dimer. The very intense  $\nu_{\text{OH}}^b$  mode of  $\text{BN}-\text{H}^+\text{W}_2$  calculated at  $2760\text{ cm}^{-1}$  appears as broad absorption band D starting at  $3200\text{ cm}^{-1}$  and extending down to the edge of the scanning range at  $2650\text{ cm}^{-1}$ , where the laser intensity becomes weak. Peak A at  $3719\text{ cm}^{-1}$  is assigned to  $\nu_3$  of the W ligand and is indeed blue-shifted compared to the  $n = 1$  cluster (by  $9\text{ cm}^{-1}$ ) as predicted by the computations ( $6\text{ cm}^{-1}$ ). The intense band C2 at  $3657\text{ cm}^{-1}$  is attributed to  $\nu_f$  of the  $\text{H}_3\text{O}^+$  moiety predicted at  $3643\text{ cm}^{-1}$ , which is a unique signature of the  $\text{BN}-\text{H}^+\text{W}_2$  isomer. The discrepancy of  $+14\text{ cm}^{-1}$  is expected because the computed OH stretch bands of bare W are also underestimated by  $+18\text{ cm}^{-1}$  using the employed scaling factor. The predicted  $\nu_1$  mode ( $3626\text{ cm}^{-1}$ ) occurs in the red shoulder of band C2 (denoted band B), which has its onset

at  $3602\text{ cm}^{-1}$ . Although the calculated binding energy of the free W in  $\text{BN-H}^+\text{W}_2$  ( $D_0 = 4933\text{ cm}^{-1}$ ) exceeds the photon energy, we observe IRPD into the single W loss channel from the population of internally hot clusters. However, we do not detect any fragmentation into the BN loss channel because of the substantially higher binding energy of this ligand with larger dipole moment ( $11\,955\text{ cm}^{-1}$ ). Interestingly, during the IRPD process of  $\text{BN-H}^+\text{W}_2$  the proton must transfer (back) to BN upon W loss, *i.e.* the overall photofragmentation reaction can be written as  $\text{BN-H}^+\text{W}_2 + h\nu_{\text{IR}} \rightarrow \text{H}^+\text{BN-W(H)} + \text{W}$ .

The much less stable  $\text{H}^+\text{BN-W}_2(\text{o/m})$  and  $\text{H}^+\text{BN-W}_2(\text{m/p})$  isomers should be much colder than the assigned global minimum (because of the low binding energy of the CH-bonded W ligand of  $D_0 < 2500\text{ cm}^{-1}$ ). Hence, they can dissociate from the ground vibrational state upon single-photon absorption. However, although the IR spectra predicted for these local minima are not in serious conflict with the measured IRPD spectrum of the  $n = 2$  cluster (Fig. S11 in the ESI†), the large change between the IRPD spectra of  $n = 1$  and  $n = 2$  in Fig. 1 (in particular the disappearance of the strong band E assigned to  $\nu_{\text{NH}}^b$ ) suggests that  $n = 2$  isomers with a single W ligand solvated at the NH group do not have significant abundance. This is in line with the roughly four times lower predicted IR intensity of  $\nu_{\text{OH}}^b$  of the assigned  $\text{BN-H}^+\text{W}_2$  isomer ( $I_{\text{OH}} = 1844\text{ km mol}^{-1}$ ) as compared to  $\nu_{\text{OH}}^b$  of both  $\text{H}^+\text{BN-W}_2$  isomers ( $I_{\text{OH}} = 5597$  and  $5724\text{ km mol}^{-1}$ ). Hence, we will not consider such isomers with interior  $\text{H}^+\text{BN}$  hydration any further for the larger clusters and instead focus on structures, in which BN is attached to a H-bonded  $\text{H}^+\text{W}_n$  cluster.

### 3.4 $\text{H}^+(\text{BN-W}_3)$

Our computational search for  $\text{H}^+(\text{BN-W}_3)$  structures has resulted in two low-energy isomers of the form  $\text{BN-H}^+\text{W}_3$ , which are obtained by adding a third W ligand to the available free OH binding sites of the  $\text{BN-H}^+\text{W}_2$  global minimum (Fig. 4). This strategy of searching for  $\text{BN-H}^+\text{W}_3$  structures with the proton attached to the solvent cluster is also motivated by the much higher PA of  $\text{W}_3$  as compared to BN ( $862$  vs.  $812\text{ kJ mol}^{-1}$ ).<sup>13,15</sup> In the most stable branched  $\text{BN-H}^+\text{W}_3(\text{b})$  isomer with  $D_0 = 17\,003\text{ cm}^{-1}$  and  $C_s$  symmetry, the  $\text{H}_3\text{O}^+$  core is fully solvated by one BN and two equivalent W ligands. Similar to the corresponding  $n = 2$  cluster, the  $\text{OH}\cdots\text{N}$  H-bond to BN is still stronger ( $R = 1.548\text{ \AA}$ ,  $D_0 = 9613\text{ cm}^{-1}$ ) than each of the two  $\text{OH}\cdots\text{O}$  H-bonds to W ( $R = 1.583\text{ \AA}$ ,  $D_0 = 5146\text{ cm}^{-1}$ ) but the difference in bond length shrinks from  $154$  to  $35\text{ m\AA}$  due to the increased PA of  $\text{W}_3$ . On the other hand, the  $\text{OH}\cdots\text{O}$  and  $\text{OH}\cdots\text{N}$  H-bonds in the  $n = 3$  cluster are weaker and longer than for  $n = 2$  (by  $161$  and  $42\text{ m\AA}$ ) due to the noncooperative effect of interior  $\text{H}_3\text{O}^+$  ion solvation resulting from enhanced charge delocalization. Consequently, charge transfer to each W and BN is reduced by  $12$  and  $76\text{ me}$  to  $68$  and  $123\text{ me}$ , the  $E^{(2)}$  energies are lowered by  $111.7$  and  $339.0\text{ kJ mol}^{-1}$  to  $138.2$  and  $418.3\text{ kJ mol}^{-1}$ , and the  $-\rho^*$  values decrease from  $0.110$  and  $0.066$  to  $0.073$  and  $0.059\text{ a.u.}$ , respectively (Fig. S2–S4 in the ESI†). The intense symmetric and antisymmetric  $\nu_{\text{OH}}^b$  modes of the  $\text{H}_3\text{O}^+$  ion involved in the  $\text{OH}\cdots\text{O}$  H-bonds are strongly red-shifted to  $2946$  and  $2878\text{ cm}^{-1}$

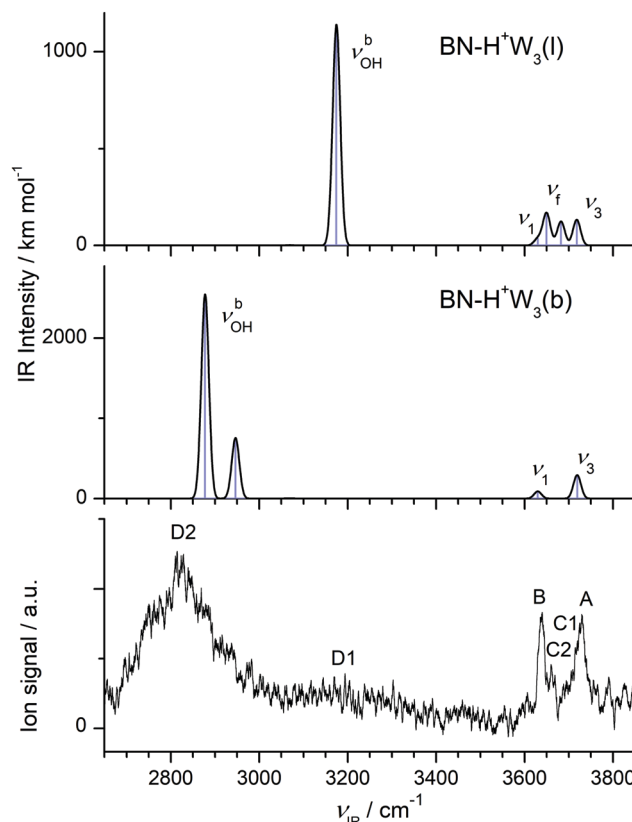

Fig. 6 Comparison of experimental IRPD spectrum of  $\text{H}^+(\text{BN-W}_3)$  with linear IR absorption spectra of the most stable  $\text{BN-H}^+\text{W}_3$  isomers (Fig. 4) calculated at the B3LYP-D3/aug-cc-pVTZ level.

( $I_{\text{OH}} = 758$  and  $2548\text{ km mol}^{-1}$ , Fig. 6), and this red shift and IR oscillator strength are even higher for the  $\nu_{\text{OH}}^b$  mode of the  $\text{OH}\cdots\text{N}$  H-bond ( $\nu_{\text{NH}}^b = 2424\text{ cm}^{-1}$ ,  $I_{\text{NH}} = 5374\text{ km mol}^{-1}$ ). Compared to the  $n = 2$  case, the  $\text{OH}\cdots\text{N}$  H-bond is more asymmetric for  $n = 3$ , with the excess proton sticking more strongly to  $\text{W}_3$ , as reflected in the shorter O–H bond ( $1.1065$  vs.  $1.0343\text{ \AA}$ ). In this branched isomer, the O–H bonds of the two equivalent W ligands do not participate in H-bonding and thus their coupled OH stretch modes appear as  $\nu_{1/3}$  bands near  $3630$  and  $3719\text{ cm}^{-1}$ , *i.e.* slightly blue-shifted by further  $5\text{ cm}^{-1}$  from the corresponding  $n = 2$  modes. The  $\text{BN-H}^+\text{W}_3(\text{b})$  isomer is essentially an Eigen ion ( $\text{H}_9\text{O}_4^+ = \text{H}^+\text{W}_4 = \text{H}_3\text{O}^+-\text{W}_3$ , Fig. S10 in the ESI†),<sup>69,106</sup> in which one W ligand is replaced by BN, resulting in a slightly asymmetric solvent configuration due to the larger dipole moment of BN. Similar to the  $n = 2$  case, also in the  $\text{BN-H}^+\text{W}_3(\text{b})$  structure the substitution of W by BN results in a destabilization of the remaining  $\text{OH}\cdots\text{O}$  H-bonds (from  $1.551$  to  $1.583\text{ \AA}$ ).

In the  $\text{BN-H}^+\text{W}_3(\text{l})$  isomer with a linear H-bonded  $\text{H}^+\text{W}_3$  chain, the central  $\text{H}_3\text{O}^+$  ion is only twofold solvated by BN and a  $\text{W}_2$  dimer. Because of the incomplete solvation of the  $\text{H}_3\text{O}^+$  ion, this isomer is less stable than  $\text{BN-H}^+\text{W}_3(\text{b})$  by  $\Delta E_0 = 1016\text{ cm}^{-1}$ . In this linear isomer, the  $\text{OH}\cdots\text{N}$  bond is much weaker and longer than the  $\text{OH}\cdots\text{O}$  bond to  $\text{W}_2$  ( $1.502$  vs.  $1.383\text{ \AA}$ ), because the PA of  $\text{W}_2$  is similar to that of BN but the solvation energy of  $\text{W}_2$  is larger than for BN. Both corresponding  $\nu_{\text{OH}}^b$  frequencies ( $2268$  and  $2254\text{ cm}^{-1}$ ) of the O–H proton donor bonds are below

the available IR photon energy. The remaining free O–H bond of the  $\text{H}_3\text{O}^+$  ion is shorter than the two H-bonded ones, with a  $\nu_f$  mode predicted at  $3650\text{ cm}^{-1}$  (Fig. 6). The remote W acts only as H-bond acceptor, whose  $\nu_1$  and  $\nu_3$  modes appear at  $3630$  and  $3718\text{ cm}^{-1}$ , respectively. The remaining middle neutral W ligand participates in H-bond formation as a single donor and single acceptor (DA) with one free and one H-bonded OH stretch,  $\nu_f = 3682$  and  $\nu_{\text{OH}}^b = 3175\text{ cm}^{-1}$ . The  $\text{BN-H}^+\text{W}_3(\text{I})$  isomer is essentially a twofold hydrated Zundel ion ( $\text{H}^+\text{W}_2\text{-W}_2 = \text{H}_5\text{O}_2^+ \text{-W}_2$ ),<sup>69,70,107</sup> in which one terminal W ligand is replaced by BN, resulting in a strongly asymmetric configuration of the Zundel ion with the excess proton localized at the W molecule next to BN, because the PA of BN is larger than the one of a single W ligand. Because of strong cooperative effects induced by the polarization of the nearby positive charge,<sup>82</sup> the  $\text{OH}\cdots\text{O}$  bond in the  $\text{W}_2$  unit in  $\text{BN-H}^+\text{W}_3(\text{I})$  is much stronger and shorter ( $D_0 = 4130\text{ cm}^{-1}$ ,  $R = 1.677\text{ \AA}$ ) than in bare  $\text{W}_2$  ( $D_0 = 1003\text{ cm}^{-1}$ ,  $R = 1.947\text{ \AA}$ ).<sup>88</sup>

The IRPD spectrum of  $\text{H}^+(\text{BN-W}_3)$  is compared in Fig. 6 to the IR spectra predicted for the two considered  $\text{BN-H}^+\text{W}_3$  isomers. The measured IRPD spectrum is dominated by the three peaks A, B, and D2 at  $3729$ ,  $3640$ , and  $2815\text{ cm}^{-1}$ , which can be assigned in a straightforward way to the  $\nu_3$ ,  $\nu_1$ , and two overlapping  $\nu_{\text{OH}}^b$  transitions of the branched  $\text{BN-H}^+\text{W}_3(\text{b})$  global minimum predicted at  $3719$ ,  $3631/3630$ , and  $2946/2878\text{ cm}^{-1}$ , respectively. Part of the signal in the blue tail of the H-bonded  $\nu_{\text{OH}}^b$  bands near  $3200\text{ cm}^{-1}$  (denoted D1) may arise from bending overtones ( $2\nu_{\text{OH}}$ ) of the W ligands, which are not included in the harmonic simulations (but predicted at  $3197$  and  $3201\text{ cm}^{-1}$  using  $0.98$  as scaling factor). While the contribution of the branched global minimum to the IRPD spectrum is obvious, the indication for the presence of the linear  $\text{BN-H}^+\text{W}_3(\text{I})$  local minimum is at first glance less certain. Its unique intense  $\nu_{\text{OH}}^b$  transition predicted at  $3175\text{ cm}^{-1}$  may contribute to the plateau near  $3200\text{ cm}^{-1}$  (D1), and its  $\nu_f$  mode at  $3682\text{ cm}^{-1}$

(band C1 at  $3694\text{ cm}^{-1}$ ) may be blended by the red wing of the  $\nu_3$  bands of the branched isomer (A). Its  $\nu_{1/3}$  modes overlap with those of the branched isomers (bands A and B). Band C2 observed at  $3660\text{ cm}^{-1}$  is considered as the clearest signature of the linear isomer arising from the free OH stretch mode of the incompletely solvated  $\text{H}_3\text{O}^+$  core ion. Its frequency is similar to the corresponding mode of the  $\text{BN-H}^+\text{W}_2$  ion both experimentally ( $+3\text{ cm}^{-1}$ ) and computationally ( $+7\text{ cm}^{-1}$ ), which occurs as a single isomer, thus confirming this interpretation. In conclusion, the  $\text{H}^+(\text{BN-W}_3)$  spectrum is dominated by the branched  $\text{BN-H}^+\text{W}_3(\text{b})$  global minimum, while the less stable linear  $\text{BN-H}^+\text{W}_3(\text{I})$  local minimum has a smaller population (estimated to be  $\leq 20\%$  from the ratio of the integrated peak intensities of bands C2 and B and the corresponding calculated IR cross sections), consistent with the lower thermochemical stability ( $\Delta E_0 = 1016\text{ cm}^{-1}$ ).

### 3.5 $\text{H}^+(\text{BN-W}_4)$

Starting from the  $n = 3$  case, we find two related low-energy structural isomers for  $n = 4$ , namely the branched  $\text{BN-H}^+\text{W}_4(\text{b})$  global minimum and the linear  $\text{BN-H}^+\text{W}_4(\text{I})$  local minimum (Fig. 7). The  $\text{BN-H}^+\text{W}_4(\text{b})$  isomer has an Eigen-type structure with BN and two W ligands in the first complete solvation shell around  $\text{H}_3\text{O}^+$  and one W ligand in the second shell. The  $\text{OH}\cdots\text{O}$  H-bond to the  $\text{W}_2$  unit is stronger than that to W ( $R = 1.480$  vs.  $1.612\text{ \AA}$ ). The addition of W in the second shell leads to an elongation of both the  $\text{OH}\cdots\text{O}$  H-bond to the single W ( $\Delta R = 29\text{ m\AA}$ ) and the  $\text{OH}\cdots\text{N}$  H-bond to BN ( $\Delta R = 46\text{ m\AA}$ ), because of the noncooperative effects of interior ion solvation. On the other hand, the  $\text{OH}\cdots\text{O}$  H-bond to the  $\text{W}_2$  unit contracts ( $\Delta R = -103\text{ m\AA}$ ), because of the cooperative effects arising from forming the H-bonded network (and the higher PA of  $\text{W}_2$  compared to W). As a result,  $\text{W}_2$  drags more positive charge from  $\text{H}_3\text{O}^+$  ion than the single W ( $\Delta q = 105$  vs.  $62\text{ me}$ , Fig. S2 in the ESI<sup>†</sup>), and the corresponding  $\nu_{\text{OH}}^b$  mode is more red-shifted

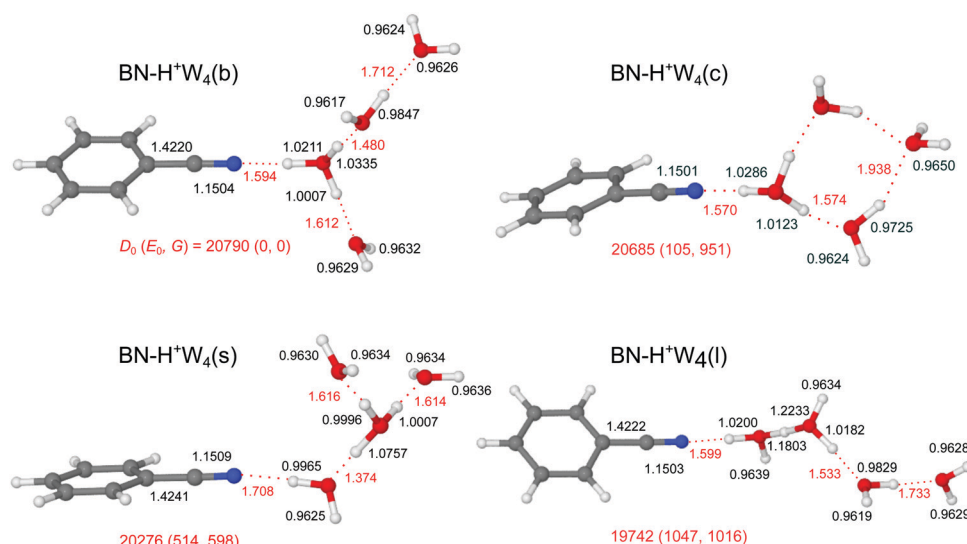

Fig. 7 Optimized structures of  $\text{BN-H}^+\text{W}_4$  calculated at the B3LYP-D3/aug-cc-pVTZ level. Binding energies ( $D_0$ ) and bond lengths are given in  $\text{cm}^{-1}$  and  $\text{\AA}$ , respectively. Numbers in parentheses correspond to relative energies and free energies in  $\text{cm}^{-1}$  ( $E_0$ ,  $G$ ).

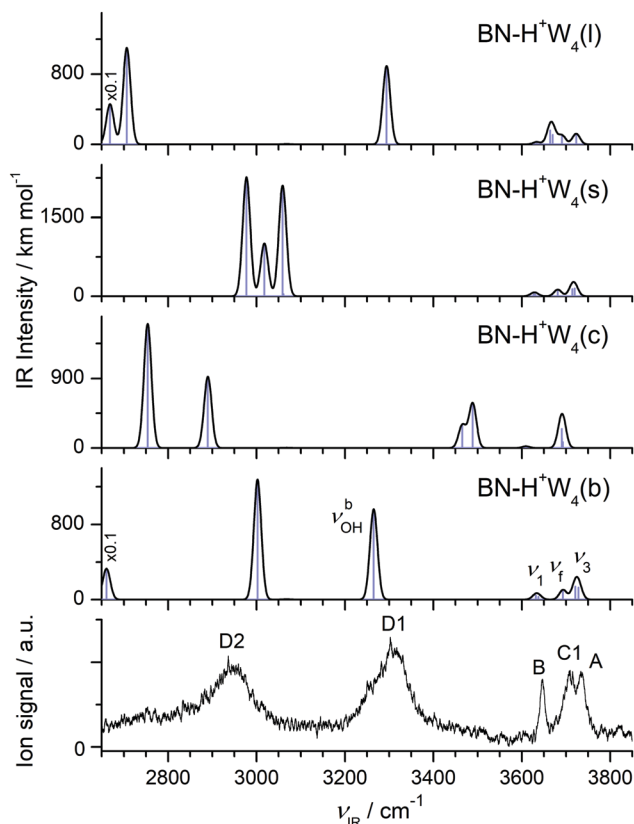

Fig. 8 Comparison of experimental IRPD spectrum of  $\text{H}^+(\text{BN}-\text{W}_4)$  with linear IR absorption spectra of the low-energy  $\text{BN}-\text{H}^+\text{W}_4$  isomers (Fig. 7) calculated at the B3LYP-D3/aug-cc-pVTZ level. High computed IR intensities are multiplied with a factor of 0.1 to display the weak features.

(2431 vs. 3002  $\text{cm}^{-1}$ ). The enhanced solvation of the  $\text{H}_3\text{O}^+$  ion in  $\text{BN}-\text{H}^+\text{W}_4(\text{b})$  as compared to  $\text{BN}-\text{H}^+\text{W}_3(\text{b})$  weakens the  $\text{OH} \cdots \text{N}$  H-bond further ( $R = 1.594$  vs.  $1.548$  Å) and reduces the charge transfer to BN (from 123 to 104 me) as well as the  $E^{(2)}$  energy (from 418.3 to 349.1  $\text{kJ mol}^{-1}$ ) and the  $-\rho^*$  value (from 0.073 to 0.065 a.u.), as documented in Fig. S2–S4 in the ESI.† Moreover, the O–H donor bond becomes shorter (by 13.2 mÅ) and its  $\nu_{\text{OH}}^{\text{b}}$  mode is blue-shifted from 2424 to 2661  $\text{cm}^{-1}$ . The two OH groups of the two remaining W ligands remain free. However, the  $\nu_1$  and  $\nu_3$  modes of W in the first solvation shell have a slightly lower frequency than those in the second shell (3632 vs. 3638  $\text{cm}^{-1}$ , 3721 vs. 3728  $\text{cm}^{-1}$ ) due to the smaller distance from the excess charge. The remaining partially solvated W has one free  $\nu_{\text{f}}$  mode (3693  $\text{cm}^{-1}$ ) and one red-shifted  $\nu_{\text{OH}}^{\text{b}}$  mode (3265  $\text{cm}^{-1}$ ).

Unlike  $\text{BN}-\text{H}^+\text{W}_3(\text{l})$  with a partially solvated  $\text{H}_3\text{O}^+$  core, the linear  $\text{BN}-\text{H}^+\text{W}_4(\text{l})$  local minimum contains a twofold solvated Zundel ion ( $\text{H}_5\text{O}_2^+$ ). Partial solvation of  $\text{H}_5\text{O}_2^+$  with  $\text{W}_2$  and BN makes the linear isomer substantially less stable than the branched isomer ( $E_0 = 1047$   $\text{cm}^{-1}$ ). The  $\nu_1$  and  $\nu_3$  modes of the terminal W are predicted at 3634 and 3723  $\text{cm}^{-1}$ , whereas  $\nu_{\text{f}}$  of the partially solvated W and the central  $\text{H}_5\text{O}_2^+$  appear at 3691, 3670, and 3664  $\text{cm}^{-1}$  (Fig. 8). The corresponding H-bonded  $\nu_{\text{OH}}^{\text{b}}$  frequencies are 3294 (to W), 2707 (to  $\text{W}_2$ ), and 2669 (to BN)  $\text{cm}^{-1}$ , consistent with the O–H and  $\text{OH} \cdots \text{O}$  bond lengths.

Motivated by the three lowest-energy structures identified for  $\text{H}^+\text{W}_5$  by IR–IR double-resonance spectroscopy,<sup>75</sup> denoted ring (R), branched (B), and chain (C), with relative energies of  $E_0 = 0, 0.6$ , and  $11.6$   $\text{kJ mol}^{-1}$  (0, 50, 970  $\text{cm}^{-1}$ ) using the very same B3LYP-D3/aug-cc-pVTZ level as used herein ( $E_0 = 100, 0, 825$   $\text{cm}^{-1}$ , Fig. S10 in the ESI†), we find two further low-energy  $\text{BN}-\text{H}^+\text{W}_4$  isomers by simply replacing a W unit with BN, namely a cyclic one (isomer c) and a surface one (isomer s). The linear and branched isomers of  $\text{BN}-\text{H}^+\text{W}_4$  discussed above are derived from the B and C isomers of  $\text{H}^+\text{W}_5$ . The  $\text{BN}-\text{H}^+\text{W}_4(\text{s})$  isomer with  $E_0 = 514$   $\text{cm}^{-1}$ , also resulting from the B isomer of  $\text{H}^+\text{W}_5$ , is essentially an Eigen ion solvated by BN, *i.e.* it differs from the branched global minimum such that BN is located in the second solvation shell of  $\text{H}_3\text{O}^+$ , *i.e.* at the surface of the  $\text{H}^+\text{W}_4$  Eigen cluster. It is less stable than the b isomer, because BN with its higher dipole moment is further away from the positive charge. As a result, the  $\text{OH} \cdots \text{N}$  H-bond of  $\text{H}^+\text{W}_4$  to BN is weaker and longer (1.708 vs. 1.594 Å). Clearly, both branched isomers (b and s) have very different IR spectra (Fig. 8), in particular in the H-bonded range.

The cyclic  $\text{BN}-\text{H}^+\text{W}_4(\text{c})$  isomer with  $E_0 = 105$   $\text{cm}^{-1}$  and  $C_s$  symmetry results from the R isomer of  $\text{H}^+\text{W}_5$ . It differs from the most stable branched isomer such that the W ligand in the second solvation shell is not forming a single H-bond to the  $\text{BN}-\text{H}^+\text{W}_3$  ion core but acts as a double acceptor with two weak H-bonds which close the cyclic  $\text{H}^+\text{W}_4$  ring in  $\text{BN}-\text{H}^+\text{W}_4(\text{c})$ . This cyclic structure has also a very characteristic IR spectrum with two OH stretch bands of these two weak H-bonds occurring near 3500  $\text{cm}^{-1}$ , a strong single free OH stretch band near 3690  $\text{cm}^{-1}$  (arising from the overlapping coupled  $\nu_{\text{f}}$  modes of the two W molecules in the ring at 3693 and 3691  $\text{cm}^{-1}$ ), and strongly red-shifted  $\nu_{\text{OH}}^{\text{b}}$  modes of the  $\text{H}_3\text{O}^+$  core.

The comparison of the IRPD spectrum of  $\text{H}^+(\text{BN}-\text{W}_4)$  to the IR spectra predicted for the four considered stable  $\text{BN}-\text{H}^+\text{W}_4$  isomers in Fig. 8 provides a clear indication for the predominant presence of the most stable branched isomer (b). There is a good match of the intense broad peaks D1 and D2 at 3310 and 2955  $\text{cm}^{-1}$  with the characteristic  $\nu_{\text{OH}}^{\text{b}}$  modes of  $\text{BN}-\text{H}^+\text{W}_4(\text{b})$  predicted at 3265 and 3002  $\text{cm}^{-1}$ , respectively. There is a similar good match between the free OH stretch peaks observed at 3646 (B), 3733 (A), and 3706  $\text{cm}^{-1}$  (C1) with  $\nu_1$  (3632/3638  $\text{cm}^{-1}$ ),  $\nu_3$  (3721/3728  $\text{cm}^{-1}$ ), and  $\nu_{\text{f}}$  (3693  $\text{cm}^{-1}$ ) of this isomer. We do not observe  $\nu_{\text{OH}}^{\text{b}}$  of the  $\text{OH} \cdots \text{N}$  moiety predicted at 2661  $\text{cm}^{-1}$ , probably owing to the low laser power in that range and/or the large anharmonicity of this mode. While band D2 is a clear indicator for the presence of the branched isomer, the possible contribution of the linear isomer is less certain, because of substantial overlap of its predicted bands with those of the branched isomer within the achieved spectral resolution. This concerns particularly bands D1 ( $\nu_{\text{OH}}^{\text{b}}$ ), B ( $\nu_1$ ), A ( $\nu_3$ ), and C1 ( $\nu_{\text{f}}$  of  $\text{W}_2$  unit). However, no pronounced signal is observed in the range of the two  $\nu_{\text{f}}$  modes of the  $\text{H}_5\text{O}_2^+$  unit (C2), which are the strongest modes predicted in the free OH stretch range at 3664/3670  $\text{cm}^{-1}$  (expected at 3682/3688  $\text{cm}^{-1}$  when accounting for the deficiency of the employed scaling factor) and characteristic of this isomer. In addition, the characteristic

bands predicted for the cyclic isomer near 3500 and 2800  $\text{cm}^{-1}$  are missing (or lost in the broader background) in the IRPD spectrum indicating that this isomer does also not contribute substantially to the observed ion population. Similarly, significant population of the surface isomer can be excluded, because of the comparable intensities of the intense bands D1 and D2 in the experimental spectrum and the lack of any transition predicted for this isomer in the vicinity of band D1 near 3300  $\text{cm}^{-1}$ . Thus, we conclude that the experimental IRPD spectrum is mostly dominated by the branched global minimum, while the population of the linear, cyclic, and surface isomers is at most minor, in line with the thermochemical data ( $D_0$ ,  $E_0$ ,  $G$ ).

### 3.6 $\text{H}^+(\text{BN}-\text{W}_5)$

Similar to bare  $\text{H}^+\text{W}_n$  clusters, the number of low-energy competing isomers increases drastically with size for the  $\text{H}^+(\text{BN}-\text{W}_n)$  clusters with  $n \geq 5$ , because of the various possibilities for the structure of the H-bonded hydration network and the position of the BN molecule within the cluster. Because the PA of BN is much lower than that of  $\text{W}_5$  (812 vs. 904  $\text{kJ mol}^{-1}$ ),<sup>13,15</sup> the excess proton is attached to the water cluster for all considered isomers,  $\text{BN}-\text{H}^+\text{W}_n$ . Starting from the most stable structures of  $\text{BN}-\text{H}^+\text{W}_4$ , and considering the low-energy  $\text{H}^+\text{W}_6$  structures with replacement of one W by BN (Fig. S10 in the ESI†),<sup>71,74,76</sup>

our computations yield three low-energy branched structures for the  $n = 5$  cluster, denoted b1–b3 (Fig. 9). In the b1 isomer ( $E_0 = 132 \text{ cm}^{-1}$ ), an  $\text{H}_3\text{O}^+$  core is fully solvated by BN and two  $\text{W}_2$  dimers. It may be derived from simple addition of BN to the chain isomer (C) of  $\text{H}^+\text{W}_5$ .<sup>75</sup> It is essentially an Eigen-type ion, with BN in the first shell of a fully solvated  $\text{H}_3\text{O}^+$  ion and two W ligands in the second shell. It may thus also be derived from the Eigen isomer of  $\text{H}^+\text{W}_6$  (6E) by simply replacing one W by BN in the first shell.<sup>76</sup> In the significantly less stable b3 isomer ( $E_0 = 575 \text{ cm}^{-1}$ ), the  $\text{H}_3\text{O}^+$  core is fully solvated by BN, W, and a linear  $\text{W}_3$  trimer, while in the somewhat more stable related b2 isomer ( $E_0 = 294 \text{ cm}^{-1}$ ), the linear  $\text{W}_3$  unit is replaced by a branched structure. Actually, the b2 isomer can also be viewed as a strongly distorted Zundel ion, which is fourfold solvated by BN and three single W ligands, and is thus derived from the Zundel isomer of  $\text{H}^+\text{W}_6$  (6Z) by replacing one W by BN.<sup>76</sup> In the three branched isomers, the  $\text{H}_3\text{O}^+$  (or distorted  $\text{H}_5\text{O}_2^+$ ) ion bearing the positive charge is fully solvated by neutral ligands, which optimizes the electrostatic and induction forces. Like for the  $n = 3$  and 4 clusters, the linear isomer of  $n = 5$  is substantially less stable than the branched isomers ( $E_0 = 1656 \text{ cm}^{-1}$ ), because it contains an  $\text{H}_3\text{O}^+$  core ion with a free O–H bond (Fig. S12 in the ESI†).

Interestingly,  $n = 5$  is the first cluster size, in which the branched structures are not the global minima at  $T = 0 \text{ K}$ .

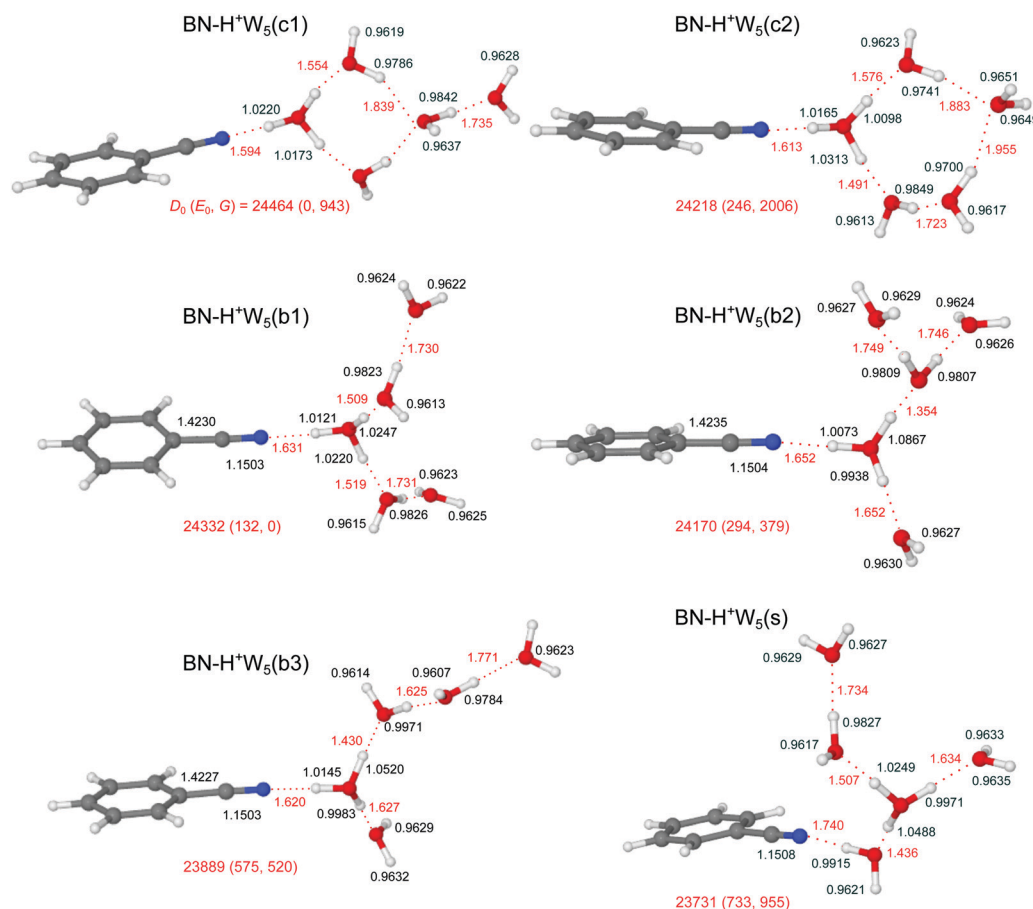

Fig. 9 Optimized structures of  $\text{BN}-\text{H}^+\text{W}_5$  calculated at the B3LYP-D3/aug-cc-pVTZ level. Binding energies ( $D_0$ ) and bond lengths are given in  $\text{cm}^{-1}$  and Å, respectively. Numbers in parentheses correspond to relative energies and free energies in  $\text{cm}^{-1}$  ( $E_0$ ,  $G$ ).

Instead, the cyclic c1 and c2 isomers, in which BN binds to a four- or five-membered  $\text{H}^+\text{W}_{4/5}$  ring become very low in energy ( $E_0 = 0$  and  $246\text{ cm}^{-1}$ ), because they exhibit one more H-bond than the branched isomers. Interestingly, at room temperature, still the branched b1 isomer is most stable, because it is most flexible and not as rigid as the cyclic structures. In the lowest-energy cyclic  $\text{BN-H}^+\text{W}_5(\text{c1})$  isomer, which is the global minimum at  $T = 0\text{ K}$  ( $E_0 = 0$ ), BN binds to the  $\text{H}_3\text{O}^+$  ion of a cyclic  $\text{H}^+\text{W}_4$  unit, while the fifth W is attached at the opposite site. Because this structure is quite rigid, the entropic contribution implies a quite high free energy for this isomer ( $G = 943\text{ cm}^{-1}$ ). The c1 isomer is derived from the ring isomer (R) of  $\text{H}^+\text{W}_5$  by simple addition of BN and exchanging BN and W such that BN is attached to  $\text{H}_3\text{O}^+$ .<sup>75</sup> In the similar  $\text{BN-H}^+\text{W}_5(\text{c2})$  isomer, BN binds to the  $\text{H}_3\text{O}^+$  ion of a cyclic  $\text{H}^+\text{W}_5$  unit, which is also characterized by low relative energy and high free energy ( $E_0 = 113\text{ cm}^{-1}$ ,  $G = 2006\text{ cm}^{-1}$ ). Finally, we consider one low-energy isomer with BN located on the surface of a branched Eigen-type  $\text{H}^+\text{W}_5$  cluster. This  $\text{BN-H}^+\text{W}_5(\text{s})$  isomer is derived from simple addition of BN to the most stable branched isomer (B) of  $\text{H}^+\text{W}_5$  or from  $\text{W} \rightarrow \text{BN}$  substitution of the 6E isomer of  $\text{H}^+\text{W}_6$ .<sup>75,76</sup> It is rather high in relative energy ( $E_0 = 600\text{ cm}^{-1}$ ), because BN with its high dipole moment is solvated in the second shell of the central  $\text{H}_3\text{O}^+$  cation, resulting in a weaker and much longer  $\text{OH} \cdots \text{N}$  H-bond compared to the other isomers in Fig. 9, in which BN is located in the first solvation shell. The shape of the solvation network in the various  $\text{BN-H}^+\text{W}_5$  isomers and the strengths of the individual H-bonds resulting from the cooperative and noncooperative effects described for the smaller clusters (resulting from PA values for BN and the  $\text{W}_m$  fragment units) are directly reflected in the O–H bond lengths and corresponding free and bound OH stretch frequencies (and IR intensities), the resulting effects on the charge distribution, and the NBO and NCI analyses discussed in detail for the smaller clusters.

The IRPD spectrum measured for  $\text{H}^+(\text{BN-W}_5)$  is compared in Fig. 10 to the IR spectra predicted for the six stable  $\text{BN-H}^+\text{W}_5$  isomers shown in Fig. 9 (b1–b3, s, c1/c2), while the comparison with the IR spectrum of the much less stable linear  $\text{BN-H}^+\text{W}_5(\text{l})$  isomer is available in Fig. S12 in the ESI.† At first glance, the measured IRPD spectrum is consistent with the one of the most stable branched structures (b1). Following this scenario, the bands B ( $3646\text{ cm}^{-1}$ ) and A ( $3729\text{ cm}^{-1}$ ) are assigned to the  $\nu_1$  ( $3640/3639\text{ cm}^{-1}$ ) and  $\nu_3$  modes ( $3731/3730\text{ cm}^{-1}$ ) of the free W ligands in the second shell of  $\text{H}_3\text{O}^+$ , each acting as a single acceptor (A). Transition C1 at  $3711\text{ cm}^{-1}$  corresponds to the overlapping  $\nu_f$  modes of the two W ligands in the first shell around  $\text{H}_3\text{O}^+$ , which are single-donor single-acceptor molecules (DA). Peak D1 at  $3357\text{ cm}^{-1}$  agrees well with the  $\nu_{\text{OH}}^b$  modes of these DA ligands in their neutral  $\text{OH} \cdots \text{O}$  H-bonds predicted at  $3307$  and  $3301\text{ cm}^{-1}$ . The IRPD spectrum of the  $n = 5$  cluster shows a continuous absorption below  $3300\text{ cm}^{-1}$ , with weak peak maxima at  $2990$  (D3) and  $3116$  (D2)  $\text{cm}^{-1}$ . Comparison with the  $n = 4$  spectrum and the calculations indicates that the latter frequencies are consistent with  $\nu_{\text{OH}}^b$  modes of a  $\text{H}_3\text{O}^+$  core with an  $\text{OH} \cdots \text{O}$  bond to a single W ligand. Such a bonding

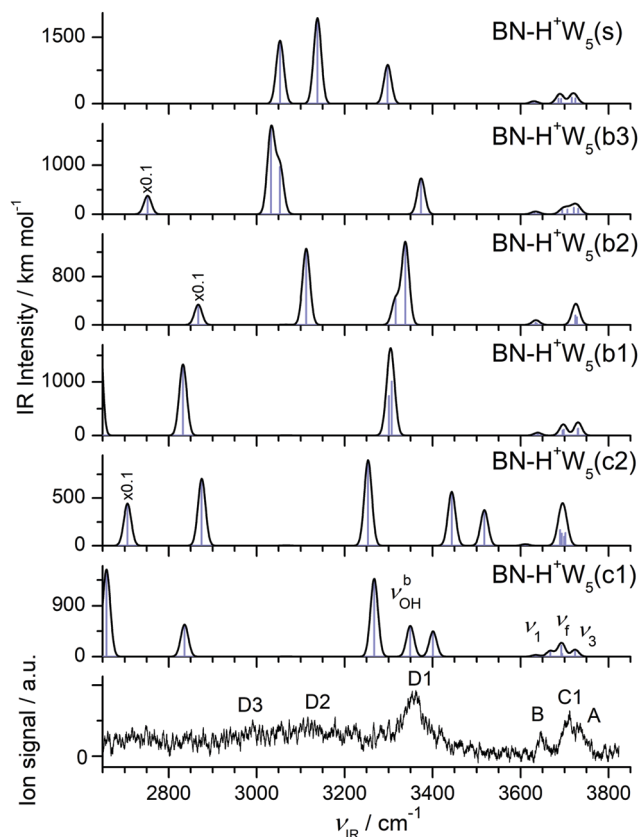

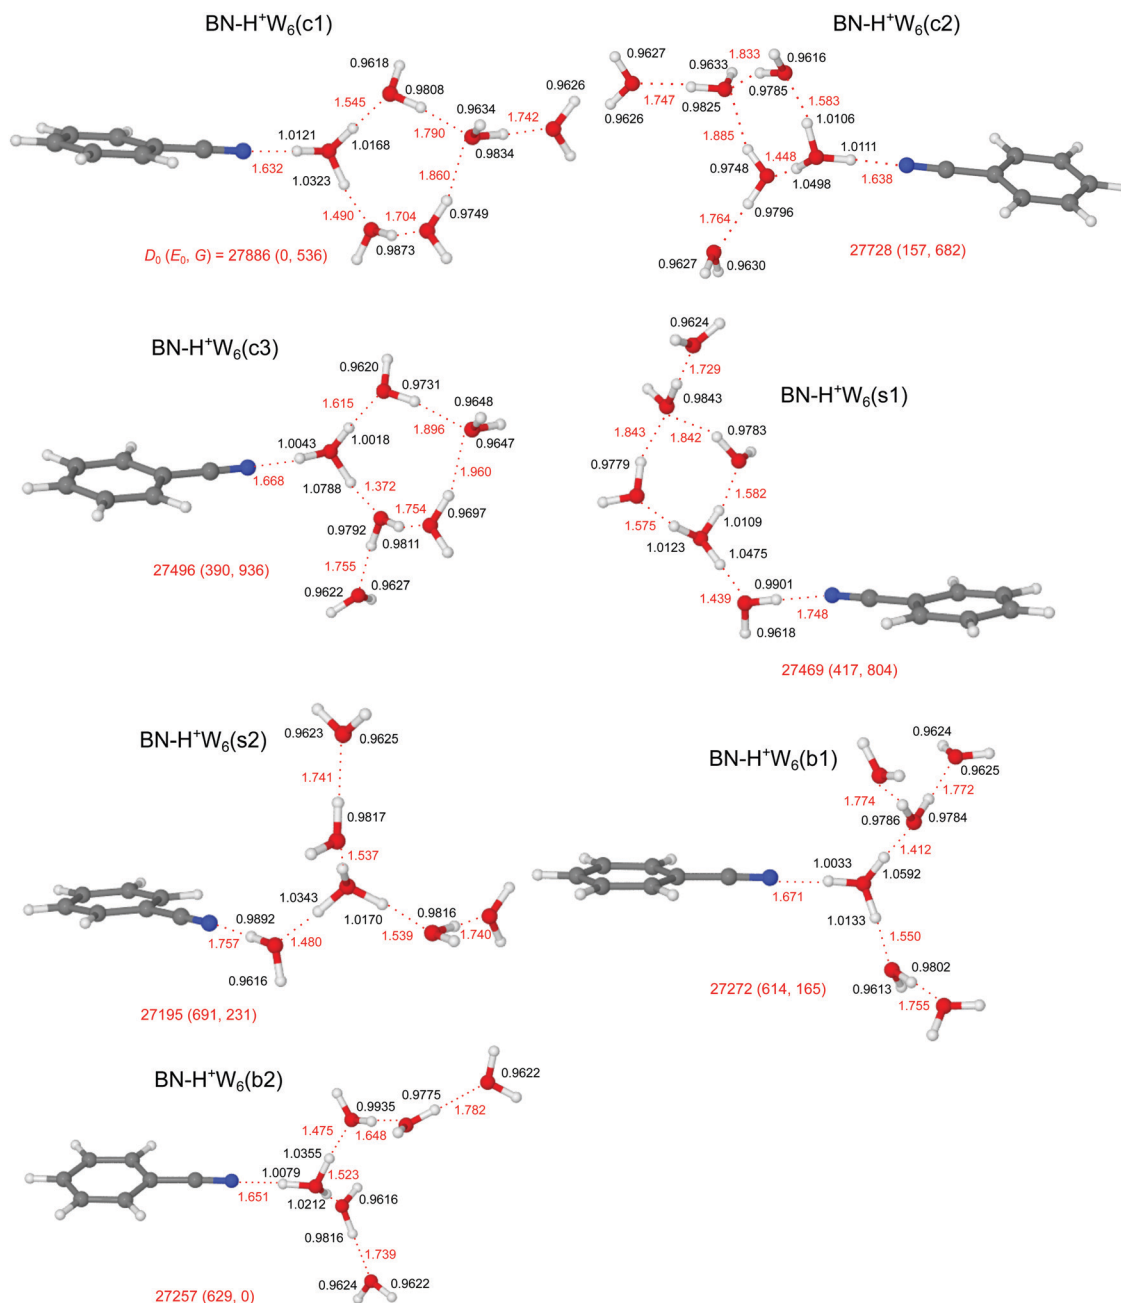

Fig. 10 Comparison of experimental IRPD spectrum of  $\text{H}^+(\text{BN-W}_5)$  with linear IR absorption spectra of the  $\text{BN-H}^+\text{W}_5$  isomers (Fig. 9) calculated at the B3LYP-D3/aug-cc-pVTZ level. High computed IR intensities are multiplied with a factor of 0.1 to display the weak features.

situation is not apparent in the b1 isomer but in the b2 and b3 isomers. Hence, these transitions may indicate a minor population of the b2/b3 structures. The pattern observed in the free OH stretch range suggests that the b2 and b3 isomers are not the dominant species. For example, the b2 structure does not possess neutral W ligands with a single dangling OH group (DA) and thus lacks the C1 band, which is the most intense transition observed in the more reliable free OH stretch range. To this end, transition D2 can only be attributed to  $\nu_{\text{OH}}^b$  of the b3 isomer when considering merely branched isomers. The remaining  $\nu_{\text{OH}}^b$  transitions of the b1 isomer predicted in the considered spectral range are the two OH stretches of the  $\text{H}_3\text{O}^+$  core binding more strongly to BN ( $2833\text{ cm}^{-1}$ ) and the two  $\text{W}_2$  units ( $2637$  and  $2548\text{ cm}^{-1}$ ). The latter modes are probably too low in frequency to be detected, while the former one may contribute to band D3 and the associated background. Part of the signal contributing to band D2 may also arise from bending overtones of the W ligands ( $2\beta_{\text{OH}}$ ). Interestingly, the spectrum predicted for the surface isomer,  $\text{BN-H}^+\text{W}_5(\text{s})$ , is also consistent with the measured spectrum, in particular when comparing only the peak positions of the bound and free OH stretch bands. Hence, we can not exclude a substantial contribution of this isomer to the observed ion population, although its relative energy is quite high at both  $T = 0$  and  $298\text{ K}$  ( $E_0 = 733$  and  $G = 955\text{ cm}^{-1}$ ).

However, this isomer can be formed by simple attachment of BN to the surface of the most stable preformed  $\text{H}^+\text{W}_5$  cluster (or by ligand exchange with  $\text{H}^+\text{W}_6$ ), and can be kinetically trapped in this geometry behind significant isomerization barriers upon rapid cooling. This scenario is supported by the similarity of the IRPD spectra recorded for  $\text{BN-H}^+\text{W}_5$  and  $\text{H}^+\text{W}_6$  recorded at high temperature.<sup>71</sup> Substantial contributions of the cyclic  $\text{BN-H}^+\text{W}_5(\text{c}2)$  isomer may be excluded because the IRPD spectrum lacks any of the transitions near 3450 and 3520  $\text{cm}^{-1}$  characteristic for this ring-like configuration. In addition, its predicted free OH stretch spectrum with a single dominant band is inconsistent with

the experimental pattern. The same arguments apply also to the most stable  $\text{BN-H}^+\text{W}_5(\text{c}1)$  isomer, whose spectrum shows a mismatch in the pattern in both the free and bound OH stretch range. Along a similar line, the much less stable linear isomer can be excluded as a major contributor, although the overall pattern of the predicted spectrum is compatible with the measured one. Apart from its high relative energy ( $E_0 = 1788 \text{ cm}^{-1}$ ), its characteristic free OH stretches of the Zundel core expected between 3676 and 3700  $\text{cm}^{-1}$  (such as band C2 for  $n = 2$  and 3) are not observed. Although there is good overall agreement of the experimental IRPD spectrum with the IR spectrum predicted for the most stable

**Fig. 11** Optimized structures of  $\text{BN-H}^+\text{W}_6$  calculated at the B3LYP-D3/aug-cc-pVTZ level. Binding energies ( $D_0$ ) and bond lengths are given in  $\text{cm}^{-1}$  and Å, respectively. Numbers in parentheses correspond to relative energies and free energies in  $\text{cm}^{-1}$  ( $E_0$ ,  $G$ ).

branched  $\text{BN-H}^+\text{W}_5(\text{b1})$  isomer, minor contributions of the less stable branched b2 and b3 isomers as well as the kinetically-trapped surface isomer cannot be ruled out because a similar match of their predicted IR spectra and the IRPD spectrum. As a conclusion, we prefer to assign the IRPD spectrum mostly to the b1 minimum, with possibly minor contributions of the s and b2/b3 isomers, while substantial contributions of the low-energy cyclic isomers are not evident.

### 3.7 $\text{H}^+(\text{BN-W}_6)$

The potential energy surface of  $\text{H}^+(\text{BN-W}_6)$  is getting very complex, as is also illustrated by the large number of computed ( $\geq 14$ ) and detected (4)  $\text{H}^+\text{W}_7$  isomers.<sup>71,77</sup> Starting by (i) adding one more W ligand to the lowest-energy isomers of  $\text{BN-H}^+\text{W}_5$  or (ii) replacing one W by BN in the most stable structures of  $\text{H}^+\text{W}_7$ ,<sup>71,77</sup> or (iii) adding one W to the identified two isomers of  $\text{H}^+\text{W}_6$ ,<sup>71,74,76</sup> we obtain for  $\text{BN-H}^+\text{W}_6$  the two branched (b1/b2), three cyclic (c1–c3), and two surface (s1/s2) structures, along with one linear isomer, as shown in Fig. 11 and Fig. S13 in the ESI.† Clearly, the large difference in PA of BN and  $\text{W}_6$  of 96.5  $\text{kJ mol}^{-1}$  implies that the excess proton remains with the solvent network. In all considered branched and cyclic structures, the  $\text{H}_3\text{O}^+$  ion is fully solvated, and BN is located in the first solvation shell due to its large dipole moment. In the branched structures,  $\text{H}_3\text{O}^+$  is solvated by BN,  $\text{W}_2$ , and  $\text{W}_3$  (either branched or linear, b1 and b2,  $E_0 = 614$  and  $629 \text{ cm}^{-1}$ ). The quite similar b1 and b2 isomers are essentially isoenergetic, whereby b1 is slightly more stable at  $T = 0 \text{ K}$  (by  $15 \text{ cm}^{-1}$ ) because the W ligands are closer to the charge. Similar to  $n = 5$ , the branched structures are not the global minima for the  $n = 6$  clusters at  $T = 0 \text{ K}$ . Instead, the four lowest-energy structures c1–c3 and s1 considered here have cyclic hydration rings, because they exhibit one more H-bond than the branched (and linear) isomers. In the c1 and c3 isomers ( $E_0 = 0$  and  $390 \text{ cm}^{-1}$ ), BN and W bind to a five-membered  $\text{H}^+\text{W}_5$  ring, while in the c2 (s1) isomer BN and two W (or BN–W and W) are attached to a four-membered  $\text{H}^+\text{W}_4$  ring ( $E_0 = 157$  and  $417 \text{ cm}^{-1}$ ). Interestingly, at room temperature, still the branched b2 isomer is most stable, because it is most flexible and not as rigid as the cyclic structures. Finally, at this cluster size, also the surface-solvated isomers become quite competitive, with  $E_0 = 417$  and  $691 \text{ cm}^{-1}$  for s1 and s2, because for larger clusters the advantage of the higher dipole moment of BN is partly compensated by the possibility of W to form a larger number of H-bonds (up to four) compared to BN (only one). The formation of H-bonded networks allows to better delocalize the excess charge and to benefit more from cooperative effects. Finally, the linear isomer is very high in energy ( $E_0 = 2220 \text{ cm}^{-1}$ ) because the  $\text{H}_5\text{O}_2^+$  ion is not fully solvated. However, as the number of W ligands increases, the excess proton moves further away from the BN end. While for  $n = 2$  and 3 BN is next to the  $\text{H}_3\text{O}^+$  core, for  $n = 4$ –6 the excess proton is closest to the second W molecule from the BN end.

The IRPD spectrum observed for  $\text{H}^+(\text{BN-W}_6)$  is compared in Fig. 12 with the IR spectra predicted for the seven  $\text{BN-H}^+\text{W}_6$  isomers considered in Fig. 11 (c1–c3, s1/s2, b1/b2), while the

comparison with the IR spectrum of the much less stable linear  $\text{BN-H}^+\text{W}_6(\text{l})$  isomer is presented in Fig. S13 in the ESI.† Although the IRPD spectrum exhibits a limited signal-to-noise ratio, three features A, B, and C1 are clearly discernible in the free OH stretch range at  $3735 (\nu_3)$ ,  $3650 (\nu_1)$ , and  $3707 \text{ cm}^{-1} (\nu_f)$ , whereas the bound OH stretch range shows a broad and unresolved absorption below  $3600 \text{ cm}^{-1}$  with three maxima near  $3509 (\text{D1})$ ,  $3390 (\text{D2})$ , and  $3220 (\text{D3}) \text{ cm}^{-1}$  due to  $\nu_{\text{OH}}^{\text{b}}$  modes. Because of the limited spectral resolution, it is difficult to infer any reliable assignment to specific considered structures, and it is likely that several of the low-energy isomers contribute to the measured spectrum. The IRPD spectrum shows some unresolved signal in the spectral range between  $3450$  and  $3550 \text{ cm}^{-1}$  (D1), which is characteristic for cyclic isomers. This signal is certainly higher than in the  $n = 5$  case, which may indicate that, similar to the bare  $\text{H}^+\text{W}_n$  clusters,<sup>71–73,77,80</sup> cyclic (and eventually cage-like) structures become more important for increasing cluster size. Quite a good match is observed between the IRPD spectrum and the IR spectra predicted for the two surface isomers in both the free and bound OH stretch ranges. This is particularly true for the s2 isomer, which is derived by simple addition of BN to the detected Eigen isomer of  $\text{H}^+\text{W}_6$  (6E)<sup>76</sup> or by simple  $\text{W} \rightarrow \text{BN}$  substitution of the most stable noncyclic  $\text{H}^+\text{W}_7$  isomer.<sup>77</sup> This interpretation is supported by the similarity of the IRPD spectrum of  $\text{BN-H}^+\text{W}_6$  with that recorded for  $\text{H}^+\text{W}_7$  at elevated temperature.<sup>71</sup>

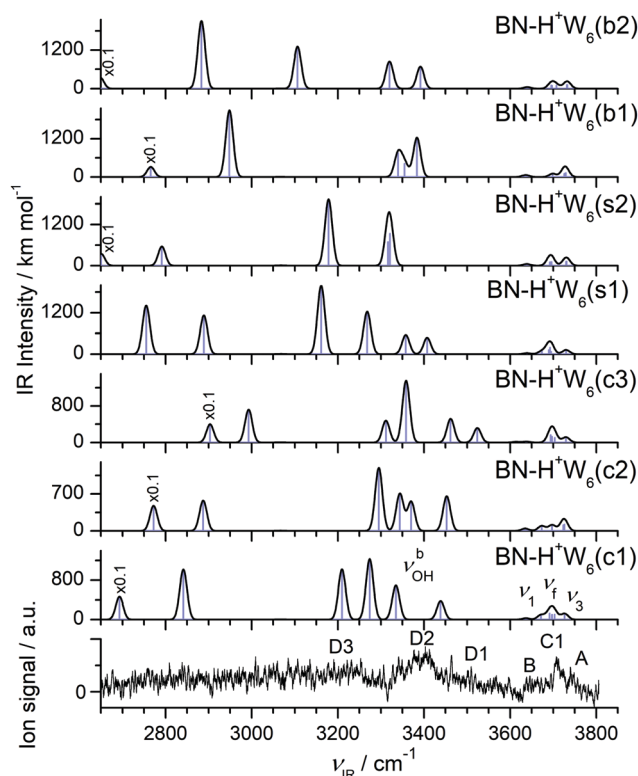

Fig. 12 Comparison of experimental IRPD spectrum of  $\text{H}^+(\text{BN-W}_6)$  with linear IR absorption spectra of the  $\text{BN-H}^+\text{W}_6$  isomers (Fig. 11) calculated at the B3LYP-D3/aug-cc-pVTZ level. High computed IR intensities are multiplied with a factor of 0.1 to display the weak features.

The high-energy linear isomer can be excluded for its high energy and its incompletely solvated  $\text{H}_5\text{O}_2^+$  core ion, which should produce a C2 band which is absent in the IRPD spectrum.

## 4. Further discussion

The present work combines IRPD spectroscopy of mass-selected  $\text{H}^+(\text{BN}-W_n)$  clusters with DFT calculations to investigate the protonation and hydration processes in mixed clusters of BN and W in the size range  $n = 1-6$ . Comparison with the previously studied  $\text{H}^+\text{BN}-L_n$  clusters with  $L = \text{Ar}$  and  $\text{N}_2$  ( $n \leq 4$ ) reveals the differences between aprotic hydrophobic and protic hydrophilic ligands.<sup>68</sup> Furthermore, comparison with neutral BN-W and the  $\text{BN}^+-W$  radical cation demonstrates the drastic impact of protonation and ionization on the intermolecular potential.<sup>49</sup> In case of the smaller  $\text{H}^+(\text{BN}-W_n)$  clusters (up to  $n \leq 4$ ), the observed IRPD spectra are safely assigned to the most stable structures predicted by the calculations, while for the larger clusters several low-energy isomers may compete, and the observed structures may depend on the preparation conditions. Of particular interest is also the comparison of  $\text{H}^+(\text{BN}-W_n)$  with bare  $\text{H}^+W_{n+1}$  clusters to unravel the effects of substituting a W ligand by the aromatic and strongly dipolar but aprotic BN molecular impurity on the structure of the hydration network. The salient results may be summarized as follows.

The cluster growth of  $\text{H}^+(\text{BN}-L_n)$  with the protic, hydrophilic, and dipolar W ligands differs qualitatively from that with hydrophobic, aprotic, and nonpolar ( $L = \text{Ar}$ ) or quadrupolar ( $L = \text{N}_2$ ) ligands.<sup>68</sup> The  $L \cdots L$  interaction between the aprotic ligands is very weak so that the  $\text{H}^+\text{BN}-L_n$  cluster structures are dominated by the  $\text{H}^+\text{BN} \cdots L$  interaction.<sup>82</sup> This drastic imbalance results in interior ion solvation, in which individual ligands  $L$  bind separately to the  $\text{H}^+\text{BN}$  cation core without the formation of a solvent network (at least for small  $n$ ). The thermodynamically favoured solvation process begins by H-bonding of  $L$  to the acidic NH proton of  $\text{H}^+\text{BN}$  and is continued by attachment to the less favourable  $\pi$  and CH binding sites. While for  $L = \text{Ar}$ , the population of the  $\pi$ -bound local minimum in the molecular beam is estimated as 20%, the concentration of  $\pi$ -bound and CH-bound minima is below the detection limit for  $L = \text{N}_2$  (and also W), because of the much larger energy gap to the H-bound global minimum. Significantly, the proton affinity of  $L = \text{Ar}$  and  $\text{N}_2$  is much smaller than that of BN so that the excess proton in the clusters remains at BN, justifying the  $\text{H}^+\text{BN}-L_n$  notation for all cluster sizes. In contrast, solvating  $\text{H}^+\text{BN}$  with the protic W ligands leads to the formation of an H-bonded hydration network due to strong cooperative effects. For  $n = 1$ , W is connected as a proton acceptor to the NH proton of  $\text{H}^+\text{BN}$ , whereas for larger clusters with  $n \geq 2$  exothermic intracluster proton transfer from  $\text{H}^+\text{BN}$  to  $W_n$  occurs for the most stable isomers leading to structures of the type  $\text{BN}-\text{H}^+W_n$ . Common to all considered  $\text{H}^+\text{BN}-L$  dimers is that the global minimum structure of the intermolecular potential features a linear  $\text{NH} \cdots L$  ionic H-bond of the neutral ligand to the acidic NH proton. The strength of this ionic H-bond increases with the PA of the ligand

along the series  $\text{Ar} < \text{N}_2 < \text{W}$ , and this effect is visible in the intermolecular  $\text{NH} \cdots L$  bond length ( $R$ ), dissociation energy ( $D_0$ ), and stretch frequency ( $\nu_s$ ), the complexation-induced changes in the properties of the intramolecular N-H donor bond ( $\Delta r_{\text{NH}}$ ,  $\Delta \nu_{\text{NH}}$ ,  $\Delta I_{\text{NH}}$ ), the charge transfer from  $\text{H}^+\text{BN}$  to  $L$  ( $\Delta q$ ), the NBO donor-acceptor orbital interaction ( $E^{(2)}$ ), and the NCI analysis ( $\rho^*$ ), as discussed in detail in Section 3.2. The monotonic correlation between the PA of  $L$  and the resulting computed and measured red shift in  $\nu_{\text{NH}}$  is visualized in Fig. 13. The IRPD spectra of the  $\text{H}^+\text{BN}-L$  dimers confirm the previous indirect mass spectrometric experimental evidence<sup>66</sup> that protonation of BN occurs exclusively at the N end of the CN group, in line with the computational thermochemical prediction.<sup>67,68</sup>

It is instructive to compare the structure and bonding of  $\text{H}^+\text{BN}-W$  with that of neutral  $\text{BN}-W$ <sup>50-54</sup> and the  $\text{BN}^+-W$  radical cation<sup>49</sup> to infer the effects of protonation and ionization on the shape of the intermolecular interaction potential and resulting hydration network. Neutral BN-W has a cyclic and nearly planar structure, in which W acts both as a proton donor and a proton acceptor, thereby bridging the gap between the *ortho* CH proton and the CN group *via*  $\text{CH} \cdots \text{O}$  and  $\text{OH} \cdots \text{N}$  H-bonds ( $D_0 = 1562 \text{ cm}^{-1}$ ).<sup>49,50</sup> This structure becomes repulsive for the  $\text{BN}^+-W$  radical cation, which favours a charge-dipole configuration with a bifurcated  $\text{CH} \cdots \text{O}$  H-bond and a much higher binding energy ( $D_0 = 3191 \text{ cm}^{-1}$ ).<sup>49</sup> In N-protonated  $\text{H}^+\text{BN}-W$ , which also has a charge-dipole configuration, W forms a very strong  $\text{NH} \cdots \text{O}$  ionic H-bond to the newly available NH proton ( $D_0 = 6924 \text{ cm}^{-1}$ ).

In general, the cluster growth found in neutral  $\text{BN}-W_n$  clusters<sup>52,53</sup> is quite different from that of  $\text{H}^+(\text{BN}-W_n)$ . IR-UV double resonance spectra provide clear evidence for nearly planar H-bonded cyclic structures of  $\text{BN}-W_n$  with  $n = 1-3$ , in which the chain-type  $W_n$  unit closes a ring including the *ortho* CH and CN groups of BN by  $\text{CH} \cdots \text{O}$  and  $\text{OH} \cdots \text{N}$  H-bonds.

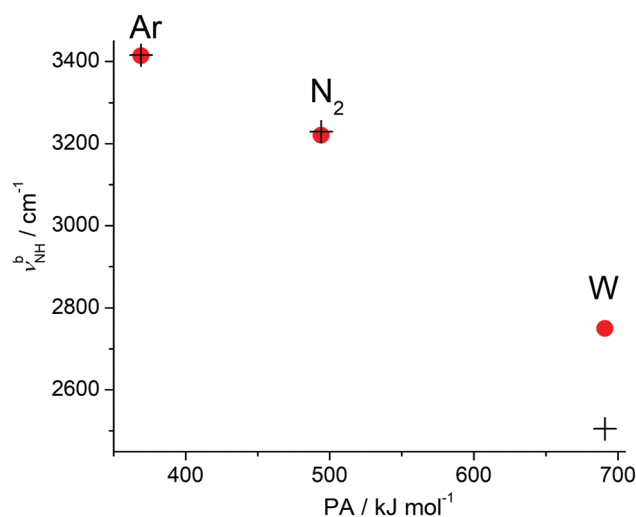

Fig. 13 Observed (filled circles) and calculated (crosses, B3LYP-D3/ aug-cc-pVTZ) NH stretch frequencies ( $\nu_{\text{NH}}^b$ ) of the H-bonded  $\text{H}^+\text{BN}-L(\text{H})$  dimers with  $L = \text{Ar}$ ,  $\text{N}_2$ , W as a function of the proton affinity (PA) of the ligands.

These cyclic rings maximize the number of H-bonds, in which all W molecules act as single-donor single-acceptor molecules (DA), thereby maximizing the cooperative effects. Such hydration motifs are not stable for the protonated clusters, in which the  $\text{H}_3\text{O}^+$  core in  $\text{BN-H}^+\text{W}_n$  with  $n \geq 2$  serves as double-donor or triple-donor but cannot be an H-bond acceptor. Thus,  $\text{BN-H}^+\text{W}_n$  clusters with small  $n$  ( $n = 2-4$ ) prefer branched structures with BN in the first solvation shell because the dipole moment of BN is larger than that of W. Branched structures also ensure that the protonated  $\text{H}_3\text{O}^+$  moiety is fully solvated (starting from  $n = 3$ ), which makes them more stable than the linear structures with their incomplete hydration of  $\text{H}_3\text{O}^+$  (or  $\text{H}_5\text{O}_2^+$ ). The energy gap between the linear and most stable branched or cyclic structure substantially increases with  $n$  ( $\Delta E_0 = 1016, 1047, 1788, 2220 \text{ cm}^{-1}$  for  $n = 3-6$ ), clearly proving that linear hydration motifs are unfavourable. This is in line with results previously reported for  $\text{Np}^+-\text{W}_n$  ( $\text{Np} = \text{naphthalene}$ ) clusters using IRPD and DFT calculations.<sup>45</sup> This result is however in contrast to the earlier prediction of linear hydration structures for  $\text{Np}^+-\text{W}_n$  suggested on the basis of mass spectrometry and DFT calculations, indicating that structural assignments of clusters without spectroscopy is often highly unreliable.<sup>108</sup> Interestingly, the excess proton in the linear  $\text{BN-H}^+\text{W}_n(\text{l})$  isomers moves away from the BN end as  $n$  increases. This observation is in line with the increasing PA of  $\text{W}_m$  subclusters as  $m$  increases. Nonetheless, the excess proton remains closer to the BN end than to the W end, because the PA of BN is larger than that of W. For larger  $\text{BN-H}^+\text{W}_n$  clusters, cyclic structures become possible ( $n \geq 4$ ) and competitive in energy as  $n$  increases. In fact, they are the most stable structural motif at  $T = 0 \text{ K}$  starting from  $n = 5$ , because the ring structures can maximize the number of H-bonds. However, at elevated temperature, the branched structures benefit from entropy because they are more flexible than cyclic rings. As a result, branched structures remain the global minima on the free energy surface for all cluster sizes investigated ( $n \leq 6$ ), although the energy gap to cyclic structures becomes smaller as  $n$  increases ( $\Delta G = 951, 943, 536 \text{ cm}^{-1}$  for  $n = 4-6$ ). Finally, as the cluster grows further, surface isomers, in which BN is located in the second shell of a hydrated  $\text{H}_3\text{O}^+$  ion, become lower in energy because BN can only act as a single acceptor in the H-bonded network (when neglecting  $\text{OH} \cdots \pi$  bonding), while W can be involved in as many as four H-bonds (double-donor double-acceptor, DDAA). However, in the investigated size range of up to  $n = 6$ , BN is always located in the first solvation shell of  $\text{H}_3\text{O}^+$ , although the relative energy of the most stable surface isomer tends to become smaller ( $E_0 = 514, 733, 417 \text{ cm}^{-1}$  for  $n = 4-6$ ).

The PA of  $\text{W}_n$  clusters increases with size as 691, 808, 862, 900, 904, and 908  $\text{kJ mol}^{-1}$  for  $n = 1-6$ .<sup>13-17</sup> The PA of BN is reported as 812  $\text{kJ mol}^{-1}$ ,<sup>13</sup> and thus the difference in PA between BN and  $\text{W}_n$  amounts to  $\Delta\text{PA} = +121, +4, -50, -88, -92$ , and  $-96 \text{ kJ mol}^{-1}$ . From this consideration, it is expected that the excess proton in  $\text{H}^+(\text{BN-W}_n)$  is located at BN for  $n = 1$  ( $\text{H}^+\text{BN-W}$ ) and at  $\text{W}_n$  for  $n \geq 3$  ( $\text{BN-H}^+\text{W}_n$ ), because of the large absolute values of  $\Delta\text{PA}$  ( $\geq 50 \text{ kJ mol}^{-1}$ ). For  $n = 2$ , the proton is

expected to be roughly equally shared between BN and  $\text{W}_2$  ( $\text{BN} \cdots \text{H}^+ \cdots \text{W}_2$ ) due to the similar PA values. However, first one has to keep in mind that the PA values of  $\text{W}_n$  are not accurately measured (in particular for larger  $n$ ). Moreover they substantially depend on the exact geometry of both  $\text{W}_n$  and  $\text{H}^+\text{W}_n$  and thus may be substantially modified when changing from bare  $\text{H}^+\text{W}_n$  to the molecularly doped  $\text{H}^+(\text{BN-W}_n)$  cluster. Second, for the correct prediction of the position of the excess proton, one has not only to consider  $\Delta\text{PA}$  but also differences in the solvation energy of  $\text{H}^+\text{BN-W}_n$  and  $\text{BN-H}^+\text{W}_n$ . For example, protonation of benzene- $\text{H}_2\text{O}$  leads to the formation of  $\text{C}_6\text{H}_6\text{-H}_3\text{O}^+$  rather than  $\text{C}_6\text{H}_7^+-\text{H}_2\text{O}$ ,<sup>25,26</sup> although the PA of benzene (750.4  $\text{kJ mol}^{-1}$ ) exceeds the one of  $\text{H}_2\text{O}$  by as much as 59.4  $\text{kJ mol}^{-1}$ ,<sup>13</sup> indicating that solvation energy differences can be quite substantial.

In the case of  $\text{H}^+(\text{BN-W}_n)$ , the IRPD spectra and computations give a clear answer to the question of the position of the excess proton. For  $n = 1$ , the observation of the H-bonded NH stretch band is a clear indication for the  $\text{H}^+\text{BN-W}$  structure expected from  $\Delta\text{PA}$  and the DFT computations. Hence, the assignment of a  $\text{BN-H}_3\text{O}^+$  structure in the mass spectra in ref. 103 is clearly wrong. Indeed, our DFT calculations could not locate any  $\text{BN-H}_3\text{O}^+$  (local) minimum with either an  $\text{OH} \cdots \text{N}$  or  $\text{OH} \cdots \pi$  H-bond. The absence of any  $\nu_{\text{NH}}^{\text{b}}$  band and appearance of the  $\nu_{\text{OH}}^{\text{b}}$  band for  $n = 2$  are clear indications for a proton-transferred  $\text{BN-H}^+\text{W}_2$  structure. Moreover, the excess proton is clearly closer to  $\text{W}_2$  than to BN (1.107 vs. 1.387 Å), suggesting that the solvation energy of  $\text{BN} \cdots \text{H}^+\text{W}_2$  is substantially higher than the one of  $\text{H}^+\text{BN} \cdots \text{W}_2$ . It is difficult to compute the latter energy because this intracluster proton transfer reaction is barrierless and no stable  $\text{H}^+\text{BN} \cdots \text{W}_2$  minimum is obtained. Thus, the IRPD spectra and DFT calculations agree that the critical size for proton transfer to solvent in  $\text{H}^+(\text{BN-W}_n)$  clusters is  $n_c = 2$ .

The IRPD spectra of  $\text{H}^+(\text{BN-W}_n)$  in Fig. 1 provide some further general conclusions about the cluster growth and hydration structure after proton transfer occurs at  $n_c = 2$ . First, the appearance of the H-bonded  $\text{OH} \cdots \text{O}$  bands ( $\nu_{\text{OH}}^{\text{b}}$ , bands D) and the uncoupled free OH stretch bands ( $\nu_{\text{f}}$ , bands C) for  $n \geq 2$  provide unequivocal evidence for the formation of the H-bonded hydration network of the  $\text{H}^+\text{W}_n$  subunit in  $\text{BN-H}^+\text{W}_n$ . Second, the transition C2 is an indicator of a free and uncoupled OH stretch band ( $\nu_{\text{f}}$ ) of an  $\text{H}_3\text{O}^+$  core, and its disappearance at  $n = 4$  implies that in all clusters with  $n \geq 4$ , the  $\text{H}_3\text{O}^+$  unit is fully solvated either by BN or W, leading to the Eigen analogue of  $\text{H}^+\text{W}_4$  ( $\text{H}_3\text{O}^+-\text{W}_3$  or  $\text{H}_9\text{O}_4^+$ ). This result is expected because of the strong electrostatic charge-dipole forces involved in hydration or solvation of a cation with dipolar ligands. Third, the pronounced appearance of the transitions C1 assigned to a free and uncoupled OH stretch band ( $\nu_{\text{f}}$ ) of a neutral W ligand at the cluster size  $n = 4$  indicates the presence of incompletely solvated W ligands (single-donor single-acceptor, DA) in the cluster. Indeed, the computations predict such clusters to be dominant only for  $n \geq 4$ . Fourth, all spectra exhibit the coupled free OH stretch modes  $\nu_1$  and  $\nu_3$  of W ligands not acting as a proton donor (*i.e.*, A or AA), and

indeed all computed structures possess such W molecules. Fifth, cyclic structures are becoming more prominent at larger cluster sizes, as indicated by the increasing signal in the 3500–3600 cm<sup>−1</sup> range. Finally, as the cluster size increases, all related free and bound OH stretch transitions (A–D) shift monotonically to higher frequency, indicating that the H-bonds of W become gradually weaker because of increasing delocalization (dilution) of the excess positive charge. For example, band A shifts from 3710 to 3735 cm<sup>−1</sup> ( $n = 1-6$ ,  $\nu_3$ ), band B from 3620 to 3650 cm<sup>−1</sup> ( $n = 1-6$ ,  $\nu_1$ ), band C2 from 3657 to 3660 cm<sup>−1</sup> ( $n = 2-3$ ,  $\nu_f$  of H<sub>3</sub>O<sup>+</sup>), band C1 from 3694 to 3707 ( $n = 3-6$ ,  $\nu_f$  of W), band D1/D2 from 2850 to 3390 cm<sup>−1</sup> ( $n = 4-6$ ,  $\nu_{OH}^b$  of W··W), and band D2/D3 from 2815 to 3200 cm<sup>−1</sup> ( $n = 3-6$ ,  $\nu_{OH}^b$  of H<sub>3</sub>O<sup>+</sup>··W or H<sub>3</sub>O<sup>+</sup>··BN).

The latter spectral observations can readily be explained by the computed structures (bond distances of inter- and intramolecular bonds), intermolecular binding energies of the H-bonds, charge transfer, NBO interactions, and NCI analysis. To this end, we consider the data obtained for the most stable branched isomer found for each cluster size at  $T = 298$  K ( $G = 0$  for isomers b for  $n = 2-4$ , b1 for  $n = 5$ , and b2 for  $n = 6$ ), because these are safely assigned to the measured IRPD spectrum at least for  $n = 2-4$ . For example, the OH··N H-bond of H<sup>+</sup>W<sub>*n*</sub> to BN becomes gradually weaker as  $n$  increases from 2 to 6, as seen by the H-bond length and binding energy ( $R = 1.387, 1.548, 1.594, 1.631, 1.671$  Å;  $D_0 = 11\,955, 9613, 7247, 6505, 5292$  cm<sup>−1</sup> for  $n = 2-6$ ). This trend is also reflected in the decreasing charge transfer from H<sup>+</sup>W<sub>*n*</sub> to BN ( $\Delta q = 199, 123, 104, 89, 81$  me),  $E^{(2)}$  energy (757, 418, 349, 183, 169 kJ mol<sup>−1</sup>), and NCI parameter ( $-\rho = 0.111, 0.073, 0.065, 0.059, 0.056$  a.u.) as illustrated in Fig. S2–S4 in the ESI.† The weakest OH··O H-bonds between neutral W ligands become longer ( $R = 1.712, 1.731, 1.782$  Å for  $n = 4-6$ ). At the same time, the intramolecular free O–H bonds of terminal W ligands become shorter (0.935, 0.932, 0.9625, 0.9624, 0.9622 Å for  $n = 2-6$ ), explaining the gradual blue shifts of  $\nu_1$  and  $\nu_3$ .

The size-dependent proton transfer to solvent has been observed for a number of closed-shell aromatic H<sup>+</sup>(A–W<sub>*n*</sub>) clusters, including A = benzene (PA = 750.3 kJ mol<sup>−1</sup>,  $n_c = 1$ ),<sup>25,26</sup> naphthalene (PA = 802.9 kJ mol<sup>−1</sup>,  $n_c = 2$ ),<sup>109</sup> BN (PA = 812 kJ mol<sup>−1</sup>,  $n_c = 2$ ), and benzaldehyde (PA = 834 kJ mol<sup>−1</sup>,  $n_c = 3$ ).<sup>23</sup> As can be seen, the larger the PA of A, the larger is the critical hydration size  $n_c$ . Moreover, in all these cases (except for benzene as explained above), the observed  $n_c$  value is consistent with the difference to the size-dependent PA values of W<sub>*n*</sub>. The case of phenol is more complex because this substituted arene has two competing protonation sites, with largely different PA values for the ring and the substituent. While the PA for ring protonation (PA = 817.3 kJ mol<sup>−1</sup> for *C<sub>ortho/para</sub>*) is much higher than for protonation at the substituent ( $\sim 740$  kJ mol<sup>−1</sup> for O),<sup>110</sup> hydration is strongly preferred at the OH group(s) in both cases, so that  $n_c$  is strongly dependent on the protonation site and concluded to be in the  $n_c = 3-4$  range.<sup>59</sup> In these clusters, the hydration structure includes OH··π H-bonds between the H<sup>+</sup>W<sub>*n*</sub> subcluster and the aromatic ring. Similar structures with OH··π docking to the aromatic ring are observed for benzene and naphthalene, which do not possess a polar functional group.<sup>26,109</sup> This behaviour is

different from the BN–H<sup>+</sup>W<sub>*n*</sub> clusters studied here, in which the strongly directional OH··N H-bond between H<sup>+</sup>W<sub>*n*</sub> and the linear CN group of BN causes the hydration network to grow away from the aromatic ring. In that sense, BN behaves similar to benzaldehyde, in which also the large spacing between the polar C=O group (to which H<sup>+</sup>W<sub>*n*</sub> is attached) and the aromatic ring prevents the formation of OH··π H-bonds.<sup>23</sup>

Comparison between BN–H<sup>+</sup>W<sub>*n*</sub> and the well-studied bare H<sup>+</sup>W<sub>*n*</sub> clusters with the same  $n$  is interesting, because it reveals the effects of simple addition of BN to H<sup>+</sup>W<sub>*n*</sub>. On the other hand, comparison of BN–H<sup>+</sup>W<sub>*n*</sub> with H<sup>+</sup>W<sub>*n+1*</sub> unravels the effects of W → BN substitution by keeping the same number of molecules in the cluster. In this scenario, BN may be considered as a dopant or impurity molecule in the cluster. BN has several properties different from W. First, while W has four possible binding sites for H-bonding (two lone pairs of O acting as acceptor, two OH donor groups), BN offers only a single binding site for σ H-bonds (the N lone pair along the CN bond acting as acceptor). As discussed above, π H-bonding to the aromatic ring is not feasible in BN–H<sup>+</sup>W<sub>*n*</sub> clusters in the size range studied herein and π H-bonding to the C≡N triple bond is energetically unfavourable. The lower number of binding sites of BN only comes into play for clusters with larger  $n$ , where the bulky and hydrophobic phenyl ring can not readily be involved in the formation of a solvation network for both steric reasons and the modest strength of the aromatic OH··π interaction. For smaller  $n$ , BN does not need to be incorporated into the hydration network to form the most stable structures. Further, when acting as a single H-bond acceptor, BN produces a much stronger OH··N H-bond than the OH··O H-bond formed by W, because BN has a much larger dipole moment and PA. This is only true as long as single W ligands are considered, because the PA of W<sub>*n*</sub> with  $n \geq 2$  is comparable or larger than the PA of BN. Nonetheless, this difference in molecular parameters is the reason why BN is located in the first solvation shell of the H<sub>3</sub>O<sup>+</sup> core ion in the most stable BN–H<sup>+</sup>W<sub>*n*</sub> isomers for clusters in the size range  $n = 2-6$ . Interesting aspects of introducing the BN dopant molecule into the H<sup>+</sup>W<sub>*n*</sub> clusters include the impact on structure, including the position of BN and the excess proton in the cluster, the degree of asymmetry caused by symmetry breaking through steric factors and changes in the strength of the H-bonds, and the energy ordering of the various related isomers. The lowest-energy structures of H<sup>+</sup>W<sub>*n*</sub> are well known,<sup>69–80</sup> and their geometries, binding energies, and IR spectra computed at the B3LYP-D3/aug-cc-pVTZ level are shown in Fig. S10 in the ESI.† Briefly, only a single low-energy isomer is observed for  $n = 1-4$ , namely the hydronium ion ( $n = 1$ , H<sub>3</sub>O<sup>+</sup>), the Zundel ion ( $n = 2$ , H<sub>5</sub>O<sub>2</sub><sup>+</sup>), a symmetrically twofold solvated hydronium ion ( $n = 3$ , H<sub>7</sub>O<sub>3</sub><sup>+</sup>, W–H<sub>3</sub>O<sup>+</sup>–W), and the Eigen ion ( $n = 4$ , H<sub>9</sub>O<sub>4</sub><sup>+</sup>, H<sub>3</sub>O<sup>+</sup>–W<sub>3</sub>) which is a symmetrically threefold solvated hydronium ion with a completed first solvation shell. Starting from  $n = 5$ , more than a single isomer is observed even at low cryogenic temperature, and their geometries have been determined by elegant IR–IR double resonance experiments for  $n = 5-7$ , namely the three ring (R), branched (B), and chain (C) isomers of  $n = 5$ ,<sup>75</sup> the two

Eigen and Zundel type isomers of  $n = 6$  (6E and 6Z),<sup>76</sup> and the four 7Z, 7E<sub>C</sub>, 7E<sub>4R</sub>, and 7E<sub>5R</sub> isomers of  $n = 7$ .<sup>77</sup> Moreover, it was shown that the relative abundance of the various isomers depends on temperature and choice of tagging ligand.<sup>71,74,75</sup> Similar to the bare  $\text{H}^+\text{W}_n$  clusters, we observe a dominant single isomer for  $\text{H}^+(\text{BN}-\text{W}_n)$  clusters up to the size range of four molecules. However, there are important differences in the energetics and structures. For example, while the Zundel ion has a symmetric  $\text{W}-\text{H}^+-\text{W}$  configuration with a shared proton,  $\text{H}^+\text{BN}-\text{W}(\text{H})$  has a strongly asymmetric structure, with the excess proton clearly localized at BN. The  $\text{BN}-\text{H}^+\text{W}_2$  structure is similar to the one of  $\text{H}_7\text{O}_3^+$ , with a twofold solvated  $\text{H}_3\text{O}^+$  ion, although again BN breaks the symmetry because the  $\text{H}_3\text{O}^+ \cdots \text{BN}$  H-bond is stronger than the  $\text{H}_3\text{O}^+ \cdots \text{W}$  H-bond. A similar situation results from comparison between  $\text{BN}-\text{H}^+\text{W}_3(\text{b})$  and the  $\text{H}^+\text{W}_4$  Eigen ion. Interestingly, we have evidence for the minor presence of the less stable linear  $\text{BN}-\text{H}^+\text{W}_3(\text{l})$  isomer, while the corresponding asymmetric  $\text{H}^+\text{W}_4$  isomer has not been detected.<sup>78</sup> As a general rule, the H-bond to BN is stronger than the one to W, and as a result  $\text{W} \rightarrow \text{BN}$  substitution weakens the remaining H-bonds of  $\text{H}_3\text{O}^+$  to W. Because the IRPD spectra of cryogenic  $\text{H}^+\text{W}_n$  clusters with  $n = 5-7$  have been assigned to three, two, and four isomers, we expect a similar situation for the related  $\text{BN}-\text{H}^+\text{W}_n$  clusters with  $n = 4-6$ , because all low-energy structures identified by the DFT calculations can be derived from the low-energy  $\text{H}^+\text{W}_n$  structures as outlined in the sections dealing with the individual cluster sizes. Interestingly, the IRPD spectra of  $\text{BN}-\text{H}^+\text{W}_n$  are similar in appearance and trends to those recorded for  $\text{H}^+\text{W}_{n+1}$  recorded at elevated temperature for  $n = 4-6$ ,<sup>71</sup> suggesting that, at least in these clusters one W ligand is simply substituted by BN. Clearly, the achieved resolution of the corresponding IRPD spectra recorded for  $n = 4-6$  does not allow for a detailed isomer identification. To this end, future efforts will have to employ cryogenic cooling or tagging of the clusters and/or IR-IR double resonance experiments.<sup>74-78</sup>

## 5. Concluding remarks

The analysis of IRPD spectra of mass-selected  $\text{H}^+(\text{BN}-\text{W}_n)$  clusters in the size range  $n = 1-6$  with the aid of DFT calculations reveals detailed information about the location of the excess proton and the structure of the hydration network. The spectra of the clusters with small  $n$  ( $n \leq 4$ ) are dominated by the most stable isomers, while several isomers contribute to the spectra of the larger clusters with  $n = 5$  and 6. The  $n = 1$  dimer has a  $\text{H}^+\text{BN}-\text{W}$  type structure, in which W is attached to the NH proton of N-protonated  $\text{H}^+\text{BN}$ .  $\text{H}^+(\text{BN}-\text{W}_n)$  clusters with  $n \geq 2$  have proton-transferred structures of the type  $\text{BN}-\text{H}^+\text{W}_n$ . This intra-cluster proton transfer to solvent at the critical size  $n_c = 2$  is consistent with thermochemical predictions from the relative proton affinities of BN and  $\text{W}_n$  when including effects of solvation energy. The  $n = 2$  and 3 structures are derived from the related Eigen ions of the corresponding  $\text{H}^+\text{W}_n$  clusters by simple  $\text{W} \rightarrow \text{BN}$  substitution. The symmetry is reduced by the

aromatic dopant molecule, and the H-bonds of  $\text{H}_3\text{O}^+$  to BN are stronger than those to W, because of the larger dipole moment and PA of BN as compared to W. In particular, BN substitution weakens the H-bonds to the remaining W ligands, as a result of noncooperative effects of interior ion solvation. In the size range  $n = 4-6$ , cyclic isomers with four- and five-membered  $\text{H}^+\text{W}_n$  rings become energetically more stable than the branched isomers, because they feature one more H-bond. However, the more flexible branched isomers remain the global minima on the free energy surface because of entropy. Clearly, linear isomers with incompletely solvated  $\text{H}_3\text{O}^+$  (or  $\text{H}_5\text{O}_2^+$ ) ion cores are not favoured, and the energy gap to the most stable branched or cyclic isomers increases substantially with increasing  $n$ . In the most stable structures, BN is located in the first solvation shell of the  $\text{H}_3\text{O}^+$  ion, because of its larger dipole moment and PA. However, the strength of the H-bond between BN and the  $\text{H}^+\text{W}_n$  cluster decreases with  $n$ . It is extrapolated that surface isomers will become more favourable for the larger clusters, because W can be better integrated in the hydration network than BN with its bulky hydrophobic phenyl ring. As a general trend, the excess charge becomes more delocalized as the cluster grows in size, and as a result individual H-bonds become weaker as indicated by incremental blue shifts (or reduced red shifts) in the free and bound OH stretch frequencies. The cluster growth in  $\text{H}^+(\text{BN}-\text{W}_n)$  differs from that in  $\text{H}^+\text{BN}-\text{L}_n$  with the hydrophobic aprotic Ar and  $\text{N}_2$  ligands. While  $\text{H}^+\text{BN}-\text{L}_n$  with the inert ligands  $\text{L} = \text{Ar}$  and  $\text{N}_2$  exhibit interior ion solvation around the N-protonated  $\text{H}^+\text{BN}$  core ion, clusters with  $\text{L} = \text{W}$  prefer the formation of an H-bonded hydration network and display intracluster proton transfer from  $\text{H}^+\text{BN}$  to  $\text{W}_n$  for clusters larger than  $n_c = 2$ . Protonation of  $\text{BN}-\text{W}_n$  cluster has a drastic impact on both the cluster structure, the shape of the hydration network, and the interaction strength. The major astrochemical implication of this study is the prediction that  $\text{H}^+\text{BN}$  is unstable in and on ice grains because of exothermic and barrierless proton transfer to the ice structure. Although the isomer assignment is very clear up to the size range  $n \leq 4$ , the achieved resolution of the IRPD spectra recorded for  $n = 5-6$  is limited and does not allow for a detailed isomer identification. To this end, future efforts will have to employ cryogenic cooling or tagging of the clusters and/or IR-IR double resonance experiments.<sup>74-78,111</sup>
