Synthesis of organometallic pentalenide complexes

Stuart M. Boyt, Niko A. Jenek and Ulrich Hintermair

While a number of reports have established the unique structures and electronic properties of mono- and dinuclear pentalenide complexes of s, p, d and f block elements, access to these intriguing compounds is restricted by synthetic challenges. Here we review various strategies for the synthesis, functionalisation and (trans)metalation of pentalenide complexes from a practical point of view, pointing out promising avenues for future research that may allow wider access to novel pentalenide complexes for application in many different areas.

1. Introduction

Pentalene (Pn, C₈H₆) has long fascinated theoretical and synthetic organic chemists for its anti-aromatic 8π system. Unlike the flexible 8π cyclooctatetraene (COT, C₈H₈) Pn is planar due to its bicyclic ring structure, enforcing its anti-aromaticity. As a result, it readily dimerises above −196 °C to form two fulvene units isolated from each other by a cyclobutane linkage (Fig. 1). Due to its inherent instability, Pn itself is of limited use for applications in synthetic chemistry. However, similar to other 8π anti-aromatics like COT, double reduction of Pn to pentalenide (Pn⁻², C₈H₆⁻²) generates a stable 10π aromatic system that presents itself as a useful π ligand for organometallic chemistry. Its dianionic nature makes it a stronger donor for Lewis-acidic metals than neutral 10π hydrocarbons such as

Stuart M. Boyt, Niko A. Jenek, Ulrich Hintermair

Stuart M. Boyt graduated from the University of Warwick with an MChem in Chemical Biology but developed a taste for organometallic chemistry after a masters thesis with Adrian Chaplin looking at NHC complexes of group 9 metals. In 2015 he moved to the University of Bath to pursue his PhD in the Hintermair lab. His project involves synthesizing new pentalenide ligands from readily available precursors and investigating their reactivity towards a range of s-, d- and p-block compounds.

Niko A. Jenek obtained his BSc in Chemistry from the University of Stuttgart in 2013, after which he moved to the University of Freiburg to finish his master’s studies with a thesis on the fluorination of silicon surfaces with Ingo Krossing in 2017. After further fluorination adventures at the Fraunhofer Institute for Solar Energy Systems he joined the Hintermair group at the University of Bath for his PhD on novel pentalenide complexes for catalysis.

Ulrich Hintermair studied Chemistry and Chemical Engineering in Würzburg and Lyon with a stint at the University of St Andrews. After completing his PhD with Walter Leitner at Aachen he was a Humboldt postdoctoral fellow with Bob Crabtree at Yale University. In 2013 he started his independent academic career at the CSCT in Bath where he currently holds a Royal Society University Research Fellowship. Research in his group revolves around catalysis with metal complexes, including organometallic chemistry and real-time spectroscopy for mechanistic investigations.
Developed the expertise and equipment required for pentalestry. Historically, only few dedicated organometallic labs have naphthalene, and the two five-membered ring systems enable symmetrical charge distribution for reversible hapticity shifts of the metals bound to it (Fig. 2).

Due to this facile hapticity shift and a large degree of flexibility around the central C–C bridge, Pn2⁻⁻ ligands exhibit some uniquely adaptive coordination abilities that neither COT nor naphthalene derivatives display. Pn²⁻⁻ may wrap itself around, electron-deficient metal centres in η⁵ coordination mode, or form doubly η⁵/η¹ coordinated homo- and heterobimetallic complexes with direct metal–metal interactions within syn-bimetallics and strong electronic coupling in anti-bimetallic systems. Given these intriguing properties, it may appear surprising that organometallic Pn²⁻⁻ chemistry is far less explored and developed than that of its 6π congener cyclpentadienide (Cp⁻⁻, C₅H₅⁻⁻), arguably the most important and most widely used organometallic ligand to date. Whereas thousands of Cp⁻⁻ complexes including almost every metal in the periodic table are known and widely used in numerous applications including sensing, electrochemistry, magnetism, material synthesis, and, of course, catalysis, only about 150 examples of variously substituted Pn²⁻⁻ and HPn⁻⁻ complexes (including precursor salts) have been reported so far. This limitation is in no small part due to the practical challenges associated with accessing suitable synthons for Pn²⁻⁻ chemistry. Historically, only a few dedicated organometallic labs have developed the expertise and equipment required for pentalenide chemistry, each following their own preferred synthetic method. However, a number of routes to suitable precursors have emerged in different parts of the chemical literature over the past 50 years. Here we summarise and compare various strategies for the synthesis and functionalisation of Pn²⁻⁻ complexes that promise to give more facile access to a wider range of precursors, and thus hopefully allow more widespread exploration of the intriguing properties of organometallic pentalenide complexes in different areas in the future.

2. Synthesis of pentalenides

In the context of discussing synthetic pentalenide chemistry, it is useful to distinguish the 8π antiaromatic pentalenide (Pn, C₅H₅), the non-aromatic dihydropentalene (H₂Pn, C₅H₆) existing as several double-bond isomers, the 6π aromatic hydropentalenide (HPn⁻⁻, C₅H₇⁻⁻), and the 10π aromatic pentalenide (Pn²⁻⁻, C₅H₈⁻⁻). Their structures and interconversion pathways are laid out in Fig. 3.

2.1. Deprotonation of dihydropentalenes

Mono-anionic 6π HPn⁻⁻ can easily be generated by deprotonation of H₂Pn using a weak base, as demonstrated by Katz and Mrowca. They showed that an isomeric mixture of H₂Pn would react with KOH and Tl₂SO₄ in water to furnish TlPnH as a precipitate in moderate yields (Fig. 4). In contrast to the neutral, unsubstituted H₂Pn, HPn⁻⁻ salts are thermally stable and can be isolated and stored at room temperature like the related MCp salts (M = Li, Na, K). Jones et al. later showed TIOEt in pentane to be equally effective in generating TlPnH from H₂Pn. The first pKₐ of H₂Pn must therefore be below 14, showing it to be slightly more acidic than HCp. Presumably due to charge effects, deprotonation of the second ring in HPn⁻⁻ to furnish the fully 10π delocalised Pn²⁻⁻ requires a stronger base. Katz et al. showed that Li₂Pn can be prepared by double deprotonation of H₂Pn with an excess of "butyllithium at −78 °C (Fig. 5). Although the second pKₐ value of H₂Pn is not known with certainty, using two (or more) equivalents of bases with pKₐ values >25 usually leads to quantitative double deprotonation of all H₂Pn double-bond isomers. While Katz’s original preparation used heptane...
to precipitate Li$_2$Pn, Stezowski et al. later used dimethoxyethane (DME) to obtain single crystals of $\eta^1$[Li(DME)]$_2$Pn that showed both metals to adopt *anti* configuration around the planar Pn$^{2-}$ in the solid state. A recent computational study confirmed this to be the preferred geometry for all alkali-metal Pn$^{2-}$ complexes in solution.

While these reactions look appealingly straightforward, and the utility of HPn$^-$ and Pn$^{2-}$ salts for transmetalation reactions is well documented (see section 3), the difficulty lies in generating the H$_2$Pn starting material. In the following subsections we review the most prominent methods reported.

### 2.2. Pyrolytic routes to dihydropentalenes

H$_2$Pn can be obtained from controlled, anaerobic pyrolysis of suitable precursors such as isodicyclopentadiene in Katz’s method (Fig. 4). Isodicyclopentadiene was formed by treating suitable precursors such as isodicyclopentadiene with acetic anhydride and selenium dioxide, followed by dehydration of the resulting alcohol by passing over alumina at 300 °C. Anaerobic pyrolysis of isodicyclopentadiene at 575 °C lead to the formation of 1,4-H$_2$Pn (through release of ethylene) in ~30% yield, to which hydroquinoline had to be added immediately to prevent polymerisation. However, Kazennova et al. later reported that passing the pyrolysis distillate through a plug of solid potassium hydroxide provided pure H$_2$Pn samples that were stable to polymerisation at −78 °C. They also demonstrated an improved synthesis of isodicyclopentadiene, reporting a 40% overall yield of H$_2$Pn starting from HCp.

An alternative precursor was reported by Jones and Schwab, who showed that COT undergoes thermal rearrangement between 400–665 °C to give H$_2$Pn (Fig. 6) in addition to acetylene, benzene and styrene. The selectivity to H$_2$Pn was found to be highly temperature-dependent, with the optimum conversion occurring between 500–600 °C. An optimised procedure was later reported by Cloke et al., in which a 87% yield was achieved thanks to precise temperature and residence time control during the continuous-flow pyrolysis. In this set-up, the resulting H$_2$Pn were condensed into a butyllithium solution in DME/hexane at −78 °C to be directly converted to the more stable [Li$_2$(DME)$_2$]Pn salts that precipitate to be further purified by washing with cold hexane.

While both routes are reasonably well established (with lower yields and more synthetic steps starting from inexpensive (HCp)$_2$, or fewer steps and higher yields starting from the more valuable COT), they are limited to the synthesis of the parent (unsubstituted) H$_2$Pn. Substituted iso-CpH or COT have not been explored as pyrolysis precursors for substituted H$_2$Pn, likely due to the difficulty and expense of synthesising the starting materials and/or unwanted thermal rearrangement pathways. A slightly more versatile pyrolytic method has been reported by Griesbeck, who showed the use of two protected vinyl fulvenes, synthesised by Diels–Alder reaction of HCp and acroleins followed by pyrrolidine-facilitated Knoevenagel condensation with an additional equivalent of HCp (Fig. 7).

Anaerobic pyrolysis of these compounds at 520 °C furnished H$_2$Pn (88% yield) or 2-Me-PnH$_2$ (50% yield) through thermal cyclisation accompanied by loss of HCp. This methodology is appealing as the precursors are straightforward to synthesise from inexpensive starting materials, and potentially provide a route to other substituted H$_2$Pn through use of substituted acroleins in the first step and/or substituted HCp in the second step. However, the final pyrolysis may require optimisation for each protected vinyl fulvene.

Another pyrolytic route to H$_2$Pn and 2-Me-PnH$_2$ has been reported by Stapersma et al., who showed that tetracyclo-oct-7-enes may be rearranged by anaerobic heating between 250 °C and 500 °C. These starting materials, derived from photolytic rearrangements of 7-carbomethoxynorbornadienes, are comparatively difficult to prepare, and their pyrolysis reactions gave relatively low H$_2$Pn yields of 7–16% due to the formation of a large number of side products.

**Fig. 6** Synthesis of dihydropentalene by anaerobic flash vacuum pyrolysis.
2.3. Thermal cyclisations of vinyl fulvenes

A mild thermal synthesis of H$_2$Pn has been described by Gajewski and Cavender, who found that neat 6-vinyl fulvene will undergo thermal cyclisation at 110 °C (Fig. 8). This procedure gave exclusively the 1,5-PnH$_2$ isomer due to facile 1,5-hydride shifts occurring.

6-Propenylfulvene was reported to undergo a thermal reaction at 65 °C, however, analysis of the products obtained was limited and no isolated yields were reported. The relatively low temperatures required to induce these rearrangements promise practical benefits over the higher temperature pyrolysis reactions discussed above. However, 6-vinyl fulvene is again not trivial to synthesise. Neuenschwander reported two preparations: the first reacting 1-hydroxymethyl-spiro-[2,4]-hepta-4,6-diene with HCl, the second reacting NaCp with 3-acetoxy-3-chloro-1-propene. Both routes give low yields (10% and 20%, respectively) due to significant side reactions occurring. Erden et al. describe an improved protocol, starting with condensation of HCP with 3-(methylthio)propanal, followed by oxidation with NaIO$_4$ and sulfoxide elimination with DBU. The reported yield across the three steps was 37% including a purification after each step.

Kaiser and Hafner showed that 6-(2-aminovinyl)fulvenes would undergo a solution-phase thermal cyclisation and isomerisation in boiling piperidine to give 3-amino-PnH$_2$ in high yields (Fig. 9). These species could be reduced with LiAlH$_4$ to give an organoaluminium species that, upon hydrolysis, underwent amine elimination at room temperature to yield H$_2$Pn. The syntheses of some mono- and di-substituted H$_2$Pn were also described, using 6-substituted amino fulvenes in the first step, and using alkyl/aryl lithiums in the following reduction/elimination step. However, purification procedures for these compounds were not described.

Similar to the above case of vinyl fulvenes, the amino-vinyl fulvene starting materials (derived from condensation of HCP...
with di(alkyl)-aminoacroleins are difficult to handle due to their thermal instability. In theory, starting from substituted HCP could produce more stable amino-vinyl fulvenes and provide access to more highly substituted H$_2$Pn. However, it is difficult to predict whether these species would follow the same thermal rearrangement pathways.

While some of the thermal routes reviewed above have been shown to be quite efficient in generating H$_2$Pn precursors suitable for double deprotonation to Pn$\text{^2-}$, the limitations of these rearrangement reactions are obvious: their precursors rely on multi-step syntheses and/or utilise expensive starting materials, they often require special apparatus, conditions need to be carefully controlled and optimised, and they are rather limited in scope.

### 2.4. Solution-phase rearrangement reactions

Several solution-phase syntheses of H$_2$Pn that do not involve pyrolytic steps have been described in the literature. Jones et al. reported the synthesis of Li$_2$Pn starting with the conversion of cycloheptatriene to 8,8-dibromobicyclo[5.1.0]octa-2,4-diene using bromoform and KO'Bu (Fig. 10).$^{10}$ Reacting this species with methyl lithium triggered a carbene-induced rearrangement to give H$_2$Pn which was trapped with "$\text{^7}$butyllithium in DME/pentane to give [Li$_2$(DME)$_2$]Pn. Although the overall yields are quite low (<12%), this solution-phase method can be performed with standard laboratory equipment.

The Skattebøl rearrangement of the transient carbene generated from the geminal dihalo-cyclopropane unit allows for some variability in the substitution pattern. Cycloheptatriene can be converted to 7-alkycycloheptatrienes through hydride abstraction, formation of the ethyl ether with EtOH and NaHCO$_3$, then finally substitution of the ether with a Grignard reagent. Although 7-tert-butyl-cycloheptatriene was found not to react with CHBr$_3$ and KO'Bu, the methyl, ethyl and isopropyl variants did undergo this transformation (albeit with low yields of 9–15%). Treating the gem-dibromo cyclopropane unit in these species with methyl lithium furnished 1-alkyl substituted H$_2$Pn, which gave high yields of Li$_2$[1-alkyl-Pn$^\cdot$] upon double deprotonation with "$\text{^6}$butyllithium (53–70%).$^{10}$

Another synthesis of H$_2$Pn via carbone rearrangement has been reported by Brinker and Fleischhauer.$^{29}$ trans-1,2-Bis(2,2-dibromocyclopropyl)ethane, formed by twofold reaction of trans-1,3,5-hexatriene with CHBr$_3$ and KO'Bu, was found to rearrange to H$_2$Pn when treated with methyl lithium in diethyl ether. However, significant side products were formed, and attempts to separate the mixture using vapour-phase chromatography proved unsuccessful.

Ashley et al. developed a solution-phase synthesis of hexamethylpentalenide, Pn$^{\text{2-}}$, the pentalenide analogue of penta-methylcyclopentadiene (Cp$^\text{+}$).$^{30}$ The starting material for this preparation is the so-called ‘Weiss-H$_4$’ compound, obtained from reaction of dimethyl-1,3-acetonedicarboxylate with glyoxal.$^{31}$ Reacting the ‘Weiss-H$_4$’ compound with an excess of methyl iodide and K$_2$CO$_3$, followed by hydrolysis/decarboxylation with concentrated HCl yielded 2,4,6,8-tetramethylbicyclo[3.3.0]octane-3,7-dione (Fig. 11). The so-obtained diketone could be oxidised with bromine in MeOH, then reacted with ‘methylcerium dichloride’ (derived from methyl-lithium and cerium trichloride) at $\sim$78 °C in THF. The resulting alcohol is prone to polymerisation and thus extremely sensitive to acid. The final dehydration reaction therefore required an aprotic method, and it was found that LiCl in DMSO was effective in producing 1,3,4,5,6-pentamethyl-1,2-dihydropentalen, Me$_6$Pn or Pn$^\cdot$, an exocyclic isomer of hexamethylpentalenide. This compound is stable due to its vinylic fulvene structure preventing cyclic conjugation of an otherwise anti-aromatic π system, and marks the only pentalenide synthon where the 8π Pn$^\cdot$ is stable whereas the non-aromatic H$_2$Pn$^\star$ is unknown. As outlined in Fig. 3, to transform the Pn$^\star$ into Pn$^{\text{2-}}$ it must be doubly reduced. Direct reaction with alkali metals lead to degradation of the starting material.
through polymerisation, but reaction with a bulky trialkyl borohydride (LS-selectride) allowed for 1,4-addition of a hydride to yield LiHPn⁺ (Fig. 12).32 Use of the less sterically demanding L-selectride resulted in a mixture of 1,2- and 1,4-addition products. LiHPn⁺ is reportedly insoluble in most organic solvents, requiring solubilisation with pyridine for NMR analysis. The final deprotonation of LiHPn⁺ however was performed in a refluxing hexane slurry with n-butyllithium and TMEDA to afford the TMEDA adduct of Li₂PN⁻ (Fig. 12).32 In order to obtain single crystals suitable for XRD analysis, Li₂(TMEDA)xPN⁻ had to be transmetallated again using methyl-lithium in neat TMEDA.32 Despite requiring multiple steps involving several sensitive intermediates, the overall synthesis of Li₂(TMEDA)xPN⁻ is well developed and gives access to a valuable synthon for organometallic pentalenide chemistry without the use of special apparatus. Using different electrophiles (for example, ethyl iodide or isopropyl bromide) in the first step could in principle allow for incorporation of different substituents into these four positions, but this change would likely require downstream modification of the overall synthesis. So far there is no report of such variants.

2.5. Annulation reactions of cyclopentadienes

As already exemplified in some of the previous thermal rearrangement reactions, HCp provide a convenient starting material for the synthesis of pentalene derivatives. In the following section we review examples where selective 1,2 annulation reactions of HCp have been accomplished via mild solution-phase methods. An early example was provided by Hafner and Süss, who used Li[BuCp] to synthesise Bu₃Pn through its reaction with an iminium salt derived from 5-dimethylaminooct-1-ene and triethyloxonium tetrafluoroborate (Fig. 13).33 The resulting deep blue species had to be purified by chromatography on alumina at −75 °C using pentane as the eluent. Kitschke and Lindner were later able to obtain crystals of Bu₃Pn for XRD analysis by recrystallisation from hexane.34 Its stability is interesting in that although normally one would not approach the synthesis of an organometallic PN⁻ ligand via its 8π PN version, this might be a viable approach in the case of sterically demanding substitution patterns such as 1,3,5-tris(tert-butyl) that are effective in blocking dimerization pathways. Ashley et al. have shown that a permethylated PN system may be reduced using a bulky borohydride to give HPn⁻ and then PN⁻ upon deprotonation (Fig. 11),32 so similar chemistry might be possible with other bulky PN such as Hafner’s Bu₃Pn.

Due to their known stability and ease of deprotonation, routes that give access to H₂PN synthons are still preferable in most cases. Retrosynthetic analysis shows that Hafner’s HCp annulation strategy to synthesise Bu₃Pn is well suited to give access to H₂PN as well: 1,4-Michael addition by a Cp⁻ to an electrophilic conjugated carbonyl species would yield a β-cyclopentadiene-functionalised ketone/aldehyde intermediate that is set up to undergo an intramolecular Knoevenagel condensation (Fig. 14). Compatible HCp merely require two adjacent unsubstituted carbons in order to accommodate the final ring-closing step. Thus, a wide range of mono-, 1,2 and 1,3 di-, as well as 1,2,3-trisubstituted HCp may be transformed into the corresponding H₂PN pro-ligands by reaction with simple enones (chalcones).
The simplest unsubstituted H2Pn is currently not accessible by such a transformation, as HCp and acrolein are known to undergo a Diels–Alder reaction instead of the required Michael addition. However, Griesbeck showed that moving to slightly higher substituted reaction partners, and using pyrrolidine to activate the chalcone towards 1,4 nucleophilic attack via its enamine, indeed furnishes substituted H2Pn in good yields from a single step reaction under mild conditions (Fig. 15).36

The six different 1,3-disubstituted H2Pn thus prepared were air-stable compounds that did not polymerise and could be purified by high-vacuum distillation. The initially obtained 1,2 double-bond isomers were found to isomerise to the more stable 1,5 form when contacted with Brønsted acids (e.g. trifluoroacetic acid or activated alumina) or when heated above 500 °C. Curiously, none of the 1,3-disubstituted H2Pn reported in this study have been taken forward to the Pn2− form by double deprotonation or used as organometallic synthons in other reports so far.

Another, more highly substituted example of this strategy has been reported by Le Goff,37 who reported the fluoride-catalysed condensation of 1,2,3-Ph3CpH and 1,2,3-triphenylenone to yield Ph6PnH2 (Fig. 16). Oxidation with N-bromosuccinimide reportedly afforded the corresponding Ph6Pn as another example of an 8π pentalene stabilised by suitable substitution pattern, as inferred from its UV-vis spectrum.

Its corresponding Ph6Pn2− would make an interesting organometallic ligand, however, this two-page single-author communication does not contain any synthetic or analytical details, and the synthesis has never been replicated in later literature.

2.6. Annulation reactions of fulvenes
In cases where the required chalcone is either difficult to access or does not display the desired reactivity, a step-wise approach to H2Pn synthesis via HCp annulation is also possible. Condensation of a HCp with an aldehyde yields a 6-substituted fulvene that may be attacked by an enolate to ring-close via an intramolecular Knoevenagel condensation (Fig. 17). Although apparently introducing an additional reaction step, it eliminates the need for synthesising the enone in the first place. Formation of the fulvene intermediate from HCp and aldehyde follows a straightforward condensation reaction using pyrrolidine in MeOH as described by Stone and Little (Fig. 18).38

---

Fig. 14 Retrosynthesis of substituted dihydropentalenes from cyclopentadienes and enones.

Fig. 15 Synthesis of di-substituted dihydropentalenes by pyrrolidine-facilitated condensation of cyclopentadiene and substituted enones.

Fig. 16 Synthesis of hexaphenylidihydropentalene, and its oxidation into hexaphenylpentalene.
6-Substituted fulvenes are stable enough to be isolated, however, with their exocyclic double bond being polarised to enable nucleophilic attack by a range of nucleophiles (Fig. 18). Coskun et al. have demonstrated the utility of this reactivity for \( \text{H}_2\text{Pn} \) synthesis (Fig. 19). Reaction of \( \text{HCp} \) with a range of different aldehydes afforded 6-substituted fulvenes that cleanly condensed with acetone (used as the solvent for this transformation) at room temperature in the presence of pyrrolidine to give variously substituted \( 1,3\)-RMe-PnH\(_2 \) in good yields. The air-stable products were obtained after evaporation of solvent and side products (mainly from cross-condensation of acetone) followed by flash chromatography on silica, which was reported not to induce any double bond isomerisation. Again, none of the \( \text{H}_2\text{Pn} \) synthesised have been deprotonated to the corresponding \( \text{Pn}^2^- \) in this or other studies. Coskun et al. only describe the reactivity of 6-methyl fulvene, but it could be supposed that fulvenes derived from substituted \( \text{HCp} \) and various aldehydes could be reacted in an analogous manner to give a variety of more highly substituted \( \text{H}_2\text{Pn} \) as outlined in Fig. 16. However, like the concerted double-condensation reaction using chalcones described above, the parent (unsubstituted) \( \text{H}_2\text{Pn} \) is not likely to be accessible via this step-wise condensation method either due to the instability of its hypothetical reaction partners (unsubstituted fulvene and acetaldehyde).

2.7. Acetylene oligomerisation

Akin to alkyne trimerization to give variously substituted 6π aromatics (Reppe chemistry), there are also some reports of alkyne oligomerisation reactions that produce pentalenes. Kuwabara et al. and Saito et al. reported the synthesis of bis-silylated dibenzopentalenides through reduction of phenylacetylenes with alkali metals (Fig. 20). When phenyl...
(tris'propylsilyl)acetylene was reacted with metallic lithium in Et₂O only a small amount of Li₂[Bn₂Pn] was obtained. The major product of this reaction, a 1,4-dilithio-1,3-butadiene, could be reacted with Ba[HMDS]₂ to give Ba[Bn₂Pn], the hydrolysis of which yielded the silyl-substituted Bn₂PnH₂. Reduction of phenyl(trispropylsilyl)acetylene with metallic potassium directly gave K₂[Bn₂Pn] in high yields, with other silyl-substituted phenylacetylenes reacting in the same manner (Fig. 20).

In another example, Bailey et al. described the PdCl₂ catalysed cyclotetramerisation of phenylacetylene to Ph₄PnH₂ (Fig. 21). However, of the two isomeric products obtained from this reaction only one would be suitable for deprotonation into a Ph₄Pn²⁻, and the report does not include methods of preparative work up and isolation.

Although interesting examples of an alternative, potentially elegant synthetic approach of accessing H₂Pn from simple alkyne starting materials, the generality and versatility of these methods remain to be explored more systematically.

2.8. Functionalisation of pentalenides

Although most solution-phase syntheses of H₂Pn are easier for more highly substituted starting materials, the opposite is true for pyrolytic pathways. However, post-synthetic functionalisation of the parent (unsubstituted) H₂Pn obtained from e.g. FVP is also possible to some degree. Cloke et al. for instance demonstrated the functionalisation of Li₃Pn with of trialkylsilyl-groups (Fig. 22), which in addition to modifying their electronic and steric parameters imparts the complexes with enhanced solubility in hydrocarbon solvents.

[Li(DME)₂]₃Pn was shown to react regio-selectively with two equivalents of TMS-Cl in THF to give 1,4-TMS₄PnH₂ as a mixture of syn and anti isomers. These could be doubly deprotonated again with n-butyllithium in DME/pentane to give the corresponding [Li(DME)₂][1,4-TMS₃Pn] for subsequent transmetalation reactions. When introduction of additional substituents was attempted at this stage, by further reaction of 1,4-TMS₄Pn⁻ with another two equivalents of TMS-Cl, 1,1,4,4-TMS₄PnH₂ was obtained exclusively. Due to the two bis-silylated sp³ carbons in the 1 and 4 positions this compound cannot be converted into a Pn²⁻ by way of deprotonation any more, limiting how much functionality may be introduced through this strategy. [Li(DME)₂]₃Pn failed to react analogously with tris('propyl)silyl chloride, but did react with the more activated tris('propyl)silyl triflate to give the corresponding 1,4-TIPS₄PnH₂, forming the anti isomer only, presumably due to steric reasons in this case. Reacting this compound with KNH₂ in Et₂O gave high yields of K₂[1,4-TIPS₃Pn], a useful ligand for use in f-block chemistry where lithium salts tend to form ‘ate’ complexes (see section 3.3).

The regioselectivity of the reaction of Pn²⁻ with hard electrophiles is a consequence of its charge distribution. In
addition to the fully delocalised (aromatic) \( \eta^8 \) form and the partially delocalised (allylic) \( \eta^3 \) form that govern reactivity with soft Lewis acids, its ground state \( \eta^3 \) resonance structure conjugates both charges to the 1 and 4 positions (Fig. 23). Thus, post-synthetic functionalisation of \( \text{Pn}^{2-} \) is often limited to these two positions.

3. Synthesis of pentalenide complexes of \( p-, d- \) and \( f- \) block metals

As mentioned in section 2.1 (Fig. 4 and 5), deprotonative metalation of \( \text{H}_2\text{Pn} \) with suitably strong bases gives straightforward access to stable \( \text{H} \text{Pn}^{-} \) and \( \text{Pn}^{2-} \) salts that can be used for transmetallation on to \( p-, d-, \) and \( f- \) block metals in the desired oxidation state. Before we review selected cases of these in section 3.3, there are also some examples of direct metalation reactions of neutral precursors via redox reactions (as in related \( \text{HCp} \) chemistry) that deserve mentioning. At present these appear less generally applicable than transmetalation from \( \text{H} \text{Pn}^{-} \) and \( \text{Pn}^{2-} \) salts, but serve to illustrate the rich coordination chemistry of pentalenide ligands.

3.1. Pentalenide and hydro-pentalenide complexes through direct metalation of neutral precursors

An early example of a direct redox metalation of \( \text{Pn} \) with a transition metal has been provided Hafner and Weidemüller, who reported that the reaction of \( \text{Pn} \) with an iron(0) precursor produced a small amount of \( \text{CO}_5 \text{Fe}_2 \text{Pn} \) (Fig. 24). According to the contemporary ionic electron counting model, and in line with the thermodynamic driving force of forming a 10π aromatic, this reaction implies a double reduction of \( \text{Pn} \) to \( \text{Pn}^{2-} \) accompanied by cleavage of the dimer and oxidation of two Fe\(^0\) centres to Fe\(^1\). Heating \( \text{Pn} \) to 50 °C in methylcyclohexane in the presence of \( \text{Fe}_2(\text{CO})_9 \) resulted in the formation of a yellow crystalline solid, supposed to be the syn-diiron pentalenide complex shown based on its NMR spectroscopic and mass spectrometric signatures. However, no XRD analysis is available to confirm the geometry, and work up details were not provided in the original paper. A mixture of isomers of \([1,3-\text{Me}_2\text{N} \text{Pn}]_2\) was reacted in a similar fashion to give an unidentified green diiron complex in 21% reported yield.

In related examples of directly metalating \( \text{H}_2\text{Pn} \) precursors, Hunt and Russel\(^{16} \) reported that reacting \( 3-\text{Me}_2\text{N} \text{PnH}_2 \) or \( 3-\text{Ph} \text{PnH}_2 \) with \( \text{Fe}(\text{CO})_5 \) would produce analogous syn bimetallic \( \text{CO}_5 \text{Fe}_2 \text{Pn} \) complexes in similar yields (Fig. 25). However, none of the geometries have been confirmed by XRD either.

Similar to direct metalation reactions of \( \text{HCp} \) with zero-valent metal precursors to give \( \text{M}(\text{Cp}) \) complexes, this conversion of a \( \text{H}_2\text{Pn} \) into a bimetallic \( \text{Pn}^{2-} \) complex implies a double deprotonation and proton reduction to \( \text{H}_2 \) to give two Fe\(^1\) centres in the resulting complex.

Another redox metalation of a \( \text{Pn} \) has been reported by Ashley et al.\(^{47} \) Refluxing \( \text{Pn}^+ \) (Fig. 11) with an excess of \( \text{Fe}(\text{CO})_5 \) would produce analogous \( \text{M}(\text{Cp}) \) complexes shown in Fig. 26 in good yields. In this case the syn geometry of the two metal centres has been established by XRD analysis. The same procedure could be applied to synthesise a related dico-balt complex using a stoichiometric amount of \( \text{CO}_5 \text{Fe}(\text{CO})_5 \) (Fig. 26). Notably, both compounds could be synthesised on a multigram scale.

Both reactions involve a formal double reduction of the \( \text{Pn}^+ \) scaffold by the metal(0) precursors, accompanied by a two-bond hydrogen shift to the exocyclic methylene group. The similar reactivity but increased stability and enhanced crystallinity of these \( \text{Pn}^{2-} \) compounds compared to the parent \( \text{Pn}^{2-} \) complexes are promising and provide motivation for further exploration of other substitution patterns in organometallic pentalenide chemistry.

Redox metallations of COT accompanied by skeletal rearrangement to \( \text{Pn}^{2-} \) are also known for some d-block metal
complexes. Brookes et al.\textsuperscript{48} reported the reaction of cis-[Ru(CO)\textsubscript{4}(GeMe\textsubscript{3})\textsubscript{2}] with COT in refluxing heptane or octane (Fig. 27). Of the several compounds produced from this reaction, a small amount of the pale yellow syn bimetallic Ru\textsubscript{2}Pn complex shown in Fig. 27 could be isolated and analysed by XRD.

Similarly, Howard et al.\textsuperscript{49} reported that COT would react with Ru\textsubscript{3}(CO)\textsubscript{10} in refluxing heptane to give a trinuclear RuPn complex, albeit in low yields and in a mixture with various other RuCOT complexes. Silyl-substituted COT have been reported to react in an analogous manner, giving the correspondingly substituted trinuclear RuPn complexes.\textsuperscript{50} All of these reactions were very low yielding and no work up procedures are available, so the synthetic utility of these transformations appears limited.

Akin to the alkali metal induced and palladium catalysed alkyne oligomerisation reactions that produce substituted H\textsubscript{3}Pn (section 2.7), the direct formation of HPn\textsuperscript{−} complexes from cyclotetramerization of acetylenes has also been reported. For example, Coffield et al.\textsuperscript{51} showed that heating Mn\textsubscript{2}(CO)\textsubscript{10} in THF under a pressure of acetylene resulted in the formation of η\textsuperscript{5} (CO)\textsubscript{3}MnPnH as a viscous yellow oil that was purified by distillation (Fig. 28). The same transformation could also be accomplished using MeMn(CO)\textsubscript{5} but with lower yields of 27%. Further deprotonation of the bound HPn\textsuperscript{−} was not attempted.

Komatsu et al. reported the formation of η\textsuperscript{5} RhPnH complexes through Rh\textsuperscript{1} mediated tetramerisation of bulky mono-substituted alkyynes (Fig. 29). The reaction of t-butylnacetylene with [Rh(COD)Cl]\textsubscript{2} and NEt\textsubscript{3} in cyclohexane furnished η\textsuperscript{5} (COD)Rh[t\textsubscript{Bu}4PnH] in 13% yield after purification by chromatography on alumina followed by recrystallization from EtOH.\textsuperscript{52}

The analogous reaction of TMS-acetylene with [Rh(COD)Cl]\textsubscript{2} gave the corresponding η\textsuperscript{5} (COD)Rh[TMS\textsubscript{4}PnH] complex in 50% isolated yield. Interestingly, whereas tetramerization of

3.2. Hydropentalenide complexes through transmetalation of hydropentalenides

As shown in Fig. 3 and section 2.4, and illustrated in some of the examples in section 3.1, the monoanionic, 6π aromatic {HPn}− synthon may be obtained from either hydride addition to a stable {Pn} or mono-deprotonation of {H₂Pn}. Katz and Rosenberger provided an early demonstration of its utility as a transmetalation agent: *in situ* generation from {H₂Pn} with 1.1 equivalents of *n*-butyllithium in THF/hexane followed by addition of iron(II) precursors yielded the ferrocene analogue \( \eta^5 \text{(COD)} \text{Fe}[\text{PnH}]_2 \) as a mixture of two isomers (Fig. 30).53 The *mixed* Pn complex was separated by fractional crystallisation. A pure sample of the \( \eta^1 \text{-TMT} \text{CP} \) was obtained after separation by fractional distillation and recrystallisation from hexane.

\[ \text{TiCl} \text{by-product} \]

\[ \text{TlPnH} \text{MePnH}_{2} \text{complexes as a mixture of double bond isomers.} \]

Direct metalation reactions of \( \text{H}_{2}\text{Pn} \) with other heavy p-block metal bases has also been achieved. Ustynyuk *et al.* reported the synthesis of mono- and bis-{Me₃Sn} derivatives of \( \text{H}_{2}\text{Pn} \) using tin amides.55 The reaction of \( \text{H}_{2}\text{Pn} \) with one equivalent of Me₃Sn{NET₂} in boiling hexane produced, after distillation, a mixture of 1- and 2-\( \eta^1 \text{-MePnH}_{2} \) (Fig. 31).52 Reacting a mixture of \( \text{Tl}[\text{MePnH}] \) isomers with [Re(CO)₃(THF)Br]₂ in THF yielded the corresponding \( \eta^5 \text{(CO)} \text{Re}[\text{MePnH}] \) complexes as a mixture of double bond isomers.10 Although good combined yields were obtained after purification on silica, the isomers (distinguishable by NMR) could not be separated by chromatography or fractional crystallisation.

![Fig. 30 Synthesis of di(hydropentalenide)iron from dihydropentalene.](image)

![Fig. 31 Transmetalation reactions of thallium hydropentalenide.](image)

'butylacetylene produced \( 1,1,3,5-\text{R}_4\text{PnH}^{-} \), TMS-acetylene yielded the \( 1,2,4,6-\text{R}_4\text{PnH}^{-} \) regio-isomer. While not possible with the former, the latter could in principle allow for a second deprotonation to a \( 1,2,4,6-\text{R}_4\text{Pn}^{2-} \). However, this has not been reported yet.

The same reaction with two equivalents of Me₃Sn{NET₂} produced \( 1,4-(\text{Me}_3\text{Sn})_2\text{Pn} \) in high yield without purification. A 6:1 mixture of *anti-* and syn-isomers was obtained which did not interconver; although VT \( ^{13} \text{C} \) NMR analysis showed suprafacial Me₃Sn shifts to be possible within each \( (\text{Me}_3\text{Sn})_2\text{Pn} \) isomer there was no evidence for superfacial migration or intermolecular exchange. A pure sample of the *anti-*isomer could be obtained after separation by fractional distillation

ferrocene derivatives shown in Fig. 30 in 47% isolated yield.9 Similarly, reaction of \( \text{TlPnH} \) with [Rh(COD)Cl]₂ in THF smoothly yielded \( \eta^5 \text{(COD)Rh}[\text{PnH}] \) (Fig. 31).9 The TlCl by-product was easily removed by filtration, and sublimation of the product gave the pure Rh₁ complex in high yield. The same study also demonstrated the successful reaction of \( \text{TlPnH} \) with Me₄PtI, but the \( \text{Me}_4\text{Pn}[\text{PnH}] \) complex produced required gas-phase chromatography in order to furnish pure product.

Reactions involving \( \eta^1 \text{TMT} \text{CP} \) have also been achieved. Ustynyuk *et al.* reported the synthesis of mono- and bis-{Me₃Sn} derivatives of \( \text{H}_{2}\text{Pn} \) using tin amides.55 The reaction of \( \text{H}_{2}\text{Pn} \) with one equivalent of Me₃Sn{NET₂} in boiling hexane produced, after distillation, a mixture of 1- and 2-\( \eta^1 \text{-MePnH}_{2} \) (Fig. 31).52 Reacting a mixture of \( \text{Tl}[\text{MePnH}] \) isomers with [Re(CO)₃(THF)Br]₂ in THF yielded the corresponding \( \eta^5 \text{(CO)} \text{Re}[\text{MePnH}] \) complexes as a mixture of double bond isomers.10 Although good combined yields were obtained after purification on silica, the isomers (distinguishable by NMR) could not be separated by chromatography or fractional crystallisation.

Direct metalation reactions of \( \text{H}_{2}\text{Pn} \) with other heavy p-block metal bases has also been achieved. Ustynyuk *et al.* reported the synthesis of mono- and bis-{Me₃Sn} derivatives of \( \text{H}_{2}\text{Pn} \) using tin amides.55 The reaction of \( \text{H}_{2}\text{Pn} \) with one equivalent of Me₃Sn{NET₂} in boiling hexane produced, after distillation, a mixture of 1- and 2-\( \eta^1 \text{-MePnH}_{2} \) (Fig. 31).52 Reacting a mixture of \( \text{Tl}[\text{MePnH}] \) isomers with [Re(CO)₃(THF)Br]₂ in THF yielded the corresponding \( \eta^5 \text{(CO)} \text{Re}[\text{MePnH}] \) complexes as a mixture of double bond isomers.10 Although good combined yields were obtained after purification on silica, the isomers (distinguishable by NMR) could not be separated by chromatography or fractional crystallisation.

The same reaction with two equivalents of Me₃Sn{NET₂} produced \( 1,4-(\text{Me}_3\text{Sn})_2\text{Pn} \) in high yield without purification. A 6:1 mixture of *anti-* and syn-isomers was obtained which did not interconvert; although VT \( ^{13} \text{C} \) NMR analysis showed suprafacial Me₃Sn shifts to be possible within each \( (\text{Me}_3\text{Sn})_2\text{Pn} \) isomer there was no evidence for superfacial migration or intermolecular exchange. A pure sample of the *anti-*isomer could be obtained after separation by fractional distillation.
and crystallisation from pentane, enabling structural analysis by XRD. The authors also showed how the anti- and syn-isomers may be distinguished by their $^{119}$Sn chemical shift values and assigned via characteristic $^{119}$Sn–$^{117}$Sn coupling constants within a mixture in solution.

Similar to the η$^5$ thallium reagents, η$^1$ stannylated Pn act as mild transmetalation agents in cases where alkali metal Pn$^{2-}$ salts are too reducing (see below). This reactivity is not seen with the structurally related but non-fluxional η$^1$ silylated Pn derivatives discussed in section 2.8 due to the strength of the covalent Si–C bond, preventing the trisalkylsily substituent from acting as a leaving group.

Turner et al. demonstrated the use of mono-stannylated HPn$^*$ as a ligand transfer agent for synthesising hydroptalenide complexes of group 4 metals (Fig. 33). The reaction of LiH(Pn*) with SnMe$_3$Cl in pentane gave η$^1$ (Me$_3$Sn)H(Pn$^*$) as a 1:1 mixture of syn and anti isomers in near quantitative yields after isolation by filtration.

Reacting (Me$_3$Sn)H(Pn$^*$) with TiCl$_4$(THF)$_2$ in refluxing benzene gave a single isomer of η$^5$ TiCl$_3$[Pn$^*$] in high yields, and single crystals for XRD analysis could be grown from diethyl ether. Chlorine-bridged, mono-nuclear zirconium and hafnium HPn$^*$ dimer complexes could also be prepared from (Me$_3$Sn)H(Pn$^*$). Although deprotonation of the bound HPn$^*$ ligand in the Ti complex was not attempted, the reverse reaction (mono-protonation of a titanium Pn$^{2-}$ complex) was later reported by the same group (see Fig. 40).

3.3. Pentalenide complexes through transmetalation of pentalenides

Due to their stability and ease of preparation, alkali metal Pn$^{2-}$ salts are the most prevalent reagents for synthesising organometallic pentalenide complexes. Again similar to MCp chemistry, Jonas et al. reported that [Li$_2$(DME)$_2$]Pn would react cleanly with Cp$_2$VCl by substitution of one Cp$^-$ ligand and chloride. The resulting η$^5$CpVη$^8$Pn complex (Fig. 34) is air sensitive but could be sublimed under vacuum to give pure product in high yields. η$^5$Cp$^*$Vη$^8$Pn and η$^5$IndVη$^8$Pn could be prepared in the same manner, and recrystallisation from hexane at low temperatures gave samples suitable for XRD analysis.

The reaction of CpTiCl$_2$ with [Li$_2$(DME)$_2$]Pn yielded η$^5$CpTiη$^8$Pn in high yield, and the analogous reaction of Cp$_2$ZrCl$_2$ gave η$^8$Cp$^2$Zrη$^8$Pn (Fig. 34). However, details of solvents for these transformations is missing from these reports.

Jones et al. managed to access several new bimetallic group 7 carbonyl Pn$^{2-}$ complexes by way of transmetalation. The reaction of CpTiCl$_2$ with [Li$_2$(DME)$_2$]Pn with 2 equivalents of

![Fig. 32](image-url) Reactions of dihydropentalene with trimethyltin-diethylamide.

![Fig. 33](image-url) Synthesis of a stannylated derivative of HPn$^*$ and its reaction with a titanium(iv) precursor.
[Mn(CO)3(py)2Br] in THF gave exclusively the anti-isomer of 5η5[(CO)3Mn]2Pn (Fig. 35), which after extraction and filtration in air was purified by chromatography on silica. When the analogous reaction was performed with one equivalent of [Re(CO)3(THF)Br]2, a mixture of syn- and anti 5η5[(CO)3Re]2Pn was obtained, with the ratio being dependent on the reaction temperature. The two isomers could be separated through fractional crystallisation.

Katz et al. showed that dinuclear Pn2−sandwich complexes of cobalt and nickel could be synthesised by reacting their respective dihalide salts with [Li2(DME)x]Pn in THF (Fig. 35).61 Both compounds were obtained in low yields after purification by sublimation. The analogous reaction with FeCl2 however did not produce the analogous dinuclear sandwich complex (“double ferrocene”),61b but a mononuclear sandwich complex with two bridging HPn−ligands instead.62 Binding et al. were later able to synthesise the dinuclear sandwich complex [FePn*]2 by reacting [Li4(TMEDA)x]Pn* with Fe(acac)3 in THF at room temperature,63 providing yet another example of the utility of more highly substituted pentalenide scaffolds.

Manriquez et al. showed that Cp*Fe(acac), generated in situ from LiCp* and Fe(acac)2 in THF, would react smoothly with [Li2(DME)x]Pn to produce anti 8η5[Cp*Fe]η8Pn (Fig. 35).64 The complex was obtained in high yields after recrystallization from toluene; analogous cobalt, nickel and ruthenium complexes could be prepared in the same manner.

Exploring Pn3− complexes of f-block metals, Cloke et al successfully synthesised thorium and uranium complexes of 1,4-(TIPS)2Pn2− by way of transmetallation.65 The reaction of ThCl4 and Kx[1,4-(TIPS)2Pn] suspended in THF yielded a bright orange solid containing a mixture of staggered and eclipsed isomers of 8η5[1,4-(TIPS)2Pn]2Th (Fig. 36). The product could be purified by sublimation, and crystals for XRD analysis were grown from pentane. The same reaction with UCl4 produced a dark green product as the analogous isomeric mixture of 8η5[1,4-(TIPS)2Pn]2U again in high yields.

Fig. 35 Transmetalation reactions of dilithium pentalenide with late d-block metals.

Fig. 36 Transmetalation of dipotassium bis(trimethylsilyl) pentalenide with f-block metal halides.
Balazs et al. synthesised the anionic cerium(III) sandwich complex $K[Ce(1,4\text{-TIPS}_2\text{Pn})_2]$ by reacting $K_2[1,4\text{-TIPS}_2\text{Pn}]$ with CeCl$_3$ in THF at room temperature. This sand-coloured species was purified by filtration and washing with pentane, and characterised crystallographically by complexing the potassium ion with 18-crown-6 and recrystallising the resulting solid from toluene. The oxidation of $K[Ce(1,4\text{-TIPS}_2\text{Pn})_2]$ was shown using a slurry of AgBPh$_4$ in THF, and the resulting cerium(IV) sandwich complex $[Ce(1,4\text{-TIPS}_2\text{Pn})_2]$ was purified by extraction with pentane and crystallisation. Ashley et al. showed the analogous synthesis of $\text{CePn*}_2$ by reacting $[\text{Li}_2(\text{TMEDA})_x]\text{Pn*}$ and CeCl$_3$ in THF at room temperature, followed by oxidation of the intermediate $\text{Li}[\text{CePn*}_2]$ using an excess of dichloroethane.

In another example of a substituted Pn$^{2-}$ transmetalation reaction, Cooper et al. described the reactivity of Pn*$_2$ with group 4 metal halides. ZrCl$_4$ and HfCl$_4$ mixed with $[\text{Li}_2(\text{TMEDA})_x]\text{Pn*}$ in benzene gave, after filtration and recrystallisation, halide-bridged dinuclear $\eta^8$ complexes of zirconium and hafnium as LiCl adducts (Fig. 37). Attempts to remove coordinated THF via high vacuum lead to decomposition.

When the analogous reaction was performed with titanium(IV) precursors, no titanium complex could be obtained but ligand degradation was observed instead. Reaction of $[\text{Li}_2(\text{TMEDA})_x]\text{Pn*}$ with TiCl$_3$ and subsequent oxidation with PbCl$_2$ did give a dinuclear Ti$^{IV}$ complex, however, only in 8% yield.

In order to access Ti$^{IV}_2\text{Pn*}$ complexes, less reducing transmetalation agents were required. $[\text{Li}_2(\text{TMEDA})_x]\text{Pn*}$ was thus reacted with two equivalents of Me$_3\text{SnCl}$ to give $\eta^1(\text{Me}_3\text{Sn})_2\text{Pn*}$ derivatives (Fig. 38), analogous to those reported for the parent $\text{H}_2\text{Pn}$ (section 3.2, Fig. 32), in an extension to the $\eta^1(\text{Me}_3\text{Sn})\text{HPn*}$ shown in Fig. 33.

Interestingly, the use of a non-polar solvent such as benzene lead to formation of the syn product, whereas the use of THF exclusively gave the anti-isomer. Both could be isolated in very high yields after filtration and recrystallisation from toluene or pentane. It was proposed that the second lithiation step in the synthesis of $[\text{Li}_2(\text{TMEDA})_x]\text{Pn*}$ initially precipitated the syn dilithio complex as the kinetic product, which when reacted further in a benzene slurry produced syn TMT derivatives, whereas the use THF allowed interconversion to the thermodynamic anti dilithio configuration during the dissolution, producing anti TMT derivatives. This represents an interesting opportunity to steer the face selectivity of M$_2\text{Pn}$ reagents in transmetalation reactions in general, but remains to be explored for other pentalenediy reagents than $[\text{Li}_2(\text{TMEDA})_x]\text{Pn*}$.

In terms of transmetalation ability, reaction of syn $\eta^1(\text{Me}_3\text{Sn})_2\text{Pn*}$ with TiCl$_3$ in toluene indeed smoothly produced $\eta^8[\text{TiCl}_2\text{Pn*}]_2$ in high yields after recrystallization (Fig. 39). The
analogous reactions with ZrCl₄ and HfCl₄ failed to produce the desired complexes, suggesting the presence of LiCl is required to stabilise the Zr/Hf Pn⁺ complexes shown in Fig. 37.

In a controlled hydrolysis experiment, Clement et al. showed that reacting [TiCl₂Pn⁺]₂ with one equivalent of 2,6-xylene (pKₐ ∼10) in toluene resulted in clean mono-protonation of the bound Pn⁺ ligand and cleavage of the dimer by coordination of the alkoxide (Fig. 40), giving a single isomer of the mono-nuclear hydropentalenide complex Ti(OR)Cl₂[HPn⁺] in 68% yield. This transformation represents an interesting example of accessing a HPn⁻ complex via protonation of a Pn²⁻ complex, but on its own does not allow commenting on the reversibility of the reaction.

In a further demonstration of the usefulness of (Me₃Sn)₂Pn⁺ as mild transmetalation agent, Chadwick et al. successfully synthesised dinuclear Pn⁺₂⁻ complexes of easily reducible rhodium(i) and iridium(i) precursors. Reactions of [M(CO)₂Cl]₂ (M = Rh, Ir) with syn η¹(Me₃Sn)₂Pn⁺ (generated in situ) selectively produced the corresponding syn η₅[(CO)₂M]₂Pn⁺ complexes (Fig. 41). Both the rhodium and

![Figure 39](image-url) Reactions of bis(trimethylstanny)-hexamethylpentalenide with group IV metal halides.

![Figure 40](image-url) Partial hydrolysis of a titanium(η) Pn⁺ complex with 2,6-xyleneol.

![Figure 41](image-url) Reactions of bis(trimethylstanny)-hexamethylpentalenide with group IX metal carbonyl dimers.
iridium complexes have been analysed by XRD, with suitable crystal samples grown from hexane at low temperatures.

Whether the observed syn selectivity of the transmetalation was a result of using syn (Me₃Sn)₂Pn⁺ or due to the dimeric nature of the metal precursor is not clear, however.

4. Conclusion

From the selected examples reviewed it is clear that a number of different synthetic routes to pentalenide complexes exist. Unsubstituted H₂Pn is mostly synthesised by controlled anaerobic pyrolysis of various starting materials, whereas several relatively straightforward solution-phase methods for substituted H₂Pn exist. It is interesting that not all of these, mostly developed in the realm of organic synthesis, have been put to use in organometallic pentalenide chemistry yet. Symmetrically substituted H₂Pn appear most desirable to reduce the number of possible isomers, which may be hard to separate or transform selectively from a mixture. Given that their reactivity is mostly governed by their core π electronic system, it is not unreasonable to expect that most new substituted H₂Pn would be amenable to the same deprotonation, functionalisation and transmetalation methods developed for the two archetypical synths, unsubstituted H₂Pn and per-methylated Pn⁺. This would allow a wider range of novel Pn₂⁻ complexes to be synthesised for a more systematic study of Pn²⁻ ligand effects on their electronic structure and reactivity. Thallium salts and Me₃Sn derivatives have proven to be mild double-metalation agents in a controlled manner. In general, the flexible and adaptive nature of Pn²⁻ to bind a range of different metals together with the ability of bringing two metal atoms together in close proximity with electronic coupling hold great potential for future applications in sensing, electrochemistry, and homogeneous catalysis.

Conflicts of interest
