Selective synthesis of 4-hydroxyisophorone and 4-ketoisophorone by fungal peroxygenases†

Carmen Aranda,^a Martí Municoy,^b Víctor Guallar,^{bc} Jan Kiebig,^d Katrin Scheibner,^d René Ullrich,^e José C. del Río,^a Martin Hofrichter,^e Angel T. Martínez ^{*f} and Ana Gutiérrez ^{*a}

The recently discovered unspecific peroxygenases (UPOs) from the ascomycetes *Chaetomium globosum* and *Humicola insolens* were capable of selectively hydroxylating isophorone to 4-hydroxyisophorone (4HIP) and 4-ketoisophorone (4KIP), which are substrates of interest for the pharmaceutical and flavor-and-fragrance sectors. The model UPO from the basidiomycete *Agrocybe aegerita* was less regioselective, forming 7-hydroxyisophorone (and 7-formylisophorone) in addition to 4HIP. However, it was the most stereoselective UPO yielding the *S*-enantiomer of 4HIP with 88% ee. Moreover, using *H. insolens* UPO full kinetic resolution of racemic HIP was obtained within only 15 min, with >75% recovery of the *R*-enantiomer. Surprisingly, the UPOs from two other basidiomycetes, *Marasmius rotula* and *Coprinopsis cinerea*, failed to transform isophorone. The different UPO selectivities were rationalized by computational simulations, in which isophorone and 4HIP were diffused into the enzymes using the adaptive PELE software, and the distances from heme-bound oxygen in H₂O₂-activated enzyme to different substrate atoms, and the corresponding binding energies were analyzed. Interestingly, for process upscaling, full conversion of 10 mM isophorone was achieved with *H. insolens* UPO within nine hours, with total turnover numbers up to 5500. These biocatalysts, which only require H₂O₂ for activation, may represent a novel, simple and environmentally-friendly route for the production of isophorone derivatives.

Introduction

Isophorone derivatives, such as 4-hydroxyisophorone (4HIP) and 4-ketoisophorone (4KIP), are of interest as flavour-and-fragrance additives,¹ and as intermediates in the synthesis of pharmaceuticals, vitamins and natural pigments.^{2,3} A variety of chemical methods is available for the production of 4HIP and 4KIP. Thus, both derivatives have been synthesized from β -isophorone,^{1,4} which – on its part – can be obtained by isomerization of isophorone (also known as α -isophorone). The rearrangement of β -isophorone to the α -isomer, however, is a main drawback of this process. The direct oxidation of isophorone to 4KIP with molecular oxygen (O₂) appeared to

be the solution, using copper(II) acetylacetonate or molybdenum-based systems as catalysts,⁵ but required toxic heavy metals and led to the formation of undesired side products. Moreover, a direct chemical oxidation process of isophorone to 4HIP is not available and this compound is usually synthesized by reduction of 4KIP,^{6,7} which can be a rather expensive starting material.

Alternatively, some biological processes for the synthesis of 4HIP and 4KIP have been described, often using cytochrome P450 monooxygenases (P450s). Among them, the microbial biotransformation of isophorone was described for fungi – like *Aspergillus niger*, *Alternaria alternata* and *Neurospora crassa* –^{8,9} with 4HIP and 7-hydroxyisophorone (7HIP) as main metabolites. More recently, a process using recombinant *Escherichia coli* transformed with the P450-BM3 gene (together with the gene of NADPH-regenerating glucose dehydrogenase) allowed the scaled-up selective production of 4HIP at kilogram scale.¹⁰ On the other hand, 4KIP has been produced either in an one-pot two-step enzymatic process or as a cascade process employing cells co-expressing P450-WAL and Cm-ADH10 dehydrogenase.¹¹ However, isolated P450s generally suffer the disadvantage of rather higher instability and the frequent need of auxiliary enzymes/domains and expensive cofactors.

† Electronic supplementary information (ESI) available. See DOI: 10.1039/c8cy02114g

Unspecific peroxygenases (UPOs, EC.1.11.2.1) are novel and appealing biocatalysts for organic synthesis, since their ‘simplicity’ (only H₂O₂ is required for activation) and stability (as secreted enzymes) circumvent major disadvantages of P450s while catalyzing the same kind of oxyfunctionalization reactions.¹² The first enzyme of this class was discovered in 2004 in the basidiomycete *Agrocybe aegerita*¹³ and since then, new peroxygenases came out from *Coprinellus radians*,¹⁴ *Marasmius rotula*,¹⁵ and more recently from *Chaetomium globosum*.¹⁶ Their widespread occurrence in the fungal kingdom has been demonstrated by the analysis of basidiomycete, ascomycete and other fungal genomes and revealed over one-thousand putative peroxygenase genes.¹⁷ This allowed the production of recombinant enzymes, like those of *Coprinopsis cinerea*¹⁸ or *Humicola insolens*,¹⁶ which are heterologously expressed by Novozymes A/S (Bagsvaerd, Denmark) in the mold *Aspergillus oryzae*.

The spectrum of reactions catalyzed by these enzymes is steadily increasing and includes oxygenations of both aromatic^{19,20} and aliphatic compounds,^{21–24} fatty acids epoxidation²⁵ and chain-shortening,²⁶ and also reactions of rather complex and bulky substrates like steroids,^{27,28} and secosteroids^{29,30} that are subject to epoxidation, side-chain hydroxylation or side-chain removal.

In the present work, the hydroxylation of isophorone by several UPOs with different selectivities is presented for the first time, to be included in the portfolio of reactions catalyzed by these novel and exciting enzymes.^{12,17}

Materials and methods

Enzymes

*Aae*UPO (isoform II, 46 kDa), the first UPO described in 2004, is a wild-type (*i.e.* non-recombinant) peroxygenase from cultures of *A. aegerita* TM-A1, grown in soybean-peptone medium, which was purified as described by Ullrich and Hofrichter.³¹ *Mro*UPO is another wild-type peroxygenase (32 kDa) from cultures of *M. rotula* DSM-25031 (German Collection of Microorganisms and Cell Cultures, Braunschweig), which was purified as described by Gröbe *et al.*¹⁵ *Cgl*UPO (36 kDa) is a third wild-type peroxygenase from cultures of *C. globosum* DSM-62110, which was purified as recently described by Kiebist *et al.*¹⁶ The recombinant enzymes *rCci*UPO (44 kDa) and *rHin*UPO were provided by Novozymes A/S. *rCci*UPO corresponds to the protein model 7249 from the sequenced *C. cinerea* genome available at the JGI (<http://genome.jgi.doe.gov/Copci1>) used in several studies.^{22,27,30} The *rHin*UPO sequence has been more recently reported³² and used for oxyfunctionalizations that are not catalyzed by other UPOs.¹⁶ Both UPOs were expressed by Novozymes in *Aspergillus oryzae* (patent WO/2008/119780). All UPO proteins were purified by fast protein liquid chromatography (FPLC) using a combination of size exclusion chromatography (SEC) and ion exchange chromatography on different anion and cation exchangers. Purification was confirmed by sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE)

and UV-visible spectroscopy following the characteristic heme-maximum around 420 nm (Soret band of resting-state heme-thiolate proteins). Enzyme concentration was estimated according to the characteristic UV-vis band of the reduced UPO-complex with carbon monoxide.³³

Model compounds

3,5,5-Trimethyl-2-cyclohexen-1-one (isophorone) from Sigma Aldrich (97% purity) was tested as substrate of the above UPOs. 3,5,5-Trimethyl-2-cyclohexen-1,4-dione (4-keto-isophorone, 4KIP) also from Sigma Aldrich, and chemically-synthesized 4-hydroxy-3,5,5-trimethyl-2-cyclohexen-1-one (4-hydroxyisophorone, 4HIP) by 4KIP reduction, were used as standards in gas chromatography-mass spectrometry (GC-MS) analyses. 4HIP, obtained as a racemic mixture by chemical reduction of 4KIP,⁷ was used as substrate in enzymatic reactions together with isophorone.

Enzyme reactions

Reactions (1 mL volume) with isophorone (0.1 mM) were performed at 30 °C, in 50 mM phosphate buffer, pH 7. The enzyme concentrations ranged from 50 nM to 10 μM, using 2.5 to 5 mM H₂O₂. In control experiments, substrates were treated under the same conditions (including H₂O₂) but without enzyme. After 30 min reaction, products were extracted with methyl *tert*-butyl ether, which was evaporated under N₂, and the products dissolved in chloroform to be analyzed by GC-MS. Reactions at higher isophorone concentration (10 mM) were performed with *Cgl*UPO and *rHin*UPO (2–5 μM). H₂O₂ was added with a syringe pump to give concentrations in the reaction mixture of 1 or 5 mM h⁻¹ during 48 h or 12 h, respectively. Reactions for chiral analyses were carried out with 10 mM isophorone or 4HIP (racemic mixture) and 5 μM enzyme (*Cgl*UPO, *rHin*UPO and *Aae*UPO) for 60 min, with H₂O₂ manually added in small doses to a final concentration of 5–20 mM. Products were extracted with ethyl acetate and directly analyzed by GC-MS or dried and dissolved in the mobile phase to be analyzed by HPLC.

Enzyme kinetics

Reactions were carried out with 6.25–6400 μM substrate and 100 nM enzyme. They were initiated adding 0.5 mM H₂O₂ and stopped by vigorous shaking in 5 mM sodium azide. Reaction times, the reaction velocity of which was linear, were previously selected: 5 min for *Aae*UPO, 3 min for *Cgl*UPO and 1 min for *rHin*UPO. All reactions were performed in triplicates. Product quantification was carried out by GC-MS using external standard curves, and kinetic parameters – turnover number (k_{cat}), Michaelis constant (K_{m}) and catalytic efficiency ($k_{\text{cat}}/K_{\text{m}}$) – were obtained by fitting the data to the Michaelis-Menten equation, or to the corresponding variation of this equation when substrate inhibition is occurring, using SigmaPlot (Systat Software Inc., San Jose, CA, USA).

GC-MS

The analyses were performed in a Shimadzu GC-MS QP 2010 Ultra system, using a fused-silica DB-5HT capillary column (30 m × 0.25 mm internal diameter, 0.1 μm film thickness) from J&W Scientific. The oven was heated from 50 °C (1.5 min) to 90 °C (2 min) at 30 °C min⁻¹, and then from 90 °C to 250 °C (15 min) at 8 °C min⁻¹. The injection was performed at 250 °C and the transfer line was kept at 300 °C. Compounds were identified by comparing their mass spectra and retention times with those of available commercial or synthesized authentic standards, and by search in the NIST library.

Chiral HPLC

Chiral analyses were performed with a Shimadzu LC-2030C 3D system equipped with a photo-diode array detector using a chiral column Chiralpak IG (5 μm particle size, 4.6 mm diameter × 150 mm, Daicel Chemical Industries Ltd.) equipped with a Chiralpak IG guard column (5 μm particle size, 4.0 mm diameter × 10 mm). The column was eluted in isocratic mode with 95% hexane and 5% isopropanol at 0.5 mL min⁻¹ for 60 min, and the absorbance was monitored at 254 nm. Enantiomers were identified based on the elution order previously reported.³⁴

Molecular models

AaeUPO and *MroUPO* models were obtained from the chain-A of the 2YP1 and 5FUJ crystal structures, after removing the Cys227 dimerization disulfide bridge from the second structure. Homology models for *CglUPO*, *rHinUPO* and *rCciUPO* were obtained at the Swiss-Model server,^{35,36} with related crystal structures as templates. The heme cofactor and the Mg ion (along with its two coordinated water molecules) were then superimposed using 2YP1 and 5FUJ as templates, followed by an initial minimization to release steric clashes. An oxygen atom (iron-oxo) was finally added to all structures modeling heme compound I. All systems were prepared at pH 7 with the protein preparation wizard from Schrödinger.³⁷ Heme charges were obtained from a quantum mechanics/molecular mechanics (QM/MM) minimization using QSite at the DFT M06-L(lacvp*)/OPLS level of theory. Based on previous experience in heme-bound systems,³⁸ the charge of the Mg ion was set to 1.2. isophorone and 4HIP (*S*- and *R*-enantiomers) substrates were built with Maestro and optimized at the OPLS level of theory. In addition, two explicit water molecules were placed in the active site when exploring diffusion of the ligands. The presence of a water molecule has been highlighted in compound I activity and might be important when diffusing polar substrates such as 4HIP.³⁹

Ligand diffusion simulations

The new adaptive-PELE software⁴⁰ was used to study ligand diffusion and binding on the different UPO structures. PELE uses a Monte Carlo (MC) procedure to describe the protein-ligand conformational dynamics. At each MC iteration, the al-

gorithm performs: 1) ligand perturbation (translation and rotation); 2) protein perturbation following normal modes; 3) explicit water sampling; 4) side chain prediction; and 5) overall minimization. The final structure is then accepted or rejected based on a Metropolis criterion. The adaptive protocol improves PELE's sampling by running multiple short simulations (epochs) where initial conditions are selected through a reward function aiming at sampling non-visited areas. We also used a new version of PELE that allows for explicit water sampling, where water molecules are allowed to freely move (with 100 small translations and rotations) after the backbone sampling. Two sets of simulations were performed for each ligand and structure. In the initial one the ligand was placed on the protein surface, next to the entrance to the active site (at ~16 Å from the heme's iron atom), and allowed to diffuse freely into the heme distal site. The structure with the best (ligand) binding energy from the initial simulation was then selected for a second local refinement run, where the ligand center of mass was constrained to move within 8 Å from the heme's iron. All simulations used 50 epochs of 16 MC PELE steps each with 128 computing cores. Interaction/binding energies (kcal mol⁻¹) were derived as $E_{ab} - (E_a + E_b)$, where E_{ab} is the total energy of the complex, E_b the energy of the ligand and E_a the energy of receptor (everything but the ligand), all of them obtained at the OPLS2005 level of theory with a surface GB implicit solvent model.

Results and discussion

Regioselectivity in isophorone transformation by UPOs

In the present work, the ability of several UPOs to oxidize isophorone was analyzed, and different transformation patterns were observed (Fig. 1). The peroxygenases from the ascomycetes *C. globosum* (*CglUPO*) and *H. insolens* (*rHinUPO*), and the basidiomycete *A. aegerita* (*AaeUPO*) were found to transform the substrate, although with different regioselectivities (Table 1). In contrast, the enzymes from the basidiomycetes *C. cinerea* (*rCciUPO*) and *M. rotula* (*MroUPO*) were unable to

Fig. 1 GC-MS analysis of 0.1 mM isophorone reactions (30 min) with 0.1 μM of *MroUPO*, *rCciUPO*, *CglUPO*, *rHinUPO*, *AaeUPO* and control without enzyme, showing the remaining substrate (IP, isophorone) and the hydroxylated (4HIP and 7HIP) and oxo (4KIP and 7FIP) derivatives.

Table 1 Comparison of five UPOs in isophorone (0.1 mM) conversion (% of substrate) and relative abundance of the products 4HIP, 7HIP, 4KIP and 7FIP (% of the total products) after 30 min reaction, using different enzyme and peroxide doses

convert the substrate, even at the highest (10 μ M) enzyme doses tested.

*Cgl*UPO and *rHin*UPO selectively oxidized isophorone in position 4 (Scheme 1A) yielding mono-hydroxylated 4HIP and the keto-derivative 4KIP, which were identified by their retention times compared with authentic standards (Fig. S1†) and their mass spectra (Fig. S2†). Besides the 4HIP and 4KIP molecular ions at *m/z* 154 and 152, respectively, their mass spectra showed a shift from α -isophorone fragments at *m/z* 54 and 82 to *m/z* 70 and 98 in 4HIP and to *m/z* 68 and 96 in 4KIP, which corresponds to the insertion of a hydroxyl or keto group. Isophorone conversion by *rHin*UPO and *Cgl*UPO (84 and 95%, respectively) was already efficient at low enzyme dose (0.1 μ M) and both enzymes showed the tendency to over-oxidize 4HIP to form 4KIP. Over-oxidation was more pronounced in the case of *rHin*UPO as shown by the ratio of

Scheme 1 Isophorone (IP) hydroxylation catalyzed by *Cgl*UPO and *rHin*UPO (A) and *Aae*UPO (B), showing the hydroxylated 4HIP (4-hydroxyisophorone) and 7HIP (7-hydroxyisophorone) and the oxo 4KIP (4-ketoisophorone) and 7FIP (7-formylisophorone) derivatives.

4HIP to 4KIP of 1 : 1 (compared to 4 : 1 in the case of *Cgl*UPO) (Table 1).

*Aae*UPO was found to be less regioselective in oxidizing isophorone, since – in addition to 4HIP – other mono-hydroxylated and keto-derivatives were formed (Scheme 1B). These side products were identified as 7HIP and 7-formylisophorone (7FIP) due to their mass spectra (Fig. S3†) that matched with those previously reported,³⁴ with the singular mass fragment at *m/z* 125 in 7HIP, different from that at *m/z* 112 in 4HIP.

Reactions with low *Aae*UPO dose (0.1 μ M) showed that hydroxylation took place in similar proportion at C₄ (46%) and C₇ (54%), but 7HIP was rapidly over-oxidized to form the corresponding aldehyde, and 7FIP and 4HIP were the major final products of the reaction (Table 1). Interestingly, 4HIP was barely further oxidized to 4KIP.

The regioselectivity observed in the hydroxylation of isophorone by some UPOs is similar to that reported for certain P450s. Among them, P450cam-RhFRed variants have been reported to yield 4HIP, 7HIP and isophorone oxide (2,3-epoxy-3,5,5-trimethyl-1-cyclohexanone) as major products, with 4HIP as the only product from one of the variants.¹¹ 4HIP was also the main product of reactions with CYP102A1 and CYP101A1,

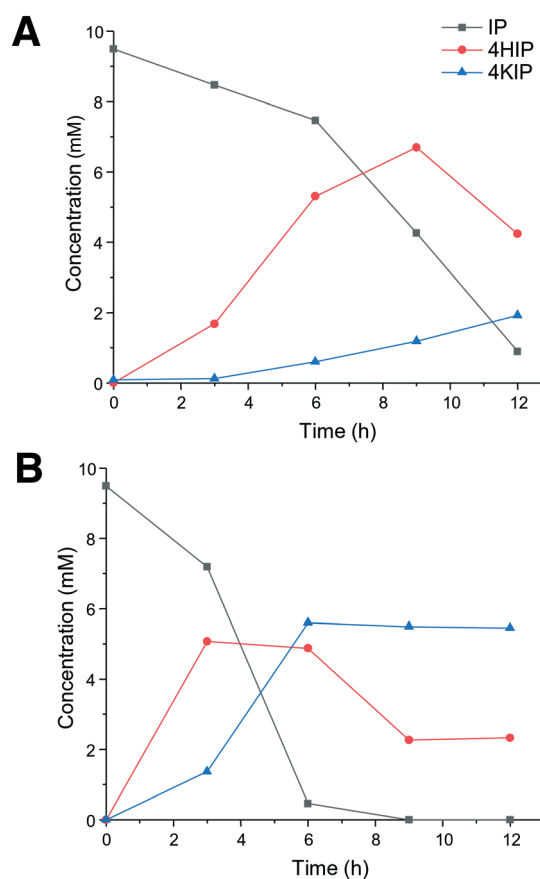

Fig. 2 Time course of 10 mM isophorone (IP) reaction with 5 μ M *Cgl*UPO (A) and *rHin*UPO (B) and H₂O₂ (added with a syringe pump to give 5 mM h⁻¹ concentration), showing substrate and products (4HIP and 4KIP) concentrations.

<i>AaeUPO</i>	20.1 ± 1.1	1380 ± 200	14.6 ± 2.2
<i>CglUPO</i>	4.4 ± 0.4	309 ± 55	14.2 ± 2.8
<i>rHinUPO</i>	42.0 ± 9.8	633 ± 201	66.4 ± 26.1

^a Data represent mean values of three replicates with standard deviations.

although minor amounts of the epoxide, 7HIP and further oxidation products were observed.³⁴ P450s, unlike *rHinUPO* or *CglUPO*, seem to be unable to oxidize 4HIP into 4KIP and, therefore, two enzymes (a P450 and an alcohol dehydrogenase) are necessary to obtain 4KIP from isophorone.¹¹

In view of the higher selectivity to form the products of interest (4HIP and 4KIP), *CglUPO* and *rHinUPO* were selected to perform reactions with higher ($\times 100$) substrate load (Fig. 2). These experiments revealed a faster substrate conversion by *rHinUPO* that completely transformed isophorone within 6 h, while *CglUPO* needed 12 h for 87% conversion. As expected, a higher proportion of 4KIP was observed in the *rHinUPO* reactions. A higher enzyme dose would be needed to complete conversion into 4KIP, as it was already found when lower substrate concentrations were tested (Table 1).

Kinetics of isophorone hydroxylation by UPOs

Despite the difficulties to determine initial enzymatic reaction rates by GC-MS, kinetic curves for isophorone hydroxylation by the three UPOs could be obtained (Fig. S4†) and reaction constants (k_{cat} , K_{m} and $k_{\text{cat}}/K_{\text{m}}$) were estimated (Table 2). There were differences in enzyme affinities, since the K_{m} values were four- and two-fold higher for *AaeUPO* than for *CglUPO* and *rHinUPO*, revealing the higher isophorone affinity of the two latter enzymes. Moreover, *rHinUPO* displayed a ten-fold higher turnover number (k_{cat}) compared to *CglUPO*, which resulted in five-fold higher catalytic efficiency, while the efficiencies of *AaeUPO* and *CglUPO* were similar.

The catalytic efficiency of these UPOs hydroxylating isophorone is in the range of previously reported for the hydroxylation of cyclohexane by other UPOs.⁴¹ On the other hand,

the K_{m} of *CglUPO* and *rHinUPO* for isophorone hydroxylation is similar to values (380–440 μM) reported for CYP102A1 variants when decoy molecules were used, and the turnover numbers of these variants (2.5–5.5 s^{-1}) were similar as well to that reported herein for *CglUPO* (4.4 s^{-1}).³⁴

Higher total turnover numbers (TTNs) were attained with *rHinUPO* (2660) than with *CglUPO* (1820) under the same reaction conditions, although these values could be up to 5600 and 3600 when lower enzyme doses were used (Table 3). The TTNs are in the range of those reported for two-step (1567) or one-step (3421) isophorone oxidation by the combination of P450-WAL and Cm-ADH10.¹¹

UPO enantioselectivity on isophorone and racemic 4HIP

Enantioselectivity in the synthesis of 4HIP by the three UPOs hydroxylating isophorone was determined by HPLC (Fig. S5†). The results of the chiral analysis showed that only the reaction with *AaeUPO* can be considered as stereoselective, with an enantiomeric excess (ee) of 88% *S*-4HIP (Table 4). The three UPOs preferentially formed the *S*-enantiomer, in contrast to P450s that rather formed the *R*-enantiomer.^{11,42}

The above values were estimated under reaction conditions where the product concentration was similar for all

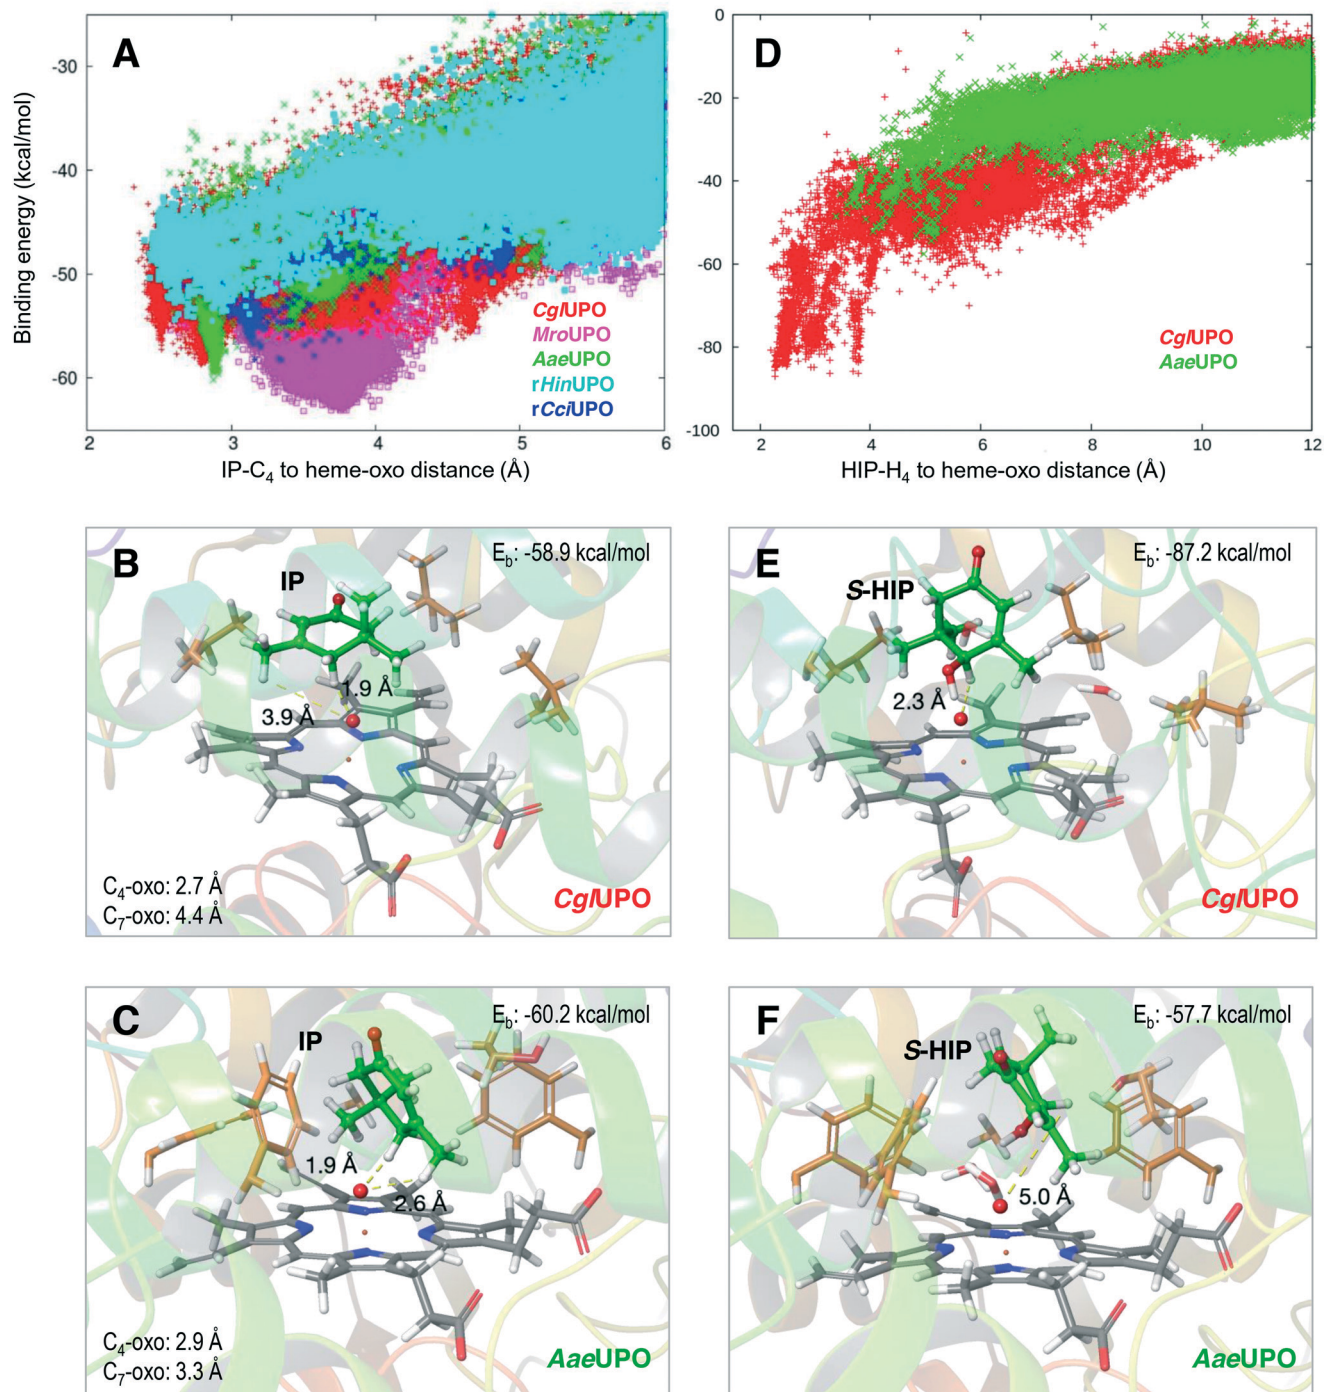

Fig. 4 Isophorone (IP, left) and (*S*)-4-hydroxyisophorone (*S*-HIP, right) diffusion refinement on five UPOs, with adaptive PELE³⁵ monitoring the distance between the substrate and the oxo atom (red sphere) of the H₂O₂-activated heme with respect to the binding energy (E_b). A) C₄ distance vs. energy plot for IP diffusion in *Cg*UPO (red), *Mro*UPO (magenta), *Aae*UPO (green), *rHin*UPO (cyan) and *rCci*UPO (blue) (see Fig. S7† for individual PELE plots of the five UPO systems). B and C) IP at the two lowest binding-energy positions during the *Cg*UPO and *Aae*UPO simulations (A), respectively. D) H₄ distance vs. energy plot for *S*-HIP diffusion on *Cg*UPO (red) and *Aae*UPO (green). E and F) *S*-HIP at the two lowest binding-energy positions during the *Cg*UPO and *Aae*UPO simulations (D), respectively.

three enzymes (2.0–3.3 mM) and 4HIP over-oxidation was minimal, since it was observed that the ee of the hydroxylation product changed when 4KIP was formed. This was due to higher velocity in the conversion of the *S*-enantiomer compared to the *R*-enantiomer, as observed in *rHin*UPO reactions

with racemic 4HIP as substrate (Fig. S6†). That way, a kinetic resolution of the racemate, with ee of 99–100% and 60–75% recovery, can be achieved with *rHin*UPO and *Cg*UPO. In contrast, *Aae*UPO just slowly converted the racemic mixture of 4HIP, as it was also observed in the reaction of the enzyme

with isophorone, where only traces of 4KIP were formed (Fig. 1), and no enantiomeric enrichment was produced.

Computational analyses: molecular modeling

Isophorone diffusion was done in two simulation steps using PELE software.⁴⁰ For the initial simulation, after preparing all systems placing isophorone on the surface next to the entrance channel, the substrate was allowed to move freely within 16 Å of the heme iron. In all systems, the substrate moved easily into the active site. Structures in direct contact with the heme produced the best binding-energy poses, although they presented different substrate orientations. Therefore, after selecting the best binding-energy structure, we run a local refinement, where the ligand was forced to move within ~8 Å of the heme iron. Fig. 3 shows an example of these two runs for *CglUPO*, where we display the binding-energy profile with respect to the C₄-oxo distance for the initial (black) and the refinement (red) simulations.

Fig. 4A shows the binding energy along the C₄-oxo distance for isophorone in the refinement runs for the five UPO structures (identified with different colors). Among them, three UPOs show distances lower than 3 Å: *CglUPO* (red), *AaeUPO* (green) and *rHinUPO* (cyan) (see Fig. S7† for the individual PELE plots). Such positioning will largely facilitate the hydrogen-atom abstraction by compound I, in agreement with the experimental results (Table 1). Interestingly, different isophorone reactive poses were detected for the different UPOs, as shown in Fig. 4B and C for *CglUPO* and *AaeUPO*, respectively. A closer examination of these structures showed shorter distances to the heme oxo for the pro-*S* (1.9 Å in both) than for the pro-*R* (3.5 and 2.6 Å, respectively, not shown) hydrogen atoms, which explained the preferential formation of the 4HIP *S*-enantiomer, as shown in Table 4.

The resulting *S*-4HIP was also diffused with PELE, and strong differences in the C₄-oxo distances and energies were obtained, as illustrated in Fig. 4D for two of the systems, with *CglUPO* closely approaching the heme oxo (Fig. 4E) while no catalytic distances were attained by *AaeUPO* (Fig. 4F). The above results agree with isophorone oxidation to 4KIP by *CglUPO*, while 4HIP is the main product from *AaeUPO* (Table 1), as well as with the deracemization results of chiral 4HIP (Fig. S6†). On the other hand, although additional PELE calculations showed a similar C₄-oxo distance for the *R*-enantiomer (data not shown), the slightly worse (5 kcal mol⁻¹) binding energy of the different pose adopted (with respect to *S*-4HIP) is in agreement with the *S* preference experimentally observed (Fig. S6†).

Finally, the dual hydroxylation at the isophorone C₄ and C₇ positions by *AaeUPO*, compared with the selective oxidation at C₄ by *CglUPO* and *rHinUPO* (Table 1) was also analyzed in the PELE simulations. The isophorone C₇ position is not at a catalytically relevant distance in *CglUPO* (4.4 Å, Fig. 4B and S8A†), while the C₇-oxo and C₄-oxo distances for *AaeUPO* (3.3 and 2.9 Å, respectively, Fig. 4C and S8B†) are within reaction limits (the oxo to hydrogen distances are also

shown in Fig. 4B and C). The above results explain the lack of C₇ hydroxylation by *CglUPO* and the similar percentages of C₇-derivatives (7HIP + 7FIP) and C₄-derivatives (4HIP + 4KIP) by *AaeUPO* (Table 1).

Conclusions

We report a new enzymatic route for isophorone oxidation to form 4HIP and 4KIP, which are interesting products for the flavour-and-fragrance and pharmaceutical industries. The direct enzymatic oxidation of isophorone to 4KIP (with only one enzyme) is reported here for the first time for two fungal peroxygenases (*CglUPO* and *rHinUPO*). The above represents an advantage over the route with P450s, since the latter needs two enzymes (a P450 and an alcohol dehydrogenase) to obtain 4KIP from isophorone. However, process optimization of isophorone conversion by UPO is needed to attain the high-scale transformations reported for whole-cell P450 systems.⁴³
