Impact of humic acid on the fate and toxicity of titanium dioxide nanoparticles in *Tetrahymena pyriformis* and zebrafish embryos†

Govind Sharan Gupta,‡ Krupa Kansara,‡ Helly Shah, Ruchi Rathod, Drishti Valecha, Saurabh Gogisetty, Pankti Joshi and Ashutosh Kumar *

The extensive usage of titanium dioxide (TiO₂) nanoparticles in daily usage products have increased their release into the environment. The present study has attempted to investigate the behaviour of titanium dioxide (TiO₂) nanoparticles in different experimental buffers in the presence of humic acid. Also, the effect of TiO₂ nanoparticles was assessed in different aquatic organisms with and without the presence of humic acid. The results demonstrate that humic acid increases the dispersion of TiO₂ nanoparticles via its adsorption on the surface of the nanoparticles, mainly due to electrostatic interactions. The maximum aggregation was observed in the zebrafish growth medium (E3 medium) even in the presence of humic acid. The intensity of TiO₂ nanoparticle sedimentation was observed in the order: E3 media > Dryl's buffer > MilliQ water. Interestingly, the ecotoxicity results for *Tetrahymena pyriformis* and *Danio rerio* showed that the presence of humic acid reduces the toxicity of TiO₂ nanoparticles.

1. Introduction

The advancement in the applications of nanotechnology from biotechnology to agriculture has increased nanoparticle (NP) emissions in the environment. NPs, after being released into the surroundings, eventually reach aquatic systems and pose a risk to the ecosystem at individual, population and community levels.¹ The estimated release of NPs in the environment has been predicted to be 21% to aquatic systems, 17% to soils, 2% to air and 60% to landfills.^{2,3} The reactivity of the nanoparticles is mainly due to their quantum size and large surface area to volume ratio, which can be diminished by their homo or hetero-aggregations in the presence of biotic and abiotic factors.^{4–7}

Titanium dioxide (TiO₂) NPs are one of the most abundantly used in consumer products such as cosmetics, paints, food additives, pharmaceuticals, electronics and textiles as well as in construction and waste-water treatment and have started appearing in the aquatic environment.⁸ Therefore, it is imperative to understand their environmental interactions and safety for aquatic organisms. Earlier studies have shown that TiO₂ NPs can cause toxic effects to different aquatic organisms such as bacteria, protozoans, algae, crustaceans and zebrafish.^{9–13} Most

of these studies have been performed under laboratory conditions, without assessing the influence of either biotic or abiotic environmental factors.

Humic acid is one of the most abundant and widespread naturally occurring organic materials in the environment.¹⁷ It exists naturally in soils, peats, oceans and fresh water representing about 25% of the carbon on earth and 50–75% of the carbon in water.¹⁸ It plays a crucial role in the speciation, transport and deposition of a variety of materials ranging from metal ions to lipophilic compounds.¹⁹ The study of nanoparticles binding to naturally abundant organic matter is of primary importance to understanding the safety of nanoparticles in aquatic systems.

The model organisms used for this study were selected from two major groups: unicellular eukaryotes (ciliated protozoan, *Tetrahymena pyriformis*) and multicellular eukaryotes (zebrafish, *Danio rerio*). *Tetrahymena* is a unicellular, eukaryotic and free living protozoan and has been extensively used as a model organism for safety assessments.^{4,20,21} It is a filter feeder organism that reduces the bacterial population and also controls the bioavailability of particulate iron in the environment.^{21,22} It connects prokaryotes to eukaryotes in the food chain and plays a significant ecological role by controlling harmful bacterial populations, nutrient cycling and iron bioavailability. *Danio rerio* is another important vertebrate research model due to its numerous properties such as easy maintenance, high fecundity, rapid development, transparent embryos, being a significant link in the food web, availability of a complete genome sequence and genetic similarity with humans (~70%).^{23,24} Early stage embryos of zebrafish have

‡ Authors contributed equally.

already been used extensively in the high throughput assessment of eco-nano-safety.²⁵

It has now been very well demonstrated that NPs interact with natural organic matter (NOM), copolymeric substances (EPS) and clay particles upon entry into the aquatic environment.^{4,14,15} Among these factors NOM such as humic acid (HA) is known to influence the stability of NPs in the aquatic system due to adsorption on the surface of the NPs.¹⁶ However, the consequent effects of HA on the toxicity of NPs to aquatic organisms have not been well studied. Therefore, the present study was designed to investigate the potential effect of HA on the stability of TiO₂ nanoparticles in different experimental buffers and their toxicity to a range of aquatic model organisms such as ciliated protozoan (*Tetrahymena pyriformis*) and early stage embryos of zebrafish (*Danio rerio*).

2. Materials and methods

2.1. Chemicals and materials

A mixed rutile and anatase phase TiO₂ nanopowder (catalogue no. RN-PL-TiO-P25-50g) was procured commercially from Reinste Nano Ventures Pvt. Ltd. (Noida, India). HA powder (CAS no. 6811-04-4) was procured from HiMedia (Mumbai, India). All other chemicals were analytical reagent grade and procured from HiMedia (Mumbai, India).

2.2. Model organisms and culture conditions

2.2.1. Zebrafish husbandry. An Assam wild-type strain of zebrafish was a kind gift from CSIR-IGIB, New Delhi, India. The fishes were maintained under laboratory conditions at Ahmedabad University (Ahmedabad, Gujarat, India). The fishes were grown as per the standard protocols of the Zebrafish Information Network (ZFIN). Briefly, the male and female zebrafish were kept separately in a 20 L aquarium filled with artificial freshwater prepared by dissolving 60 mg L⁻¹ of sea salt (Red Sea, India) in distilled water (dH₂O). The temperature was maintained at 26–28 °C with a 14 h light/10 h dark cycle. The adult zebrafish were fed with live brine shrimp (*Artemia*) thrice a day. Zebrafish eggs were collected alternately in the morning by setup breeding with a ratio of three females to two males in the breeding chamber. The eggs were collected into sterile Petriplates filled with egg water and were raised at 28.0 ± 1.0 °C in a BOD incubator (MIR-154, Panasonic, Japan). The embryos were further transferred into E3 medium (5 mM NaCl, 0.17 mM KCl, 0.33 mM CaCl₂ and 0.33 mM MgSO₄ and the pH was adjusted to 7.0–7.2) before the experiments.

2.2.2. Protozoan culture. *Tetrahymena pyriformis* was procured from Carolina Biological Supply Co. (Burlington, USA). The cells were grown in a BOD incubator at 22 °C under dark conditions by following the protocol suggested by Gupta *et al.* (2017).⁴ The overnight grown culture of *Tetrahymena* was used in the experiments. The cells were harvested by centrifugation (710 × *g* for 5 min at 4 °C) and subsequent washing was done with Dryl's buffer (2 mM sodium citrate, 2 mM NaH₂PO₄, 1 mM Na₂HPO₄, 1.5 mM CaCl₂, pH 6.9–7.0). The *Tetrahymena* cells were starved for 16–24 h in Dryl's buffer before using for

the experiment. The number of *Tetrahymena* cells per mL was counted by using haemocytometer under an optical microscope. The cells were fixed with 0.01% of neutral formalin before counting.

2.3. Preparation and characterization of TiO₂ nanoparticles

A stock suspension of TiO₂ nanoparticles (1000 µg mL⁻¹) was prepared in sterile MilliQ water using sonication at 30% amplitude and 30 watts for 10 min using a probe sonicator (Sonics Vibra Cell, Sonics & Material Inc., New Town, USA). Subsequently, the suspension was diluted to 50 µg mL⁻¹ and used for characterization of size, surface charge and optical properties. The purity of the TiO₂ nanopowder was determined using energy-dispersive X-ray spectroscopy (EDS) coupled with scanning electron microscopy (SEM).

The hydrodynamic size and zeta potential of the TiO₂ nanoparticles were determined using dynamic light scattering (DLS) and phase analysis light scattering (PALS) using a Zetasizer Nano-ZS equipped with a 4.0 mW, 633 nm laser. The actual size distribution was further validated using transmission electron microscopy (TEM). The wavelength of the maximum emission of the TiO₂ NPs was determined using UV-Vis spectroscopy, BioTek Synergy HT, USA.

2.4. Motivation for the selection of nanoparticle concentration

The fate experiments of the nanoparticles were conducted at a concentration of 50 µg mL⁻¹ due to its optimum detection in all the characterization techniques used in the measurement. In the biological experiments, the lowest concentration of TiO₂ nanoparticles (1 µg mL⁻¹) was selected as per the predicted concentration available in the environment.²⁶ Meanwhile, a range of higher concentrations (10, 50, 100 µg mL⁻¹) were selected to obtain the dose dependent response relationship.

2.5. Fate of nanoparticles in the experimental buffers

Dryl's buffer and E3 medium were exclusively used in the safety assessment of the NPs for protozoans and zebrafish embryos, respectively. HA was added in these media at a concentration of 10 µg mL⁻¹, to mimic the environmental conditions.²⁸ The fate of the NPs was determined by measuring aggregation, surface modification and sedimentation of the nanoparticles in the presence or absence of HA. The experiments were put into seven different groups as follows:

- Group 1: TiO₂ NPs (50 µg mL⁻¹) in MilliQ water (control)
- Group 2: TiO₂ NPs (50 µg mL⁻¹) in Dryl's buffer
- Group 3: TiO₂ NPs (50 µg mL⁻¹) in E3 media
- Group 4: HA (10 µg mL⁻¹) in MQ water, Dryl's buffer and E3 media (control)
- Group 5: TiO₂ NPs (50 µg mL⁻¹) + HA (10 µg mL⁻¹) in MilliQ water
- Group 6: TiO₂ NPs (50 µg mL⁻¹) + HA (10 µg mL⁻¹) in Dryl's buffer
- Group 7: TiO₂ NPs (50 µg mL⁻¹) + HA (10 µg mL⁻¹) in E3 media

The pH of all the groups remains the same between 6.7 and 6.9 throughout the experiment (Table S1†).

2.5.1. Aggregation of NPs. The aggregation of the NPs in the different groups was determined by measuring the hydrodynamic diameter (D_h) of the NPs using DLS. The aggregation pattern was followed for 96 h (0, 0.5, 1, 2, 3, 4, 24, 48 and 96 h). The increase in the size of the NPs with respect to time and experimental media will enable prediction of the aggregation intensity of the TiO₂ NPs.

2.5.2. Electro-kinetic interactions of NPs with HA. The electro-kinetic changes in the suspensions of TiO₂ NPs in all the groups were measured by determining the zeta potential using PALS. The difference in the surface charge of the NPs allowed the determination of the intensity of the electrostatic interactions between the NPs and HA.

2.5.3. Adsorption of HA on the NPs. The adsorption of HA on the TiO₂ NPs in MQ water and experimental buffers was investigated by measuring the fluorescence intensity of HA at a characteristic wavelength (350 nm) using fluorescence spectroscopy (model no. G9800A Fluorescence, Cary Eclipse, Agilent Technologies, USA). The samples for analysis were prepared by settling the NPs by centrifugation at $3220 \times g$ for 30 min. The colour of the settled NPs was also captured using a digital camera.

2.5.4. Sedimentation of NPs. The sedimentation of the NPs in the different groups was determined by measuring a time dependent change in the absorbance of the TiO₂ NPs at

a specific wavelength (320 nm). The absorbance was recorded in a quartz cuvette with a 1 cm optical path length filled with a 1 mL suspension of TiO₂ NPs. The absorbance of the TiO₂ NPs was recorded using UV-Vis spectroscopy at 320 nm at an initial (A_0) and final (A_t) time point. A breakthrough curve was plotted for A_t/A_0 as the y-axis against time (h) as the x-axis.

2.6. Ecotoxicity experiments

2.6.1. Zebrafish embryo toxicity assays. All the experiments were conducted in six well microtiter plates (Corning, NY, USA). Each well contained 15 embryos (4 h post fertilization) in 4 mL of E3 medium. The concentration of TiO₂ NPs in the treatment groups was in the range of 1, 10, 50 and 100 $\mu\text{g mL}^{-1}$. The embryos were exposed for 48 h to TiO₂ NPs under a 10/14 h dark/light cycle in a BOD incubator at 22 °C. The experiments were conducted in four groups:

Group 1: embryos in E3 medium (control)

Group 2: embryos + HA (10 $\mu\text{g mL}^{-1}$) in E3 medium (control)

Group 3: embryos + TiO₂ NPs (1, 10, 50 and 100 $\mu\text{g mL}^{-1}$) in E3 medium

Group 4: embryos + TiO₂ NPs (1, 10, 50 and 100 $\mu\text{g mL}^{-1}$) + HA (10 $\mu\text{g mL}^{-1}$) in E3 medium

Embryos were observed under a stereo-zoom microscope to determine the mortality at 0, 1, 3, 4, 24, 42, 44, and 48 h. The embryos with a ruptured yolk were considered dead. The delay

Fig. 1 Characteristics of TiO₂ nanoparticles (50 $\mu\text{g mL}^{-1}$) in MilliQ water in the presence and absence of humic acid (10 $\mu\text{g mL}^{-1}$). (a) UV-Vis spectroscopy, (b) TEM, (c) SEM and (d) EDS spectra.

in hatching time in the treated groups compared to the controls was also recorded.

2.6.2. *Tetrahymena* viability assay. The experiments were conducted in 6 well microtiter plates (Corning, NY, USA). Each well contained 10^4 *Tetrahymena* cells per mL in Dryl's buffer. *Tetrahymena* cells were exposed to TiO₂ NPs (1, 10, 50 and 100 $\mu\text{g mL}^{-1}$) in the presence and absence of HA (10 $\mu\text{g mL}^{-1}$) for 24 h in BOD incubation under dark conditions at 22 °C. The viability of the cells was determined using a direct counting method as described by Gupta *et al.* (2017).⁴ Briefly, the number of dead cells in the total number of cells in a 20 μL sample was counted under an optical microscope (Model CETi; Medline Scientific Ltd., Bangalore, India) at 400 \times magnification. The non-motile cells and cells with abnormal morphology were considered dead cells. The viability (%) was calculated using the formula:

$$\text{Viability (\%)} = \frac{[(\text{total cells} - \text{dead cells})/\text{total cells}] \times 100}{100}$$

2.7. Statistical analysis

All the experiments were performed in triplicate, and the results are expressed as the mean \pm standard error (SE) of the mean. The statistical analysis was carried out using Microsoft® Excel 2007 and GraphPad Prism® version 3.02.

3. Results and discussion

3.1. Characteristics of TiO₂ NPs

The SEM observation and consequent elemental analysis of the TiO₂ nanopowder using EDS showed titanium peaks in the spectra with no other impurities. The TEM observation demonstrated a heterogeneous dispersion of TiO₂ NPs with a range of particle sizes between 20 and 30 nm (Fig. 1). The hydrodynamic size (D_h) and zeta potential of the TiO₂ NPs in MilliQ water were 333 nm and -22 mV, respectively. The D_h of the TiO₂ NPs decreased to 268 nm after addition of HA, while the zeta potential of the suspension increased to -29 mV. UV-Vis spectroscopy analysis of the TiO₂ NP suspension in MilliQ water ($50 \mu\text{g mL}^{-1}$) showed an absorption maximum (λ_{max}) at ~ 320 nm (Fig. 1a), which was shifted slightly towards a lower wavelength of 310 nm after addition of HA ($10 \mu\text{g mL}^{-1}$).

3.2. Aggregation and sedimentation of TiO₂ NPs

An increase in the size of the TiO₂ NPs in Dryl's buffer and E3 medium was observed with respect to MQ water (Fig. 2). The size of bare TiO₂ NPs in Dryl's buffer increased with time from 589 ± 135 nm at 0 h to more than 1270 ± 25 nm at 96 h. The presence of citrate ions in Dryl's buffer provided stability to the NPs in the suspension at the initial time point due to their adsorption on the surface. Meanwhile, at later stages these NPs start aggregating due to dominant hydrophobic interactions between the TiO₂ NPs. The addition of HA to the suspension of TiO₂ NPs in Dryl's buffer reduces the size ($D_h = 249 \pm 25$ nm) and influences the stability of the suspension as measured for

Fig. 2 Aggregation of TiO₂ nanoparticles ($50 \mu\text{g mL}^{-1}$) in different experimental buffers in the presence and absence of humic acid (HA) ($10 \mu\text{g mL}^{-1}$). (a) MQ water, (b) Dryl's buffer and (c) E3 medium.

96 h ($D_h = 257 \pm 9$ nm). The increase in the stability of the TiO₂ NPs was due to the strong negative charge intensity on the surface of the NPs generated after adsorption of HA, leading to strong electrostatic repulsion.

Furthermore, rapid aggregation of TiO₂ NPs was observed in the E3 medium due to the presence of a high mineral content (Na, K, Mg and Ca) to support the survival of the zebrafish embryos. The initial size of the TiO₂ NPs in the E3 medium was ~ 2900 nm and this further increased up to 3400 nm. Surprisingly, the addition of HA to the E3 medium influences the size of the NPs up to 3500 nm in the initial 2 h, which then further reduces to 1800 nm at later time points (Fig. 2c). This could be due to delayed adsorption of HA on the surface of the NPs. A delay in adsorption of HA on NP surfaces could be possible due

to the presence of inorganic ions (SO_4^{2-} , Cl^-) in the media that shielded the NP surface and prevented rapid binding. The polydispersity index of the NPs in E3 medium was high due to greater heterogeneity in the sizes of the NP clusters that also influences the inter-assay variations in the experiments (Table S2†). Moreover, the generation of large clusters of NPs in the test media leads to their sedimentation in the aquatic system (Fig. 3a–c). A breakthrough curve was plotted for the change in the absorbance of the NPs at a specific wavelength (320 nm) against time. Photographs of the NP suspension were also captured in a time dependent manner that confirms the sedimentation of the NPs (Fig. 3d). The intensity of TiO_2 NP sedimentation was in the order: E3 medium > Dryl's buffer > MilliQ water. These results indicate that sedimentation of NPs in both media was initiated after 4 h and stopped at 24 h in the case of Dryl's buffer, while it continued up to 48 h in E3 medium. In Dryl's buffer, sedimentation was observed up to 24 h due to the formation of large aggregates at initial time

points and no aggregates formed at later time points. However, in E3 medium, the NP aggregate formation continued up to 48 h, hence sedimentation was observed up to 48 h. The presence of HA inhibited the sedimentation of NPs to some extent in both media. A slight increase in the sedimentation of the NPs was also observed in MilliQ water in the absence of HA due to aggregation of the NPs.

Studies have demonstrated that HA prevents the aggregation of NPs in an aqueous suspension *via* their adsorption on the NP surface.^{29,30} In contrast, it has also been demonstrated that the presence of a higher salt concentration can induce NP aggregation even in the presence of HA. The stability of the NPs plays a critical role in their impact on organisms. The E3 medium and Dryl's buffer are frequently used in laboratory-based ecotoxicity experiments on zebrafish embryos and ciliated protozoans (*e.g.* *Tetrahymena* or *Paramecium*), respectively. The results obtained in the present study demonstrate that the aggregation and sedimentation behaviour of TiO_2 NPs increased due to the

Fig. 3 Sedimentation of TiO_2 nanoparticles in the different experimental buffers in the presence and absence of humic acid (HA). (a) MilliQ water, (b) E3 medium, (c) Dryl's buffer and (d) photographs of nanoparticles suspension up to 48 h.

buffer used for ciliated protozoan to zebrafish. However, addition of HA to the experimental media prevented the aggregation of NPs to some extent. Therefore, our study demonstrates that the use of HA in ecotoxicity experiments will not only closely mimic environmental conditions but also help in conducting long term ecotoxicity assays.

3.3. Adsorption and electro-kinetic interactions of HA with TiO₂ NPs

The adsorption of HA on TiO₂ NPs was mainly driven by the complex interplay between electrostatic and steric interactions. Fig. 4 shows a change in the ζ-potential of the TiO₂ NPs after interaction with HA. The increased intensity of the negative ζ-potential of the NPs varied between the experimental buffers and MilliQ water. In MilliQ water, the ζ-potential of TiO₂ NPs was -23 mV and it increased to -33 mV in the presence of HA due its adsorption on the surface. The adsorption of HA on TiO₂ NPs in MilliQ water could be mainly possible either due to the steric interactions or through ligand exchange. An increase in the magnitude of the ζ-potential on the NP surface after binding of HA indicated the electrostatic interactions. Similarly, Jayalath *et al.* 2018²⁷ have shown that HA adsorbs on the surface of NPs under neutral pH conditions *via* electrostatic interactions between negatively charged NPs and HA of a different surface charge magnitude. In E3 medium, the surface potential of the TiO₂ NPs was in the range of -3.0 mV to -8.0 mV, and it increased to -19 mV immediately after addition of HA. In Dryl's buffer, the surface potential of the TiO₂ NPs was -30 mV, which increased to -33.0 mV after addition of HA. The change in the surface potential of the TiO₂ NPs was not significant in Dryl's buffer after addition of HA, which might be due to poor binding as the presence of citrate ions interfered with the adsorption of HA on the surface of the TiO₂ NPs. In E3 media the presence of electrolytes (Ca²⁺, Na⁺, Mg²⁺ and K⁺) increases the ionic strength of the suspension, which compresses the diffused layer present over the NPs and consequently reduces the ζ-potential on the surfaces and diminishes the repulsions between NPs, and therefore promotes particle aggregation. However, addition of HA to this suspension to bind to the surface of the NPs induces electrostatic repulsion and reduces the aggregation of NPs. In E3 media, there was a range of mineral ions (Ca²⁺, Na⁺, Mg²⁺ and K⁺) that were present that facilitated the electrostatic attractions between the NPs and HA in the suspension. Fig. 5 shows the fluorescence spectroscopy results

Fig. 5 Adsorption of humic acid (HA) on the surface of TiO₂ nanoparticles in MQ water and experimental buffers. (a) Fluorescence intensity of nanoparticles in the presence of humic acid and (b) photographs of settled nanoparticle suspensions in the presence and absence of humic acid.

for the adsorption of HA on the surface of TiO₂ NPs in the different buffers and MQ water. These results show a higher adsorption of HA on the NPs in the E3 medium compared to that in the MQ water and Dryl's buffer (Fig. 5a). The higher adsorption of HA in E3 medium was further confirmed in photographs captured after settling the NPs (Fig. 5b). A colour change was clearly observed with increasing adsorption of HA on the NPs in different experimental buffers. In previous studies, it has been shown that HA can influence the stability of TiO₂ NPs through electrostatic repulsion, steric hindrance and bridging effects.^{28,31} Yang *et al.* (2009) showed that phenolic -OH of HA was responsible for its ligand exchange with TiO₂ NPs.¹⁴

3.4. Effect of HA on the toxicity of TiO₂ NPs in *Tetrahymena* and *Danio rerio* embryos

It was observed that NPs were internalised in cells within 1 h of exposure to TiO₂ NPs (100 µg mL⁻¹) in the presence and absence of HA (Fig. 6a–c). The black vesicles that appeared in the cytoplasm of *Tetrahymena* cells exposed to the TiO₂ NPs (50 µg mL⁻¹) were due to the internalization and accumulation of NPs in the cytoplasm. The internalization of NPs in *Tetrahymena* could occur through the phagocytosis process as demonstrated in previous studies.^{21,32} The adsorption of HA on the surface of the NPs may reduce their internalization in the *Tetrahymena* cells due to their higher negative charge intensity compared to bare TiO₂ NPs. *Tetrahymena* images captured after exposure to bare TiO₂ NPs (without HA) showed a large number of cytoplasmic vesicles compared to samples in the presence of HA (Fig. 6a–c). Hence, the presence of a lower number of vesicles in

the cytoplasm indicated the reduced internalization of TiO₂ NPs in the presence of HA. Furthermore, the viability of *Tetrahymena* cells was also investigated after exposure to TiO₂ NPs in the presence and absence of HA. The results showed that ~25% of the *Tetrahymena* cells were dead after exposure to bare TiO₂ NPs (without HA) for 24 h (Fig. 6d). However, no significant decline in the population of *Tetrahymena* cells was observed in the presence of HA after 24 h (Fig. 6e). This shows that HA was protecting the *Tetrahymena* cells from the toxic effects of the TiO₂ NPs.

In *Danio rerio* embryos, the most significant effect of the addition of HA was the reversal of the viability in the embryos exposed to TiO₂ NPs. The exposure of embryos to bare TiO₂ NPs (without HA) affected the viability of 15% of the embryos as compared to the control. However, in the presence of HA, >95% embryos were viable and healthy at each time point in the control and treatment groups (Fig. 7). Furthermore, the assessment of the hatching delay in the embryo after TiO₂ NP exposure showed a ~2 h delay in hatching in the presence or absence of HA. The continuous microscopic observation of NP exposed zebrafish embryos showed an adsorption of NPs over the chorion surface that prevented their interactions with the embryo (Fig. 7). The extensive adsorption of NPs over the chorion surface might also be a reason for the short delay in the hatching of the embryos. In previous studies, it has been shown that HA can cause a reversal effect on the toxicity of NPs.³³ Hall *et al.* (2009) have shown that total organic carbon decreased the toxicity of NPs for *Ceriodaphnia dubia*.³⁴ Lin *et al.* (2012) have also shown that an intracellular level of reactive oxygen species (ROS) generation by TiO₂ NPs was significantly limited in the

Fig. 6 TiO₂ nanoparticle uptake and viability in *Tetrahymena* cells in the presence and absence of humic acid. presence of HA, which consequently diminished their cytotoxicity.³⁵ In contrast, Seitz *et al.* (2016) have demonstrated that in addition to the quantity, also the quality (including the aromaticity) of natural organic matter (NOM) influences the ecotoxicity of the TiO_2 NPs.³⁶ Yang *et al.* (2013) have shown that the presence of HA decreases the exposure to TiO_2 NPs, but elevates their toxicity in the developing zebrafish under dark and simulated light conditions.³⁷ In our zebrafish embryo toxicity studies, a 12 h light/14 h dark cycle was maintained to represent the actual toxicity outcome of TiO_2 NPs under light-dark cycle conditions. However, in case of *Tetrahymena* toxicity, light exposure was not included because *Tetrahymena* cells were cultured and grown under dark conditions.

The present observation showed that the availability of such factors can influence the stability of NPs in experimental buffers, which is a major concern in conducting ecotoxicological assays using top order aquatic organisms *e.g.* *Daphnia* and zebrafish embryo. The findings of the present research will

help regulatory agencies to design more reliable and stable ecotoxicological assays.

4. Conclusions

The observations of the present study demonstrate that humic acid increases the dispersion of TiO_2 NPs in experimental buffers *via* adsorption on the surface of the NPs, mainly due to electrostatic interactions. The maximum aggregation was observed in the E3 medium even in the presence of HA. The intensity of TiO_2 NP sedimentation was observed in the order: E3 media > Dryl's buffer > MilliQ water. However, the ecotoxicity results for *Tetrahymena pyriformis* and *Danio rerio* showed that the presence of HA reduces the toxicity of TiO_2 NPs. The study provides significant insights into the effects of humic acid on the experimental buffers extensively used in ecotoxicological assays. The finding suggests that the use of HA in

ecotoxicological assays will facilitate the long-term risk assessment of NPs by increasing the stability.
