Starting a subnanoscale tank tread: dynamic fluxionality of boron-based B₁₀Ca alloy cluster†

Ying-Jin Wang, ‡ab Lin-Yan Feng‡a and Hua-Jin Zhai b**

Alloying an elongated B_{10} cluster with Ca is shown to give rise to a dynamically fluxional B_{10} Ca cluster, the latter behaving like a tank tread at the subnanoscale. Computer global search identifies the B_{10} Ca C_2 (1 A) global-minimum structure, which is chiral in nature and retains the quasi-planar moiety of bare B_{10} cluster with Ca capped at one side, forming a half-sandwich. The rotation barrier of B_{10} Ca cluster is reduced with respect to B_{10} by one order of magnitude, down to 1 kcal mol $^{-1}$ at the PBE0/6-311+G* level, which demonstrates structural fluxionality at 600 K and beyond via molecular dynamics simulations. Structurewise, the Ca alloying in B_{10} Ca cluster generates rhombic defect holes, preactivating the species and making it flexible against deformation. Chemical bonding analyses indicate that the B_{10} Ca cluster is a charge-transfer $[B_{10}]^{2-}[Ca]^{2+}$ complex, being doubly π/σ aromatic with the 6π and 10σ electron-counting. Such a pattern offers ideal π/σ delocalization and facilitates fluxionality. In contrast, bare B_{10} cluster has conflicting aromaticity with 6π and 8σ electrons, which is nonfluxional with a barrier of 12 kcal mol $^{-1}$. Double π/σ aromaticity versus conflicting aromaticity is a key mechanism that distinguishes between fluxional B_{10} Ca and nonfluxional B_{10} clusters, offering a compelling example that the concept of aromaticity (and double aromaticity) can be exploited to design dynamically fluxional nanosystems.

1. Introduction

Molecular rotors are interesting nanoscale or subnanoscale systems, $^{1-18}$ in which the constituent fragments move collectively and concertedly against each other, akin to nanomachines. Such nanosystems are rare in chemistry and were primarily discovered during the past decade. Boron appears to be a magic element for nanorotors. Several types of boron-based nanorotors have been developed. Firstly, a Wankel motor $B_{19}^{}$ cluster was described by Merino and coworkers with a negligible in-plane rotation barrier (less than 0.1 kcal mol^{-1}), immediately following an experimental study of the gas-phase $B_{19}^{}$ cluster with concentric dual π aromaticity via photoelectron spectroscopy (PES) in 2010. 19 Similar molecular dynamics

was discussed earlier in mixed B-C clusters (C₂B₈, C₃B₉³⁺, and

 $C_5B_{11}^+$), although those species are highly energetic on their

The ultimate mechanisms of boron-based nanorotors should lie in the electron-deficiency of boron, which leads to highly unusual geometries of boron clusters, $^{19-36}$ featuring planar or quasi-planar (2D) structures up to 40 atoms for anions. 30 Among other notable boron clusters are a bowl-like $\rm B_{36}$ borophene 29 and cage-like $\rm B_{40}^{-}/B_{40}$ borospherenes. 30,37 In terms of chemical bonding, boron clusters are governed by π/σ aromaticity, antiaromaticity, double aromaticity, and

potential energy surfaces and thus not viable. Molecular Wankel motors have since been expanded to other systems, 3-9 such as the B₁₃ + cluster. Second, Zhai and coworkers to discovered in 2015 the so-called subnanoscale tank treads, which feature elongated rather than circular geometries with a peripheral ring gliding freely around an elongated inner core. Typical examples are the B₁₁ and B₁₁ clusters, which have a rotation barrier of 0.35 and 0.60 kcal mol⁻¹, respectively. An isoelectronic $B_{10}C$ model cluster¹² was designed subsequently for mechanistic insights into subnanoscale tank treads. Third, a binary Mg2B8 cluster was shown to function like a nanocompass14 and a coaxial triple-layered Be₆B₁₁ cluster was characterized in 2017 with dual dynamic modes: revolution (orbiting) of the peripheral B₁₁ ring versus rotation (twisting) of the prismatic Be₆ core. 15 Intriguingly, the Be₆B₁₁ cluster mimics the dynamic Earth-Moon system at the subnanoscale and yet miniaturizes the latter in size by 18 orders of magnitude.

Nanoscale Advances

conflicting aromaticity,35 which underlie their 2D geometries (as well as their unique structural dynamics). Note that the delocalized π/σ electrons in boron clusters are clouded over a 2D plane, 19,25-36 rather than on a single ring such as in

It is of fundamental importance to "tune" the rotation barrier of molecular rotors, which not only provides key insights into mechanisms for structural dynamics, but also facilitates control of the movements: halting or starting. Merino and coworkers⁷ showed that one C substitution stops the B₁₉ Wankel motor, resulting in a nonfluxional B₁₈C cluster with a barrier of 27.6 kcal mol⁻¹. On the other hand, Popov et al.¹⁷ reported that complexation of B₁₂ with a metal atom can reduce the rotation barrier of half-sandwich RhB₁₂⁻ and CoB₁₂⁻ clusters from 19.5 kcal mol⁻¹ down to 8.7-8.9 kcal mol⁻¹. Likewise, Liu et al. 18 designed a metal doped IrB₁₂ Wankel motor with a barrier of 5.0 kcal mol⁻¹. Nevertheless, these barriers are still quite substantial. It is highly desirable to further reduce the barrier, for example, down to 1 kcal mol⁻¹ or less.

We shall meet the above challenge using the B₁₀Ca and B₁₀ clusters. The clusters are chosen for a couple of reasons. First, the bare B₁₀ cluster is known to be nonfluxional, with a triangularly close-packed 2D structure. Second, its elongated shape intuitively makes it rather challenging to control or reduce the dynamic barrier. Lastly, as will be shown below, the B₁₀ cluster is an unusual bonding system with $6\pi/8\sigma$ conflicting aromaticity. Thus, the present work offers a case to tune/control dynamic fluxionality using the concepts of aromaticity, double aromaticity, and antiaromaticity. The strategy has not been exploited in the literature, to our knowledge.

In this contribution, we report on the structural, bonding, and dynamic properties of a binary B₁₀Ca cluster using quantum chemical calculations and chemical bonding analyses. The alloy cluster assumes a half-sandwich structure, in which an elongated B₁₀ moiety largely inherits that of bare B₁₀ cluster (with subtle variations) and the Ca atom is capped on the B₁₀ moiety. This alloy cluster is used to tune the dynamics of bare B₁₀ cluster, starting structural fluxionality of the B₁₀Ca cluster as a subnanoscale tank tread. The rotation barrier is effectively reduced by one order of magnitude and down to 1 kcal mol⁻¹ for B₁₀Ca cluster at the PBE0 level, in contrast to 12.32 kcal mol⁻¹ for the B₁₀ cluster. The relevant mechanisms are fully elucidated via chemical bonding analyses, which should guide further designs of fluxional dynamic nanosystems.

2. Methods

Global-minimum (GM) search for the B₁₀Ca cluster was conducted using the unbiased Coalescence Kick (CK) algorithm^{38,39} at the B3LYP/3-21G level. About 3000 stationary points were probed on the potential energy surface. Low-lying isomers were then fully reoptimized and their relative energies evaluated at the PBE0/6-311+G* level.40,41 Vibrational frequencies were calculated at the same level to ensure that the reported structures are true minima unless stated otherwise. To benchmark the energetics, single-point CCSD(T) calculations42-44 were carried out for the top two lowest-energy structures, that is, at the CCSD(T)/6-311+G*//PBE0/6-311+G* level, which also serve to validate the PBE0 method for the present system. The OST2 and intrinsic reaction coordinate (IRC) calculations were performed at the PBE0/6-311+G* level to locate and confirm transition state (TS) structures associated with in-plane rotation.

Natural bond orbital (NBO)45 calculations were carried out at the PBE0/6-311G* level to obtain Wiberg bond indices (WBIs) and natural atomic charges. Chemical bonding was understood via CMO analyses and AdNDP.46 The latter was done at the PBE0/6-31G level owing to the fact that such analysis is not sensitive to the level of theory or basis sets used. Born-Oppenheimer molecular dynamics (BOMD) simulations were accomplished at the PBE/DZVP level using the CP2K package.47 All electronic structure calculations were performed using Gaussian 09.48 AdNDP analyses were conducted using the AdNDP program.46 The visualization of AdNDP results was realized using Molekel 5.4.0.8.49

3. Results

3.1. Global-minimum and transition-state structures of the B₁₀Ca cluster

The GM structure of $B_{10}Ca(C_2, {}^{1}A)$ cluster at the PBE0/6-311+G* level is shown in Fig. 1, along with that of bare B_{10} (C_{2h} , $^{1}A_{g}$) cluster. Alternative top 30 low-lying structures of B₁₀Ca cluster, as identified from computer CK search and reoptimized at the PBE0/6-311+G* level, are presented in Fig. S1 (ESI†). The nearest isomeric structure is 0.83 eV higher in energy at PBE0 and 0.85 eV at single-point CCSD(T), suggesting that the B₁₀Ca GM structure is well defined on its potential energy surface. The $B_{10}Ca$ (C_2 , ¹A) cluster (Fig. 1b) is chiral in nature. It contains a bowl-like convex B₁₀ fragment onto which the Ca atom caps, forming a half-sandwich complex. It is 4.48 Å in length and 3.35 Å in width (with a length-to-width ratio of 1.34), which has an elongated overall shape and yet it is more circular than bare B₁₀ cluster.50 The peripheral B8 ring is not perfectly planar, and inner B9 and B10 atoms are popped out from the ring by about 0.8 Å.⁵¹ Note that the B_{10} fragment of B_{10} Ca $(C_2, {}^1A)$ largely inherits the bare B₁₀ cluster in geometry (Fig. 1a), except that the latter has C_{2h} symmetry with sort of a rugged surface (atom B9 being slightly out-of-plane toward inside and B10 toward the opposite side), which is likely due to mismatch in size between the B₂ core and peripheral B₈ ring.

The B_{10} Ca GM cluster has a soft rotation mode (188.0 cm⁻¹). Following the mode one reaches, via QST2 and IRC calculations, two TS₁/TS₂ structures (Fig. 1b) with an imaginary frequency of 102.5i and 207.4i cm⁻¹, respectively, were observed. Both TS₁ and TS_2 have C_{2y} symmetry and the former is practically circular.50 The IRC data confirm that the two TS structures are truly associated with the GM, corresponding to a clockwise/ anticlockwise rotation of the peripheral B₈ ring around the B₂ core. Their rotation barriers are 0.95 and 1.25 kcal mol⁻¹ at PBE0, respectively. In contrast, the TS structure of bare B₁₀ cluster (Fig. 1a) has C_s symmetry. The energy barrier amounts to 12.32 kcal mol⁻¹ at PBE0, one order of magnitude greater than those of B₁₀Ca cluster. Notable structural changes occur between GM and TS of the B₁₀ cluster: expansion at one end,

Fig. 1 Optimized structures of (a) B_{10} (C_{2h} , ${}^{1}A_{g}$) global minimum (GM) and (b) B_{10} Ca (C_{2} , ${}^{1}A$) GM at the PBE0/6-311+G* level. Also shown are their transition-state (TS) structures associated with in-plane rotation: B_{10} TS (C_s , 1 A'), B_{10} Ca TS₁ (C_{2v} , 1 A₁), and B_{10} Ca TS₂ (C_{2v} , 1 A₁). Two TS structures are found for $B_{10}Ca$, which effectively correspond to clockwise and anticlockwise rotations of the peripheral B_8 ring around the B_2 core, respectively. See Fig. S2 (ESI†) for their bond distances.

shrinkage at the other, and atom B10 being substantially popped out.51 The changes hinder the interconversion between GM and TS. The anticipated barrier lies in the distinct coordination environments: two hexacoordinate B centers in GM versus one heptacoordinate B and one pentacoordinate B in TS.

Structural parameters of B₁₀Ca and B₁₀ GM/TS clusters at PBE0 are presented in Fig. S2 (ESI†). All five structures have similar perimeters for the outer B₈ ring: 12.5-12.8 Å. However, bond distances in the inner B2 core are slightly expanded from 1.63–1.66 Å in B_{10} to 1.70–1.72 Å in B_{10} Ca. Radial B–B links are 1.79 Å in average for B₁₀Ca GM, which are elongated relative to B₁₀ GM (1.70 Å in average). Thus, upon Ca alloying, interior B-B links undergo discernible expansion, leading to bowl-like B₁₀Ca clusters (GM, TS1, and TS2). Note that such changes do not necessarily imply that interior B-B links in B₁₀Ca have lower bond orders (vide infra).

3.2. Wiberg bond indices and natural atomic charges

The NBO analyses provide quantitative data for WBIs (Fig. 2) and natural atomic charges (Fig. S3, ESI†). WBIs are highly nonuniform among peripheral and interior B-B links, between GM and TS structures, and between B₁₀Ca and B₁₀ clusters. We mention a couple of general observations. First, WBIs on the periphery are greater than 1.0, whereas those for interior links are below 1.0. The observation implies that the periphery is bound by two-center two-electron (2c-2e) skeleton σ bonds along with delocalized π/σ bonds. In contrast, interior B–B links are entirely held together by delocalized π/σ clouds. Second, there appears to be enhanced peripheral bonding in B₁₀Ca GM (WBIs in total: 10.1) as compared to B_{10} GM (WBIs in total: 9.6). Third, WBIs of B-Ca links in B₁₀Ca GM are minor: 0.07/0.10/ 0.15 for the B9-Ca/B3-Ca/B4-Ca links, suggesting negligible covalent bonding between Ca and B atoms.

Natural atomic charges in the B₁₀Ca GM cluster (Fig. S3b, ESI†) are consistent with a charge transfer complex: $[B_{10}]^{2-}[Ca]^{2+}$. Specifically, Ca atom has a positive charge of +1.52 |e|, with the peripheral B_8 ring collectively carrying a negative charge of -1.44|e| and the inner B2 dimer being roughly neutral. Note that atoms B4 and B8 each has -0.31 |e|, which are the most negative due to their closeness to the Ca center. The B₁₀ GM (Fig. S3a, ESI†) shows intramolecular charge redistribution, so that the central B9B3B10B7 diamond carries negative charges (-0.22/-0.17 |e|per atom) and the four B2/B4/B6/B8 corners are positive ($\pm 0.20 |e|$ per atom). Going from B_{10} GM to B_{10} Ca GM, the major change in charges also lies in the above four corners, where the B4/B8 centers each gains -0.51 | e | from Ca and B2/B6 each gets -0.35 |e|. Overall, the distribution of negative charges is more uniform in B₁₀Ca GM relative to B₁₀ GM.⁵²

4. Discussion

Chemical bonding in the B₁₀Ca cluster

The nature of bonding ultimately governs the dynamic fluxionality of a molecular system. Therefore, we start our discussion with chemical bonding in B₁₀Ca cluster. Considering the electron configurations of B 2s²2p¹ and Ca 4s², the B₁₀Ca cluster has 32 valence electrons. The occupied CMOs are all based on the B10 fragment (Fig. 3), consistent with a $[B_{10}]^{2-}[Ca]^{2+}$ charge-transfer complex; see above. The CMOs can be straightforwardly sorted into three categories. Subset (a) is primarily clouded on the periphery with major contributions from B 2s atomic orbitals (AOs). These CMOs have 0 to 4 nodal planes from bottom up (with three quasi-degenerate pairs in the middle), which follow the orbital building principles and readily recombine as eight 2c-2e Lewis B-B σ single bonds on the periphery.⁵³

For the π framework in subset (c), three CMOs have 0 and 1 (quasi-degenerate) nodal planes, where the intrinsic nodal plane associated with p_z AOs is not counted, as routine. The Nanoscale Advances Paper

Fig. 2 Calculated Wiberg bond indices (WBIs) from natural bond orbital (NBO) analysis at the PBE0/6-311G* level. (a) B_{10} GM and TS. (b) B_{10} Ca GM, TS₁, and TS₂.

three CMOs are analogous to the prototypical π sextet in benzene, thus endowing the B₁₀Ca cluster with π aromaticity according to the (4n+2) Hückel rule. The Ca atom only contributes less than 7% in these π CMOs. For the delocalized σ framework (subset (b)), the five CMOs again follow the orbital building principles with 0 up to 2 nodal planes (including two quasi-degenerate pairs). This CMO pattern makes it imperative to claim σ aromaticity for the B₁₀Ca cluster. Indeed, the 10 σ

electron-counting conforms to the (4n + 2) Hückel rule. In summary, the CMO analysis indicates that the B_{10} Ca cluster possesses π/σ double aromaticity with 6π and 10σ electrons, respectively. In this model, there are no 2c–2e Lewis B–B π/σ bonds inside the peripheral B_8 ring, which explains why all those B–B links have low WBI values (less than 1.0; Fig. 2b).

The bonding picture is borne out from electron localization functions (ELFs)⁵⁴ and AdNDP analysis (Fig. 4). The ELF $_{\pi}$ and

Fig. 3 Pictures of occupied canonical molecular orbitals (CMOs) of B_{10} Ca GM cluster, calculated at the PBE0/6-311+G* level. The CMOs are sorted to three subsets: (a) peripheral two-center two-electron (2c–2e) Lewis B–B σ single bonds; (b) global, delocalized 10σ framework; and (c) global, delocalized 6π framework.

Fig. 4 (a) Electron localization functions, ${\rm ELF}_{\sigma}$ and ${\rm ELF}_{\pi}$, of ${\rm B}_{10}{\rm Ca}$ GM cluster. (b) Chemical bonding pattern of ${\rm B}_{10}{\rm Ca}$ GM cluster on the basis of adaptive natural density partitioning (AdNDP) analysis, wherein the global 10σ framework is approximated to "island" σ bonds. Occupation numbers (ONs) are indicated.

ELF $_{\sigma}$ data are consistent with localized Lewis bonds on the periphery, as well as delocalized π/σ frameworks. The AdNDP scheme of B₁₀Ca cluster (Fig. 4b) reproduces peripheral 2c–2e σ bonds⁵³ and global π bonds. For the delocalized σ framework, we chose to partition it as one 2c–2e σ bond on the inner B₂ dimer and four 3c–2e/4c–2e σ bonds around the four corners, as hinted by the ELF $_{\sigma}$ data. It should be stressed that this "island" σ scheme is only an approximation. In particular, the 2c–2e σ bond has an occupation number (ON) of 1.61 |e| only. Nonetheless, the scheme is useful in elucidating the structural dynamics (*vide infra*).

The CMOs, ELFs, and AdNDP schemes of TS₁/TS₂ structures of the B₁₀Ca cluster are shown in Fig. 5 and S4-S6 (ESI†). The basic bonding information is similar to that described above, except for a slight spatial shift of the π/σ clouds, which is associated with geometric changes between GM and TS₁/TS₂ structures. For example, the AdNDP scheme for the 10σ framework in TS₁ (Fig. 5b) is similar to that in the GM (Fig. 4b). However, upon clockwise rotation of TS₁ relative to GM, two diamond 4c-2e σ bonds in the GM shrink spatially and become 3c-2e ones. This effectively generates a flow of σ clouds within the islands, whose direction is anticlockwise. For a following step (not shown), certain $3c-2e \sigma$ bonds may expand to 4c-2eones. Therefore, during dynamic rotation of the B₁₀Ca cluster, delocalized σ clouds flow (and shrink/expand) continuously like a liquid and counter the direction of geometric rotation, which are maintained approximately on the four corner islands and underlie the low rotation barrier. The delocalized π clouds behave similarly.

For comparison, the CMOs, ELFs, and AdNDP patterns of GM/TS structures of bare B_{10} cluster are shown in Fig. 6 and

S7–S9 (ESI†). The B_{10} GM cluster (Fig. S7b, ESI†) differs from B_{10} Ca GM (Fig. 3b) by one CMO less in the delocalized σ framework, which becomes the lowest unoccupied molecular orbital (LUMO) in the former species. Based on the above understanding of B_{10} Ca, bare B_{10} cluster should be classified as σ antiaromatic, which has a delocalized 8σ system and follows the 4n Hückel rule. 55,56 Indeed, the B_{10} cluster is more elongated than B_{10} Ca, a typical consequence of σ antiaromaticity; see Section 3.1. 50 Overall, the B_{10} cluster has conflicting aromaticity with 6π and 8σ electrons.

It is interesting to quantitatively follow the orbital contributions of the inner B₂ core in B₁₀Ca GM and B₁₀ GM clusters. The B_2 core in B_{10} Ca contributes 3.32, 1.84, and 0.87 |e| to subsets (a)-(c), respectively (Fig. 3), compared to 3.89, 1.02, and 1.52 |e| in B_{10} (Fig. S7, ESI†). In other words, the B_2 core has similar total contributions to σ CMOs: 5.16 |e| in B₁₀Ca versus 4.91 |e| in B_{10} . However, its contributions to π CMOs differ for the species: 0.87 |e| in B_{10} Ca versus 1.52 |e| in B_{10} . The latter observation suggests that the π clouds are probably more delocalized on the plane in B₁₀ GM, which is a con for the dynamic fluxionality of bare B₁₀ cluster, in particular considering that it has a rugged shape. In contrast, the π clouds in B₁₀Ca GM appear to lean to the periphery, which benefits a low dynamic barrier, as supported by the comparative ELF_{π} patterns (Fig. 4a *versus* Fig. 6a). The above data also indicate that the B₂ core has collectively 5.84 |e| in B₁₀Ca GM versus 6.43 |e| in B_{10} GM. Indeed, NBO data on natural atomic charges show that the B2 core is practically neutral in B10Ca and negatively charged in B_{10} (by -0.22 |e| per atom; Fig. S3, ESI†).

Fig. 5 (a) ELF_{σ} and ELF_{π} of $B_{10}\text{Ca}$ TS₁ cluster. (b) AdNDP bonding pattern of $B_{10}\text{Ca}$ TS₁ cluster, wherein the global 10σ framework is approximated to island σ bonds. ONs are indicated.

4.2. Starting a subnanoscale tank tread: distinct structural dynamics of $B_{10}Ca$ and B_{10} clusters

Two key structural features of the present B₁₀Ca and B₁₀ systems make it rather challenging to tune/control their rotation barriers. First, the clusters assume elongated (rather than circular) geometries akin to tank treads, which are generally less fluxional than molecular Wankel motors. Second, bare B₁₀ cluster is composed entirely of close-packed B3 triangles without "defect" holes, which is intuitively anticipated to be rigid against deformation. Nonetheless, the energetics data in Section 3.1 clearly show that Ca alloying in the B₁₀Ca GM cluster effectively diminishes its rotation barrier down to 0.95 and 1.25 kcal mol⁻¹ at the PBE0 level, with respect to TS1 and TS2, respectively. This is a remarkable achievement considering that bare B₁₀ cluster is nonfluxional with a barrier of 12.32 kcal mol⁻¹. To our knowledge, this is the first example of barrier reduction of a molecular rotor by one order of magnitude and down to \sim 1 kcal mol⁻¹, ^{17,18} a highly desirable level for dynamic fluxionality.

With the GM and TS_1/TS_2 structures of the B_{10} Ca cluster being identified (Fig. 1b), the dynamic structural evolution is relatively simple as illustrated in Fig. 7, assuming that the peripheral ring rotates clockwise. Starting with GM_1 and let the B9–B2 link rotate by about 18.9° , one reaches TS_{1-2} that corresponds to TS_1 in

Fig. 1b. From GM_1 to TS_{1-2} , rhombic B2B3B10B9 and B7B9B10B6 holes turn to squares. Going down the barrier, the B9–B2 link rotates by another 17.5° and the system returns to GM_2 . Due to the chiral nature of $B_{10}Ca$ cluster with C_2 symmetry, GM_1 and GM_2 are a pair of enantiomers and thus isoenergetic. However, the system does not recover its initial orientation. Further rotating the B9–B2 link slightly by 7.1° and making the B10–B2 and B9–B6 links, one reaches TS_{2-3} . The latter differs from TS_{1-2} with a higher barrier and it corresponds to TS_2 in Fig. 1b. From TS_{2-3} to GM_3 , the B9–B2 link rotates another 7.1° and breaks, generating two new rhombic holes: B1B2B10B9 and B6B9B10B5. This completes a fully cycle, in which the cluster returns to its initial structure as well as orientation. During this process, the peripheral ring moves by one B–B link (or about 51°).

Despite being nonfluxional with a substantial barrier, the structural evolution of bare B_{10} cluster can be followed on the basis of GM and TS structures identified. The process is simpler (Fig. 8). Upon rotation of the B9–B2 link clockwise by 12.0°, the B9–B3 link breaks and two rhombic B9B2B3B10 and B7B9B10B6 holes emerge, which leads to TS_{1-2} that corresponds to TS in Fig. 1a. Further rotate the B9–B2 link by 38.1° and the system recovers GM_2 . Overall, the peripheral atoms move by one B–B link (or about 50°) from GM_1 to GM_2 .

Fig. 6 (a) ELF_{σ} and ELF_{π} of B_{10} GM cluster. (b) AdNDP bonding pattern of B_{10} GM cluster, wherein the global 8σ framework is approximated to island σ bonds. ONs are indicated.

Fig. 7 Structural evolution of the B_{10} Ca GM cluster during dynamic rotation, assuming that the peripheral B_{8} ring moves clockwise around the B_{2} $core.\ Two\ energy\ barriers,\ TS_{1-2}\ and\ TS_{2-3},\ are\ to\ be\ overcome\ for\ the\ cluster\ in\ order\ to\ fully\ recover\ its\ initial\ structure\ and\ orientation.\ These$ barriers correspond to the TS₁ and TS₂ structures (Fig. 1b), respectively.

Nanoscale Advances

To demonstrate the dynamic fluxionality of B₁₀Ca cluster, we performed BOMD simulations at selected temperatures of 300, 600, and 900 K. A typical simulation at 900 K is presented in the form of a short movie (see the ESI†), which was carried out for 50 ps using the CP2K package at the PBE0/DZVP level. Initial conditions were chosen to correspond to the microcanonical ensemble (NVE). The extracted movie roughly covers a time span of 2.5 ps. It is obvious that at 900 K the B₁₀Ca cluster behaves vividly like a subnanoscale tank tread, with the peripheral B₈ ring gliding freely as a flexible chain around the B₂ core. In particular, the peripheral B₈ ring appears to be rather robust during rotation, which rotates but does not break. Similar motion is observed at 600 K except that it is slower, whereas preliminary data at 300 K do not reveal dynamic fluxionality.

As for mechanisms that distinguish between the dynamic properties of B₁₀Ca and B₁₀ clusters, the most important one is their bonding, as detailed in Section 4.1. Note that in prior studies people have attempted to unravel the connection between aromaticity (or electron delocalization) and fluxionality, in which the magnetic response is discussed.⁵⁷ The present data offer key insights using the CMOs and AdNDP analyses. While both B_{10} Ca and B_{10} are 6π aromatic, they differ in the σ framework: B_{10} is σ antiaromatic^{55,56} with 8σ electrons and B_{10} Ca has σ aromaticity (10 σ electrons). Double π/σ aromaticity in B₁₀Ca cluster makes it sort of circular with a smooth bowl-shaped surface, facilitating π/σ delocalization and structural fluxionality. In contrast, the B₁₀ cluster has a rugged surface⁵¹ and deteriorated π/σ delocalization.

In terms of geometry, the C2 symmetry of B10Ca GM cluster (Fig. 1b) has two rhombic defect holes, while B₁₀ GM cluster features triangular close-packing. Such defects are known to be critical for the dynamic fluxionality of subnanoscale tank treads (and nanorotors in general).10 Thus, alloying with Ca induces structural flexibility for B₁₀Ca cluster, which serves as "preactivation" of the system and effectively reduces the dynamic barrier. As for the B_{10} cluster, 8σ antiaromaticity leads to an elongated GM as well as substantial geometric changes between GM and TS (Fig. 1a): expansion at the left side versus shrinkage at the right. In fact, while delocalized σ clouds in the GM are balanced for left versus right (Fig. 6b), they become highly uneven in the TS so that the left side only has one 5c–2e σ bond and the right has three 3c-2e/4c-2e bonds (Fig. S9b, ESI†). Such a change is induced entirely by a rotation of the peripheral ring, which is an intriguing consequence of σ antiaromaticity and clearly underlies its large barrier. Lastly, we comment on a consequence of the two inequivalent TS structures of B₁₀Ca cluster (Fig. 1b). All molecular rotors to date move randomly (clockwise or anticlockwise). However, the occurrence of two inequivalent TS structures for B₁₀Ca hints that the system can at least be initiated with one direction preferred to another, which simplifies further control or manipulation of the dynamics.

4.3. Change in WBIs as a semi-quantitative indicator of dynamic fluxionality

To shed further light on the distinct dynamics of B₁₀Ca and B₁₀ clusters, we make use of the WBI data from NBO analyses.

Fig. 8 Structural evolution of the B₁₀ GM cluster during dynamic rotation, assuming that the peripheral B₈ ring moves clockwise around the B₂ core. Energy barrier TS_{1-2} is associated with the TS structure (Fig. 1a).

Fig. 9 Change in WBIs (that is, Δ WBIs) for the radial B-B links in the B₁₀Ca cluster from GM to TS₂ during dynamic rotation. The WBI data are obtained explicitly from GM_3 to TS_{2-3} in Fig. 7 (anticlockwise rotation). The B-B links are labelled numerically, starting from the far-left link (B9-B8) as "1" and counting clockwise up to "10" (links B9-B2 and B10-B6 included). Positive ΔWBI indicates elongation and negative compression. Red dots are Δ WBIs of the B₁₀Ca cluster and a horizontal blue line is their average. Comparative data of the B₁₀ cluster are shown with filled squares.

Intuitively, the barrier of a molecular rotor is connected to the WBI change between the GM and TS structures, which is denoted here as Δ WBI. In the present systems, the radial links govern in-plane rotation and determine the barrier. Thus, we follow all radial B-B links. As an example, ΔWBI values of the B₁₀Ca cluster with respect to TS₂ are plotted in Fig. 9, which are compared to those of bare B₁₀ cluster. Here the B-B links are labeled numerically based on GM3 and TS2-3 (anticlockwise rotation; Fig. 7). Link B9-B8 at the far left is labeled "1", counting clockwise up to "10". These include B9-B2 and B10-B6 as "3" and "8", respectively. By definition, a positive Δ WBI is associated with bond elongation, and vice versa.

The B₁₀Ca cluster shows a smooth Δ WBI curve with relatively minor and uniform values for all radial B-B links, consistent with a low barrier. In contrast, large Δ WBIs and in particular spikes are present for the B₁₀ cluster, whose B-B links are labeled again with the far-left one (B9-B1) being "1" and counted clockwise up to "10". Specifically, link "8" (B10-B7; Fig. 1a) has the largest ΔWBI, which has to elongate substantially and eventually break in order for the cluster to reach the TS structure, thus defining the barrier height of B₁₀ cluster. For comparison, links B9-B3 and B10-B7 in B₁₀Ca GM₁ (Fig. 7) are "preactivated" upon alloying with Ca atom, and they are no longer the bottleneck for fluxionality, which effectively diminish the barrier (for TS₁). Moreover, there is no need to break any B-B links from GM_3 to TS_{2-3} (anticlockwise; Fig. 7), but to shrink links B9-B2 and B10-B6, which have the largest negative Δ WBIs, in line with a low barrier for TS₂. The comparative Δ WBI data of B₁₀Ca and B₁₀ clusters distinguish between the two species, demonstrating a semi-quantitative measure for dynamic fluxionality.

Conclusions

We have demonstrated, via alloying with Ca atom, a means to tune the structural dynamics of a subnanoscale tank tread B₁₀Ca cluster. The strategy efficiently reduces the rotation barrier by one order of magnitude, from 12 kcal mol⁻¹ in B₁₀ down to around 1 kcal mol⁻¹ in B₁₀Ca. The B₁₀Ca globalminimum cluster is half-sandwich in shape, which is dynamically fluxional at 600 K and beyond, whereas bare B₁₀ cluster is nonfluxional. In terms of structures, Ca alloying generates two rhombic defect holes in B₁₀Ca cluster, which preactivates the system for fluxionality. Chemical bonding analyses show that the B₁₀Ca cluster is a charge-transfer complex and can be formulated as $[B_{10}]^{2-}[Ca]^{2+}$, featuring double $(6\pi \text{ and } 10\sigma)$ aromaticity. The bonding pattern leads to a more circular geometry and ideal π/σ delocalization, facilitating dynamic fluxionality. In contrast, the B₁₀ cluster has conflicting aromaticity (6π versus 8σ), as well as a more elongated and rugged shape. Thus, our work demonstrates that π/σ aromaticity can be utilized as a key concept to design dynamically fluxional nanosystems. To semi-quantitatively describe dynamic fluxionality, the change in Wiberg bond indices between global-minimum and transition-state structures serves as a useful indicator, which clearly distinguishes between a fluxional B₁₀Ca cluster and a nonfluxional B₁₀ cluster.

- 50 The B₁₀ GM cluster has a length of 4.76 Å and width of 3.13 Å (with length-to-width ratio of 1.52). Those of the B_{10} TS, B₁₀Ca TS₁, and B₁₀Ca TS₂ species are 4.13/3.54, 4.01/3.38, and 4.50/3.28 Å, with ratios of 1.17, 1.19, and 1.37, respectively. Thus, there is a marked ratio change from B₁₀ GM to B₁₀ TS. Also, B₁₀Ca TS₁ is particularly circular.
- 51 Of all five key structures in Fig. 1, the peripheral B₈ ring is perfectly planar only in B₁₀ GM. For other species, the out-ofplane distortions of central B atoms are estimated roughly. In B₁₀ GM cluster, atom B9 is slightly out-of-plane toward inside (by 0.3 Å) and B10 toward the opposite side. For the B₁₀ TS, B₁₀Ca TS₁, and B₁₀Ca TS₂ species, atoms B9/B10 are popped out by 0.3/1.0, 0.9/0.9, and 0.8/0.8 Å, respectively.
- 52 There appears to be a general trend that a B center with a higher coordination and stronger bonds gets some net negative charges from surrounding B atoms. In this way, the hexacoordinate B9/B10 centers and tetracoordinate B3/ B7 atoms in B_{10} GM carry negative charges (Fig. S3a; ESI†). For B₁₀ TS, the B10 center remains strongly coordinated by five B atoms, whereas the B9 center is only loosely bound

- despite its heptacoordination nature. The latter leads to less negative charge.
- 53 Strictly speaking, the assignment of eight peripheral Lewis σ bonds is an approximation. The bottom five of these CMOs have nonnegligible contributions from central B9/B10 atoms (Fig. 3a). Quantitatively, the B9/B10 core accounts for 20.7% of these eight σ CMOs, which explains why their occupation numbers (ONs; Fig. 4b) in the AdNDP scheme deviate from an ideal value of 2.00 |e|.

- 55 A previous work⁵⁶ assigned the delocalized σ framework of B_{10} GM cluster as one 2c-2e σ bond in B_2 core (although specifically called for caution) and three global σ bonds. The latter were proposed to render σ aromaticity for B₁₀ cluster, due to the 6 σ electron-counting. Our present analysis suggests that all these 80 electrons should be treated collectively (Fig. S7b, ESI \dagger) and B₁₀ cluster is σ antiaromatic rather than σ aromatic. Indeed, the ELF_{σ} data and our AdNDP scheme (island version; Fig. 6) do not support the idea of a 2c-2e σ bond within the B₂ core.
