Slow magnetic relaxation in Ni–Ln (Ln = Ce, Gd, Dy) dinuclear complexes†

Anna Vrábllová, Milagros Tomás, Larry R. Falvello, Lubor Dlháň, Juraj Černák and Roman Boča

Three new isomorphous complexes [Ni(o-van-en)LnCl3(H2O)] [H2(o-van-en) = N,N'-ethylene-bis(3-methoxysalicylaldiminate; Ln = Ce (1), Gd (2), Dy (3)] were prepared by a stepwise reaction using mild conditions and were structurally characterised as dinuclear molecules in which Ni and Ln are coordinated by the compartmental Schiff base ligand (o-van-en) and doubly bridged by O atoms. While the nickel(i) centre is diamagnetic within the N2O2 square-planar coordination of the Schiff base ligand, the lanthanide atoms are octa-coordinated to give an (Ln3Cl2O2) chromophore with a fac-arrangement of the chlido atoms. AC magnetic measurements revealed that all three complexes, including the nominally isotropic Gd(III) system, show field induced slow magnetic relaxation with two or three relaxation channels: at T = 1.9 K the low-frequency relaxation time is $\tau_L(1) = 0.060 \text{ s}$ at $B_{DC} = 0.5 \text{ T}$, $\tau_L(2) = 0.37 \text{ s}$ at $B_{DC} = 0.3 \text{ T}$, and $\tau_L(3) = 1.29 \text{ s}$ at $B_{DC} = 0.15 \text{ T}$.

Introduction

Since the identification of the first single-molecule magnet (SMM) $\text{[Mn}_{12}\text{]}$ in 1993, research on this phenomenon has continued apace and has also been extended to lanthanide based materials. As early as 2004, heteronuclear 3d–4f complexes were observed to display slow magnetic relaxation. The advantage of transition metal and lanthanide complexes lies in a fusion of the properties of both. In fact, the magnetic study of complexes comprising transition metals and lanthanides dates back to 1985, when Gatteschi et al. observed unexpected ferromagnetic coupling between copper(II) and gadolinium(III) ions.

More recent research has yielded a few examples of a significant reduction in quantum tunnelling magnetization (QTM) due to non-negligible magnetic exchange interactions between lanthanide and transition metal ions. A recent study on 3d–4f complexes with diamagnetic 3d metal ions such as zinc(II) or cobalt(III) showed an enhancement of the $U_{eff}$ barrier in comparison to their mononuclear lanthanide analogues; it was suggested that the presence of a diamagnetic 3d cation near the lanthanide central atom, with a monatomic O bridge, induces a large charge polarisation on the bridging oxygen atom that favours an increase in the $U_{eff}$ barrier. This observation suggests a new strategy in designing 3d–4f complexes with diamagnetic 3d ions.

Regarding the 4f elements, heavy lanthanide ions were widely used for the preparation of SMM materials due to their large angular momentum $J$ and large magnetic anisotropy. However, a recent study of light lanthanide ions revealed surprising magnetic behaviour for cerium(III). Despite the small magnetic moment, which arises from its small angular momentum $J$ and small Landé $g$ factor, the spin–orbit coupling is strong enough to create significant magnetic anisotropy and thus an energy barrier between the two orientations of the magnetization. The first cerium(III) based SMM was reported in 2013 and later other cerium(III) complexes were reported to be SMMs.

Among the lanthanide ions, the case of gadolinium(III) complexes represents another breakthrough in the theory of slow relaxation of magnetization. Despite its essentially isotropic ground state with $L = 0$, several materials have been reported for which magnetic anisotropy around the gadolinium(III) centre was induced by local coordination, magnetic exchange coupling or electron density donation.
materials containing gadolinium(III) may be considered as members of a new class of SMMs with the highest known spin state (4f⁷) for a single ion.

Some considerable effort has been extended to produce strictly dinuclear 3d–4f molecular complexes to serve as building blocks for the further preparation and study of polynuclear clusters and polymers. A related fact in the context of the present work is that salen-type Schiff bases originating from o-vanillin and related aldehydes have been used in coordination chemistry due to their ability to form complexes with a rich variety of geometries and structural dimensions.

In what follows we describe the preparation, chemical and structural characterization and magnetic properties of three isomorphous dinuclear [Ni(o-van-en)Ln(H₂O)Cl₃] complexes [Ln = Ce (1), Gd (2), Dy (3)]. The choice of Ce(III), Dy(III) and Gd(III) was designed to expose the main differences in the magnetic behaviours of a light lanthanide ion, a heavy lanthanide ion and the lanthanide ion with a spherical orbital ground state, respectively.

Results and discussion

Synthesis and identification

The three complexes [Ni(o-van-en)LnCl₃(H₂O)] [Ln = Ce (1), Gd (2), Dy (3)] were first synthesized in microcrystalline form using mild solution techniques in a modification of the method of Costes and co-workers. The synthetic procedure is depicted in Scheme 1. The products were characterized using chemical analysis and IR spectroscopy; the observed absorption bands are listed in the ESI.† The imine group absorption, ν(C=N), observed slightly above 1600 cm⁻¹, can be considered as a characteristic band. In the IR spectrum of the ligand, this vibration was observed at 1631 cm⁻¹ which agrees with the reported value of 1628 cm⁻¹ reported for the same Schiff base, and is similar to the value of 1625 cm⁻¹ for a related Schiff base L [L = N,N'-bis([E]-3-phenylallylidene)-3-methyl-1,2-phenylene diamine]. The ligand bonded in the complex [CdLX₃] (X = Cl, Br, I, SCN) exhibits a shift of 1–7 cm⁻¹ to lower wavenumbers. In the spectra of the complexes 1, 2 and 3 the vibration ν(C=N) was observed at 1622–1623 cm⁻¹.

Recrystallization of these microcrystalline products or reaction by diffusion techniques yielded single crystals of 1–3. The phase identities of the microcrystalline products with the corresponding single-crystal samples were established by LeBail refinement using the powder diffraction patterns for all three samples (see Fig. S1†).

Crystal structures

Compounds 1–3 are isomorphous, so we will limit our description and discussion to complex 1 with the corresponding geometric parameters of 2 and 3 given in parentheses. We note that all three crystal structures were studied at room temperature. The crystal structure of 1 consists of neutral heterodinuclear molecules of [Ni(o-van-en)Ce(H₂O)Cl₃] (Fig. 1). The Ni(II) atom is coordinated in square-planar form by the N₂O₂ ligands, yielding an {LnCl₃O₅} chromophore (Fig. 1). The Ce(III) central atom is octa-coordinated by four oxygen atoms from the (o-van-en)²⁻ ligand, one aqua and three chlorido ligands, yielding an {LnCl₃O₅} chromophore (Fig. 1). Calculations using the program SHAPE indicate that the coordination polyhedron is close to a bicapped (O1 and O4) trigonal prism [Fig. S2†; the same holds for the Dy(III) and Gd(III) complexes]. It is significant (vide infra) that the three chlorido ligands form a single face of the polyhedron.

Analogous [Ni(o-van-en)Ln(NO₃)₂(CH₃)₂CO] heterodinuclear complexes with auxiliary nitrate ligands and contain-
ing various lanthanide atoms have been reported, but to our knowledge no analogous complexes with other 3d elements with auxiliary chlorido ligands have been studied. On the other hand, eight analogous heterodinuclear complexes containing chlorido ligands were reported with modified Schiff base ligands. An interesting example is the complex [NiCl₂(o-van-bu)YbCl(H₂O)₃] with a hexacoordinated Ni(n) central atom (donor set Cl₂O₂N₂).48

The observed Ni–N and Ni–O as well as the Ce–O bond distances are similar to those reported in the analogous complexes [Ni₃(o-van-en)Ce(NO₃)₃][NO₃].52 [(Cu(o-van-en)Gd(NO₃)₃): 0.25H₂O]₅₃ [Co(o-van-en)(CH₃COOO)₂Dy(NO₃)₃]⁵⁴ (Table 1). The Ln–Cl bond distances in 1 are in the range of 2.717(2)–2.802(2) Å (2.630(3)–2.714(3) Å for 2 and 2.6005(10)–2.6955(9) Å for 3), which can be compared to the average Ce–Cl distance of 2.7467 Å (2.6829 Å for Gd–Cl and 2.6357 Å for Dy–Cl) found in the CSD. The CSD further reveals that in all Ni–Ln (Ln = Ce, Gd, Dy) with Ln–Ni distances shorter than 5 Å the two metal atoms are bridged by monatomic O bridges, and the mean values of the Ni–Ln distances are 3.58 Å, 4.53 and 4.45 Å for Ce–Ni, Gd–Ni and Dy–Ni, respectively. In our compounds 1–3 the observed Ln–Ni distances are significantly shorter than the corresponding calculated mean values (Table 1). The remaining geometric parameters in all three complexes exhibit expected values.

Although molecular compounds with Ln–Cl bonds are known, these represent only about 6% of all molecular lanthanide complexes. Those in which the lanthanide is bonded to known, these represent only about 6% of all molecular lanthanide compounds that have been characterized, there are only close contacts of the C–H···Cl type between planes, involving methyl and methylene groups of the ligand.

### DC magnetic data

In compounds 1–3 the central Ni(n) atom is in a square planar environment formed by four oxygen donor atoms. Thus, it is magnetically silent, except for some temperature-independent magnetism arising from the presence of low-lying excited states. The lanthanide Ln(n) centres bear orbital and spin angular momentum and the ground multiplet is ²F₅/₂ for Ce(n), ⁸S₇/₂ for Gd(n) and ⁴H₁₅/₂ for Dy(n), with the magnetogyratic ratios γₗ = 6/7, 2 and 4/3, respectively. Thus the magnetization per formula unit should saturate to Mₛ = Mₕ₀₀/[Nₛμₗₙ] = γₗJ = 6/7 × 5/2 = 15/7, 2 × 7/2 = 7, and 4/3 × 15/2 = 10. The high-temperature limit of the effective magnetic moment, based upon the magnetic susceptibility, is μₑffective = g [[(J + 1)]⁻¹ = [(6/7)(5/2 × 7/2)⁻¹] = 2.54, 2 × (7/2 × 9/2)⁻¹ = 7.94, and (4/3) (15/2 × 17/2)⁻¹ = 10.6.

The DC magnetic data for 1 are shown in Fig. 2. Clearly visible linear dependence of the effective magnetic moment between T = 9–300 K indicates some temperature-independent paramagnetism as expected for the Ni(n) centre in a square planar environment: δχₚₚₚ = 6 × 10⁻⁹ m³ mol⁻¹. With the above correction the room-temperature effective magnetic moment (the high-temperature limit) adopts a value of μₑffective = 2.36μₙₙ that is not far from the single ion value (2.54). The magnetization data at T = 2.0 and B = 7 T, Mₛ = 1.0, is much lower relative to isolated multiplet ²F₅/₂ for Ce(n) (2.1).

Owing to the effect of the crystal field, the six-fold degenerate ground atomic multiplet ²F₅/₂ |Mₗ ;Mₛ⟩ = |5/2;±1/2, ±3/2, ±5/2⟩ is split into three sublevels ²F₅/₂ |Mₗ ;Mₛ⟩ = |5/2;±1/2, ±3/2, ±5/2⟩, ²F₅/₂ |Mₗ ;Mₛ⟩ = |5/2;±1/2, ±3/2, ±5/2⟩, and ²F₅/₂ |Mₗ ;Mₛ⟩ = |5/2;±1/2, ±3/2, ±5/2⟩.

**Fig. 2** DC magnetic data for 1. Solid lines – fitted. Colored circles – TIP corrected data.
\[ H_{\text{eff}} = \mu_B B \left( g_z \mu_B \cos \theta_a + g_{\text{eff}} \mu_B \sin \theta_a \right) \]

with \( g_{\text{eff}} = 1/2 \); \( \theta_a \) denotes grids distributed uniformly over the meridian. To this end, the optimization routine converged to the following set of magnetic parameters: \( g_{\text{eff}} = 0.80(19) \), \( g_z = 4.50(1) \), and the molecular-field correction (operative at low temperature) \( zJ/\hbar \approx -0.27 \text{ cm}^{-1} \). Large \( g_z \) and small \( g_{\text{xy}} \) are typical values for the anisotropic lanthanide ions.

\textit{Ab initio} calculations gave the values \( g(0.035, 0.251, 3.880) \) that support the magnetic data analysis. The first excited Kramers doublet lies 300 cm\(^{-1}\) above the ground one and its thermal population at \( T = 300 \text{ K} \) is only 9%.

The DC magnetic data for 2 confirms the behaviour of the \( ^{8}\text{S}_{7/2} \) ground term (Fig. 3): the effective magnetic moment is almost constant over the whole temperature range with \( \mu_{\text{eff}} = 7.8 \pm 0.6 \mu_\text{B} \); the magnetization per formula unit at \( B = 7.0 \text{ T} \) and \( T = 2.0 \text{ K} \) saturates to \( M_1 = 6.6 \). This data is consistent with an isotropic \( g \)-factor slightly below 2.0. The data fitting to the Curie law and the Brillouin function gave \( g = 1.952(6) \). A superposition of the magnetization data vs. \( BT^{-1} \) confirms an invisible magnetic anisotropy of 2.

The DC magnetic data for 3 is shown in Fig. 4. The effective magnetic moment displays the high-temperature (HT) limit of \( \mu_{\text{eff}} = 12.15 \mu_\text{B} \) that decreases only slightly down to \( T \approx 60 \text{ K} \); then it decreases more rapidly to 11.1 \( \mu_\text{B} \) at the lowest temperature of the measurements. The observed HT limit is somewhat higher than that expected for a single Dy\((\text{III})\) ion (10.6). This might be due to the presence of low-lying excited states of the cooperating Ni(II) centre. More surprising is the saturation value of the magnetization \( M_1(J) = 7.9 \) at \( T = 2.0 \text{ and } B = 7.0 \text{ T} \), which differs substantially from the single-ion expectation (\( M_1 = 10 \)). This can arise in a partial quenching of the orbital angular momentum of the Dy(III) centre by the asymmetric ligand field of the \( \text{[DyO}_4\text{OCl}_4]^{-} \) chromophore. Another reason could be the zero-field splitting of the ground crystal-field multiplet inherent to an anisotropic ion such as Dy(III). In such a case, the higher terms of the series of the crystal field potential will also contribute

\[ \hat{V} = \sum_{k=0}^{\infty} \sum_{m=-k}^{k} B^m \cdot \hat{O}^m_k (\hat{j}_z \hat{j}_-^k) \]

where \( \hat{O}^m_k (\hat{j}_z \hat{j}_-^k) \) are the equivalent appropriate operators. The sixteen members of the \( ^6\text{H}_{15/2} \) multiplet are then split into eight Kramers doublets.

**Field scan of the AC susceptibility**

The AC susceptibility data was acquired at the field amplitude of \( B_{\text{AC}} = 0.38 \text{ mT} \) and depending upon the external magnetic field \( B_{\text{DC}} \), temperature, and the frequency \( f \) of the oscillating field.

The first scan for a variable magnetic field, fixed low temperature \( T = 2.0 \text{ K} \), and a set of four representative frequencies \( f = 11, 111, \) and \( 1116 \text{ Hz} \) is shown in Fig. 5. It is seen that the out-of-phase susceptibility \( \chi'' \) is zero at \( B_{\text{DC}} = 0 \), which is traditionally explained as an effect of the fast magnetic tunneling. With the applied external field, the out-of-phase susceptibility rises to a maximum and then attenuates at higher fields. The position of the maximum slightly depends upon the frequency of the oscillating field. The subsequent data measurements were done at the external field for which the out-of-phase susceptibility component displays a maximum: \( B_{\text{DC}} = 0.1 \), 0.5, 0.3, and \( 0.15 \text{ T} \) for 1 through 3.

**Temperature scan of the AC susceptibility**

Temperature evolution of the AC susceptibility components for a set of frequencies varying between \( f = 0.1 \) and \( 1500 \text{ Hz} \) at a selected external field \( B_{\text{DC}} \) is shown in Fig. S4 (see ESI†). It can be concluded that the samples 1 through 3 show field induced slow magnetic relaxation typical for single ion magnets (SMM). On heating, the in-phase susceptibility components for various temperatures tend to merge at the critical temperature (ca. 10, >7, and 7 K); at the same time the out-of-phase component vanishes since then the system behaves as an ordinary paramagnet.

**Frequency scan of the AC susceptibility for 3, Ni–Dy complex**

The same data sets have been rearranged to the frequency dependence of the AC susceptibility components for a set of temperatures.
For 3, it is evident (Fig. 6) that the out-of-phase component consists of three contributions: low-frequency (LF), intermediate-frequency (IF), and the high-frequency (HF). For the lowest-temperature measurements ($T = 1.9$ K) the LF component dominates with the peak-position at $f_{\text{max}} \sim 0.16$ Hz. Then the corresponding relaxation time is estimated to be as long as $	au(\text{LF}) = 1/(2 \pi f_{\text{max}}) \sim 0.995$ s. Both, in-phase and out-of-phase susceptibilities were fitted simultaneously by employing the three-set Debye model, as explained in the ESL† Using the resulting relaxation parameters (thermal susceptibilities $\chi_t$, distribution parameters $\alpha_k$, and relaxation times $\tau_k$, $k = 1–3$), the convoluted susceptibility components are drawn as solid lines in Fig. 6. It is evident that these lines pass through the experimental points and this is also supported by the statistical analysis in the ESL†

At low temperature the HF component recovers only a tail; however, with increasing temperature the LF component decays progressively in favor of the HF one; the IF component balances in-between. At temperature $T > 5$ K, the IF component cannot be fitted satisfactorily and then only a two-set Debye model is applicable. At the lowest measurement temperature, $T = 1.9$ K, the mole fractions of the individual relaxation species are $x(\text{LF}) = 0.49$, $x(\text{IF}) = 0.28$, and $x(\text{HF}) = 0.23$, respectively. At the same time, the three relaxation times are $\tau(\text{LF}) = 1.29$ s, $\tau(\text{IF}) = 74$ ms, and $\tau(\text{HF}) = 964$ µs. In contrast, at $T = 6.3$ K, $x(\text{LF}) = 0.13$ and $x(\text{HF}) = 0.87$ hold true.

In Fig. 7, the Argand diagram is shown; it is a convolution of three distorted semicircles (arcs) of different height, position and width. Also an Arrhenius-like plot $\ln \tau$ vs. $T^{-1}$ is shown on the right for the individual relaxation processes. The three highest-temperature points for the HF relaxation channel have been fitted by a straight line in order to get parameters for the Orbach relaxation process $\tau = \tau_0 \exp(U_{\text{eff}}/k_B T)$: $U_{\text{eff}}/k_B = 65$ K and $\tau_0 = 1.9 \times 10^{-10}$ s.

The temperature evolution of the HF relaxation time can be represented by various graphs as shown in Fig. S5 (see ESI†). The dependence $\ln \tau$ vs. $\ln T$ at its two edges can be recovered by straight lines: $\ln \tau = -8.81 + 11.3(\ln T)$ at the highest temperatures, and $\ln \tau = -D_1$ at the lowest temperatures. Therefore, the whole dataset has been fitted via the equation

$$\tau^{-1} = CT^n + D_1$$

where the first term refers to the Raman process and the second one the quantum tunnelling process. The optimization routine gave $n = 10.8(3)$, $C = 3.6(16) \times 10^{-4}$ K$^{-n}$ s$^{-1}$, and
\[ D_1 = 1.0(1) \times 10^3 \text{ s}^{-1} \]. This means that the high-temperature limit of the high-frequency relaxation process can be equally reproduced by the Raman process itself. A value of \( n = 12 \) has been found for a Co(II) compound.\(^5\)\(^7\)

**Frequency scan of the AC susceptibility for 1, Ni–Ce complex**

The frequency dependence of the AC susceptibility components for 1 is shown in Fig. 8. For \( T = 1.9 \text{ K} \) the well-developed peak of \( \chi'' \) at \( f \sim 10 \text{ Hz} \) implies the relaxation time \( \tau(\text{LF}) \sim 16 \text{ ms} \). This is much shorter relative to 3. However, the peak is slightly asymmetric with an arm, and its reliable fit requires a two-set Debye model where the HF component is also considered. On heating the peak is shifted to higher frequencies but for \( T > 4 \text{ K} \) the two-set model becomes unstable; then the single-set model has been applied for higher temperatures. The resulting relaxation parameters are listed in the ESI† along with statistical analysis.

The Argand diagram and the Arrhenius-like plot for 1 are displayed in Fig. 9. In this case the LF relaxation time was fitted via eqn (3) giving \( n = 6.59(7) \), \( C = 174(22) \times 10^{-4} \text{ K}^{-n} \text{ s}^{-1} \), and \( D_1 = 51(1) \text{ s}^{-1} \). At the same time the parameters of the Orbach relaxation process are \( U_{\text{eff}}/k_B = 43 \text{ K} \) and \( \tau_0 = 3.1 \times 10^{-7} \text{ s} \).

As expected, the external magnetic field has a visible effect on the relaxation behaviour of 1 (see ESI†): the relaxation time at \( T = 1.9 \text{ K} \) and \( B_{\text{DC}} = 0.5 \text{ T} \) becomes \( \tau(\text{LF}) = 60.3(5) \text{ ms} \) as compared to 18.7(11) ms at \( B_{\text{DC}} = 0.1 \text{ T} \). A successful data fitting requires the two-set Debye model for \( T > 3.5 \text{ K} \). SIM behaviour of the Ce(III) ions has been reviewed recently.\(^1\)\(^4\) For instance, AC susceptibility studies of single-molecule magnet behaviour in polynuclear assembly of Ce(III) with polymolybdates reveal a two-channel slow relaxation with the relaxation times \( \tau(\text{HF}) = 6009 \text{ and } 217 \mu\text{s} \) at \( T = 1.9 \text{ K} \) and \( B_{\text{DC}} = 0.02 \text{ T} \).\(^1\)\(^8\) There is a sizable field influence since at \( B_{\text{DC}} = 0.14 \text{ T} \) the relaxation times merge to \( \tau = 605 \mu\text{s} \).

**Frequency scan of the AC susceptibility for 2, Ni–Gd complex**

The frequency dependence of the AC susceptibility components for the Gd compound 2 is shown in Fig. 10. In this case the two-set Debye model reproduces the experimental data with well separated branches. The existence of slow relaxation is unexpected in the case of the isotropic gadolinium centre. Even more surprising is the Arrhenius-like plot drawn in Fig. 11 where the HF relaxation time is only slightly temperature dependent between 1.9 and 6.5 K. Moreover, the HF branch shows a “strange” behaviour (Fig. S6†): on cooling the relaxation time passes through a maximum and then it is shortened: \( \tau(\text{HF}) = 223 \mu\text{s} \) at \( T = 3.9 \text{ as compared to } \tau(\text{HF}) = 120 \mu\text{s} \) at \( T = 1.9 \text{ K} \).

The strange behaviour has been observed recently in Cu(II), Ni(II), Co(II), and Mn(II) complexes showing distorted octa-

**Fig. 11** Argand diagram (left) and the Arrhenius-like plot (right) for 2.
hedral geometry.\textsuperscript{58-61} It was possible to reproduce such data by using a phenomenological equation

\[ \tau^{-1} = CT^2 + E_1T^{-k} \]  

that contains the conventional Raman term (parameters \( C \) and \( n > 0 \)), along with the “strange” term (parameters \( E_1 \) and \( k > 0 \)).

Linear fits for the truncated data allowed bracketing starting values for data fitting via eqn (4); the final parameters are: \( n = 1.18(26), C = 4.7(26) \times 10^2 K^2 \text{s}^{-1}, E_1 = 2.43(3) \times 10^4 K^3 \text{s}^{-1}, \) and \( k = 1.7(2) \). Two slow relaxation processes have also been described for several Gd(m) compounds.\textsuperscript{20,22,23,28,29} For instance, for a Gd(m)EDTA chelate compound,\textsuperscript{20,22,23,28,29} the values of \( U_{\text{eff}} = 6.1 \text{ K} (r = 4 \times 10^{-2} \text{ s}) \) and \( U_{\text{eff}} = 84 \text{ K} (r = 8 \times 10^{-7} \text{ s}) \) were reported (\( B_{\text{DC}} = 0.45 \text{ T} \)).

The geometry and the electron density of the coordination sites have been proved to exert a very important influence on the SMM behaviour of lanthanide ions. There are few studies of the influence of ions and since the number of chlorido derivatives is smaller than for instance, nitrato, the studies reported about the influence of the chlorido ligands in the SMM behaviour are very rare and it may require more research.

The magnetic study on the \([\text{Ln}_2(mq)_4X_6(\text{EtOH})_2]\) (Fig. 12, left) (mq = 8-hydroxy-2-methylquinoline) compounds which have been prepared for \( \text{Ln} = \text{Dy}, X = \text{NO}_3^− \) or \( \text{Cl}^− \) shows that for these compounds the energy barrier is higher when \( X = \text{Cl}^− (\text{NO}_3^−: \Delta/k_B = 40.0 \text{ K and } \text{Cl}^−: \Delta/k_B = 102.4 \text{ K}).\textsuperscript{62} \) We note that for \( \text{Ln} = \text{Gd}, X = \text{NO}_3^−, \text{Cl}^− \), no slow relaxation was observed. However, a recent study on \([\text{Ln}((\text{tpm})X_3)\text{MeCN}]\)\textsuperscript{63} (tpm = tris(3,5-dimethyl-pyrazolyl)methane) shows that at zero DC field, no significant out-of-phase susceptibility was detected for \( \text{Ln} = \text{Dy or Er}, \) none for \( X = \text{NO}_3^− \) nor \( X = \text{Cl}^− \), but under applied fields, it was observed for \( \text{Ln} = \text{Dy and NO}_3^− \) but not for \( \text{Cl}^− \), while for \( \text{Ln} = \text{Er} \), the situation was the opposite, indicating that \( \text{NO}_3^− \) in this case is a more suitable anion for obtaining SMM with \( \text{Dy} \) while \( \text{Cl}^− \) is a better anion for \( \text{Er} \). No such comparative information for \( \text{Ln} = \text{Gd} \) has been reported, to our knowledge.

All three of our compounds, including the Gd(m) one, with three \( \text{Cl}^− \) ligands and under applied external field, show slow relaxation. We note that the location of the three coordinated chlorido atoms in our compounds (Fig. 12, right) is different than in the above-mentioned compounds \([\text{Ln}_2(mq)_4\text{Cl}_6]\). From Fig. 12, it can be seen that in compounds 1–3 the chlorido ligands are in what can be called \( \text{fac} \)-configuration — that is, concentrated in the same part of the coordination sphere, while the other compounds present a more symmetrical distribution; that has to affect the electron distribution in the coordination sphere.

Conclusions

Using mild chemical conditions a new kind of 3d–4f dinuclear NiLn Schiff base compound, \([\text{Ni(o-van-en)}\text{LnCl}_3(\text{H}_2\text{O})]\) (\( \text{Ln} = \text{Ce, Gd, Dy} \)) was prepared and structurally characterized. In all three complexes the square four-coordinated nickel(II) atom and octacoordinated Ln(III) atom (donor set \( \text{O}_5\text{Cl}_3 \)) are located in the neighbouring compartments provided by the Schiff base ligand and linked by two monatomic O bridges. The coordination of the Ln atom is highly unsymmetrical with all chlorido ligands situated in a “fac” fashion. AC susceptibility measurements reveal that all three complexes show field supported slow magnetic relaxation. This result in the case of the Gd(m) compound suggests a need for further detailed magnetic studies, in the field of SMM, of complexes with the chlorido ligands concentrated in a face of the coordination polyhedron. AC magnetic measurements revealed that all three complexes, including the nominally isotropic Gd(m) system, show field induced slow magnetic relaxation with two or three relaxation channels: at \( T = 1.9 \text{ K} \) the low-frequency relaxation time is \( \tau_{l2}(1) = 0.060 \text{ s at } B_{\text{DC}} = 0.5 \text{ T, } \tau_{l2}(2) = 0.37 \text{ s at } B_{\text{DC}} = 0.3 \text{ T, and } \tau_{l2}(3) = 1.29 \text{ s at } B_{\text{DC}} = 0.15 \text{ T.} \)

Experimental

Syntheses

Ethylenediamine, \( \text{o-vanillin, NiCO}_3, \text{GdCl}_3\cdot6\text{H}_2\text{O, CeCl}_3\cdot7\text{H}_2\text{O, DyCl}_3\cdot6\text{H}_2\text{O, ethanol and diethyl ether, all of analytical grade, were purchased from commercial sources and used as received.} \)

Synthesis of the ligand \( \text{H}_2(\text{o-van-en}) \). For the synthesis of \( \text{H}_2(\text{o-van-en}) \) a modification of the previously reported method\textsuperscript{13} was used. Ethylenediamine (0.1 cm\(^3\), 1.5 mmol) was added to 50 cm\(^3\) of an ethanol solution of \( \text{o-vanillin (0.4542 g, 3 mmol). The mixture was placed in a boiling flask and refluxed for 5 hours. The final solution was filtered and left for crystallization. After a few hours, dark yellow crystals of the product appeared. The crude product was filtered and washed with 2 cm\(^3\) of diethylether. Yield: 90%. Purity and identity of the product were checked by CHN analysis, IR, UV-Vis, \(^1\text{H}\) and \(^{13}\text{C}\) NMR spectroscopies. The corresponding analytical data for \( \text{H}_2(\text{o-van-en}) \) as well as for complexes 1, 2 and 3 are listed in ESI.\textsuperscript{†} \)

Synthesis of \([\text{Ni(o-van-en)}\text{Ce(H}_2\text{O})\text{Cl}_3]\) (1). Solid \( \text{H}_2(\text{o-van-en}) \) (2 g, 6 mmol) and nickel(II) carbonate (0.7 g, 6 mmol) were added to 100 cm\(^3\) of water and heated in an open beaker. After one hour of reaction the resulting brown microcrystalline
product (crude nickel complex) was separated by filtration, washed with 2 ml of ethanol and dried in air. The dry product was used in the next step of the synthesis without further purification. Solid CeCl₃·7H₂O (0.3 g, 0.8 mmol) was dissolved in 10 cm³ of ethanol and the resulting clear solution was added to the brown ethanol solution of [Ni(o-van-ent)] (50 cm³ of ethanol). After 15 min of stirring, the orange microcrystalline complex [Ni(o-van-ent)Ce(H₂O)Cl₃] (1) was separated by filtration and washed three times with 2 ml of ethanol. Single crystals suitable for X-ray analysis were obtained by recrystallization of the microcrystalline complex using room temperature diffusion of a MeOH solution into iPROH.

Synthesis of [Ni(o-van-ent)Gd(H₂O)Cl₃] (2). The same procedure was used as for the Ce(III) complex with the modification that instead of CeCl₃·7H₂O, GdCl₃·6H₂O (0.3 g, 0.8 mmol) was used. Single crystals of [Ni(o-van-ent)Gd(H₂O)Cl₃] (2) were obtained by crystallization using diffusion of a MeOH solution of GdCl₃ into an iPrOH solution of [Ni(o-van-ent)] at room temperature.

Synthesis of [Ni(o-van-ent)Dy(H₂O)Cl₃] (3). For the synthesis of the complex [Ni(o-van-ent)Dy(H₂O)Cl₃] the same procedure was used as for the Ce(III) complex with the modification that instead of CeCl₃·7H₂O, DyCl₃·6H₂O (0.3 g, 0.8 mmol) was used. Crystals of [Ni(o-van-ent)Dy(H₂O)Cl₃] (3) were obtained by recrystallization using diffusion of a methanol solution of the microcrystalline product into iPrOH with a temperature gradient of from 70 °C at the bottom of the beaker to room temperature at the top of the solution.

Physical measurements
Elemental analyses (C, H, N) were performed on a PerkinElmer 2400 Series II CHNS/O analyser. Infrared spectra were recorded on a PerkinElmer Spectrum 100 CsI DTGS FTIR Spectrometer with UATR 1 bounce-KRS-5 in the range of 4000–300 cm⁻¹. Powder X-Ray data were collected using a RIGAKU D/max 2500 diffractometer equipped with a copper rotating anode, operating at 40 kV and 80 mA, with a graphite monochromator. Measurements were made for 2θ from 2.5° to 40° in steps of 0.02° with a rate of 1 s per step. The magnetic susceptibility (determined as χ = M/H) was taken at B = 0.1 T using a SQUID magnetometer (Quantum Design, MPMS-XL7) in the temperature range from 1.9 to 300 K. Raw susceptibility data was corrected for the diamagnetic contribution. The magnetization data was acquired at low temperature T = 2.0 and 4.6 K until Bdc = 7.0 T. The AC susceptibility data was taken at the applied external fields using the amplitude of the oscillating field BAC = 0.38 mT for a set of temperatures and for 22 frequencies between f = 0.1 to 1500 Hz.

Crystallography
X-ray experiments were carried out on a four-circle κ-axis Xcalibur2 diffractometer equipped with a Sapphire3 CCD detector (Oxford Diffraction). The CrysAlis software package [Oxford Diffraction 2006 CrysAlisPro CCD and CrysAlisPro RED] was used for data collection and reduction. Crystals of compound 1 were found to exhibit multiple domains. For the crystal used for data collection, two domains were indexed and data integration was conducted simultaneously for both. The structures for 1, 2 and 3 were solved using SHELXT. Refinement based on intensities was performed using SHELXL-2014/7. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in difference Fourier maps. For the final refinement, H atoms bound to C were placed at calculated positions and refined as riders with Uiso(H) = 1.2Ueq(C) for non-methyl H and with Uiso(H) = 1.5Ueq(C) for methyl H. Using the program CALC-OH the positions of the water hydrogen atoms for the O1 aqua ligand were found; their isotropic thermal parameters were tied with the parent atom [Uiso(H) = 1.2Ueq(O)]. For compound 1 the final refinement was conducted using data from both domains. The structure figures were drawn using Diamond. Crystal data and final parameters for the structure refinements are summarized in Table S1† and possible hydrogen bonds are given in Table S2.†

Ab initio calculations
Ab initio calculations were performed with ORCA 4.1.2 computational package using the experimental geometry of complex under study. The relativistic effects were included in the calculations with second-order Douglas–Kroll–Hess (DKH) procedure together with the scalar relativistic contracted version of def2-SV(P) basis function for all elements, except Ce atom. For Ce, the SARC2-DKH-QZVP basis function was used. The calculations were based on state average complete active space self-consistent field (SA-CASSCF) wave functions. The active space of the CASSCF calculations comprised of one electron in seven metal-based f-orbitals. The state averaged approach was used, in which 7 doublet states were equally weighted. The spin–orbit effects have been included through quasi-degenerate perturbation theory in which an approximation to the Breit–Pauli form of the spin–orbit coupling operator (SOMF) was utilized.
