Preparation of high-yield and ultra-pure Au₂₅ nanoclusters: towards their implementation in real-world applications†

Michael Galchenko,^a Raphael Schuster,^b Andres Black,^a Maria Riedner^b and Christian Klinke  ^{*a,c}

Colloidal approaches allow for the synthesis of Au nanoclusters (NCs) with atomic precision and sizes ranging from a few to hundreds of atoms. In most of the cases, these processes involve a common strategy of thiol etching of initially polydisperse Au nanoparticles into atomically precise NCs, resulting in the release of Au-thiolate complexes as byproducts. To the best of our knowledge, neither the removal of these byproducts nor the mass spectra in the relevant mass region were shown in previous studies. A thorough analysis of inorganic byproducts in the synthesis of [Au₂₅(PPh₃)₁₀(PET)₅X₂]²⁺ NC, abbreviated as Au₂₅ NC, reveals that published protocols lead to Au₂₅ NCs in vanishingly small quantities compared to their byproducts. Three purification methods are presented to separate byproducts from the desired Au₂₅ NCs which are proposed to be applicable to other promising Au NC systems. Additionally, critical factors for a successful synthesis of Au₂₅ NCs are identified and discussed including the role of residual water. An important finding is that the etching duration is very critical and must be monitored by UV-Vis spectroscopy resulting in synthetic yields as high as 40%.

Introduction

Among metals, Au particles surrounded by an organic monolayer (ligands) is the most studied system which is not surprising considering that their first colloidal synthesis dates back to 1857.¹ The transition between metal nanoparticles (NPs) with a continuous energy band structure and molecules with discrete energy states is embodied by metal nanoclusters (NCs) consisting of few to few-hundred atoms. Contrary to their larger counterparts, Au NCs can be synthesized in an atomically precise fashion and experience strong quantum confinement.² In this size regime unique properties appear, such as photoluminescence with quantum yields up to 40%, (photo-) catalytic activity or remarkable thermal and colloidal stability.^{3,4} Their ultrasmall size provides Au NCs with several features for potential applications beyond fundamental research: due to their high specific surface area and fraction of low-co-

ordinated atoms, they are considered to have potential in heterogeneous catalysis,^{5,6} and highly luminescent Au NCs have found tremendous application in nanomedicine.^{7,8}

Various approaches are known for synthesizing atomically precise Au particles containing up to 333 Au atoms covered with weakly or strongly bound ligands,⁹ such as triphenylphosphine (PPh₃) and phenylethanethiol (PET), respectively. Most of these involve a one-step (e.g. for [Au₁₁(PPh₃)₈Cl₂]⁺ or [Au₂₅(PET)₁₈]⁺)^{10,11} or two step (e.g. for [Au₃₈(PET)₂₄], [Au₂₅(TPP)₁₀(PET)₅X₂]²⁺ or [Au₃₇(TPP)₁₀(PET)₁₀X₂]⁺)^{12–14} synthesis and a common strategy of thiol etching. During this process, thiol molecules release gold atoms from polydisperse Au NPs to create the desired atomically precise Au NCs. The type of byproducts formed and their removal with the proposed purification protocol remained unclear, since, to the best of our knowledge, mass spectra are never shown in the mass range where few Au-atom containing complexes give rise to a signal. However, this distinct mass range contains the signal at *m/z* 1055 of the [Au₂TPP₂PET]⁺ complex which appeared to be a major byproduct in the synthesis of [Au₂₅(TPP)₁₀(PET)₅X₂]²⁺ NCs.¹⁵ In the case of purely thiol stabilized Au NCs, a thiol etching mechanism is proposed involving a Au(I)-thiolate monomer as a leaving group.¹⁶ Indeed, removal of byproducts including few Au-atom comprising and charged complexes may be relatively easy in the case of uncharged Au NCs as the main products. However, due to

the similar solubility of product and byproducts, the separation becomes more challenging for charged NCs, such as the highly fluorescent $[\text{Ag}_x\text{Au}_{25-x}(\text{PPh}_3)_{10}(\text{SR})_5\text{Cl}_2]^{2+}$, the electron transfer catalyst $[\text{Au}_{25}(\text{PET})_{18}]^+$ or the herein studied $[\text{Au}_{25}(\text{PPh}_3)_{10}(\text{PET})_5\text{X}_2]^{2+}$ NC.^{3,17} In order to implement these Au NCs successfully in an application, purity in terms of organic and inorganic byproducts is indispensable, but usually not covered sufficiently or not at all in the literature. The importance of purity becomes evident thinking of small gold-containing byproducts impacting the catalytic properties of the Au NC system.¹⁸ Most substantially, such impurities can cause quenching of catalytic activity or catalyst poisoning and explain the poor catalytic activity of specific Au NCs compared to others.²⁰ Furthermore, small gold-containing byproducts can become undesirably bioconjugated^{19,21} to a target instead of the Au NC, or quench the NCs fluorescence.

This work thoroughly analyzes the inorganic byproducts in the Au_{25} NC synthesis and reports the discovery of a previously unknown Au complex. This was achieved by high-resolution mass spectrometry (MS) covering the low m/z range and an established HPLC method, which is suggested to be applicable to a preparative separation of the above mentioned charged NCs. A hitherto unparalleled analysis by means of MS combined with UV-Vis spectroscopy was applied suggesting that all so far published protocols are mainly leading to $[\text{Au}_2\text{TPP}_2\text{PET}]^+$ complexes and Au_{25} NCs only in vanishingly small quantities. Finally, two methods for the separation of Au_{25} NCs from its byproducts are presented. In addition, potentially important key factors for a successful synthesis of Au_{25} NCs are discussed, including an optimized reaction time, the role of residual water and the relationship between these two factors.

Experimental

Synthesis of $[\text{Au}_{25}(\text{PPh}_3)_{10}(\text{PET})_5\text{X}_2]^{2+}$

Au_{25} NCs with the formula $[\text{Au}_{25}(\text{PPh}_3)_{10}(\text{PET})_5\text{X}_2]^{2+}$ ($\text{X} = \text{Cl}$ or Br) were synthesized as follows. $\text{HAuCl}_4 \cdot 3\text{H}_2\text{O}$ (0.100 g, dissolved in 3 mL of Millipore H_2O) was added into a 8 mL toluene solution of tetraoctylammonium bromide (TOAB, 0.145 g) and stirred vigorously (400 rpm) at room temperature for 15 min. Indicating the complete phase transfer of the gold compound from aqueous to toluene phase, the aqueous phase became colorless and clear and was removed by a pipette. The following steps appeared to be important for a water-free transfer of the gold compound: First, the organic phase was carefully transferred to a different glass ware with several glass pipettes, which were exchanged upon appearance of water-droplets sticking to the glass. The organic phase subsequently was poured into the 3-neck flask leaving further water-droplets behind. Subsequently, triphenylphosphine (PPh_3 , 0.180 g) was added into the flask under stirring (400 rpm). Within few to tens of seconds, the solution became cloudy white. If this color change takes more than 60 seconds to occur, water residues are present in the suspension. After 15 min freshly dissolved

sodium borohydride (NaBH_4 , 0.026 g, dissolved by ultrasonication in 5 mL of EtOH) was injected rapidly to reduce $\text{Au}^{\text{I}}(\text{PPh}_3)\text{X}$ (starting material) to Au NPs. After 2 hours, the dispersion was dried by rotary evaporation at 50 °C, resulting in a dry black solid. White solid residues in the rotary evaporator flask indicate a delayed formation of the starting material (discussed in the results). The black solid was mixed with 20 mL dichloromethane (DCM), vortexed and centrifuged at 16 000 rcf for 3 min. The resulting black supernatant was then heated to 40 °C under reflux. Phenylethanethiol (PET, 300 μL) was added to the black dispersion, which was stirred at 400 rpm.

When the UV-Vis optical spectrum has evolved as shown in Fig. 1A or latest after 96 h, the yellow/brownish dispersion was dried by rotary evaporation at 50 °C. An oily black product was obtained and transferred by means of 2 mL DCM into a glass centrifuge flask.

Purification of $[\text{Au}_{25}(\text{PPh}_3)_{10}(\text{PET})_5\text{X}_2]^{2+}$

Subsequently, the suspension was precipitated with 80 mL of hexane, centrifuged at 3000 rcf and the supernatant was removed. The DCM/hexane washing step was repeated four more times ($V_{\text{DCM}}/V_{\text{Hex}} = 1/20; 1/40; 0.5/40; 0.5/40$). Of note is that Au_{25} NCs were still stable even after eight repetitions, which indicates a colloidal stability which is different to their

larger counterparts. Finally, the $[\text{Au}_{25}(\text{PPh}_3)_{10}(\text{PET})_5\text{X}_2]^{2+}$ were extracted by mixing with 10 mL MeOH, vortexing and centrifugation at 16 000 rcf. The synthesis could easily be scaled up twofold by doubling starting and subsequently added materials mass/volume as well as purification steps.

Selective precipitation was performed as follows. 1 mL of the “purified” Au_{25} NC suspension was dried by vacuum in a 10 mL glass vial. Of note is that during drying the vial was rotated. Thereby, the suspension was spread over a large area which is beneficial for the purification process. Subsequently, a mixture of methanol/water (Millipore) (10 mL, 20/80 vol%) was added to the dry material. The brownish/black material remained undissolved and the supernatant colorless or slightly yellowish. The supernatant was discarded and the brownish/black solid could be redissolved in a residue-free fashion in 3 mL of methanol.

Alternatively, Au_{25} NCs can be crystallized with a modified protocol based on a known procedure.¹⁵ Briefly, 10 mL of the “purified” Au_{25} NC suspension (optical density = 9) was mixed with excess NaSbF_6 (240 mg) and stirred for 15 min in DCM. After removing residual NaSbF_6 (white solid) by means of centrifugation, the suspension was transferred to an unsealed 20 mL glass or Teflon vial. Subsequently, this vial was placed in a glass container, equipped with a ground glass joint. After filling hexane into the glass container until it reached a similar level as DCM, the container was left sealed in the fridge. After 5–7 days the suspension became colorless and clear leading to solid residues on glass walls and black, needle-like crystals. Further purification, like mixing with hexane and discarding it, was not applied since otherwise crystals tended to stick to the glass walls. The crystals can be transferred to a substrate for subsequent studies using a pipette filled with hexane or water or alternatively redissolved in methanol.

The following chemicals were used as received. Triphenylphosphine (99%), ethanol (99.98%) and toluene (99.85%), were purchased from Acros Organics. Methanol (99.8%) and *n*-hexane (96%) were purchased from VWR. Gold(III) chloride trihydrate (99.995%) and tetraoctylammonium bromide (98%) were obtained from Alfa Aesar. Dichloromethane (DCM, 99.5%) was obtained from Grüssing. Water was purified using a Millipore-Q System (18.2 MΩ cm). UV/Vis extinction spectra were obtained with a Cary 50 spectrophotometer. Transmission electron microscopy (TEM) images were obtained using Philips CM 300. High-resolution TEM images were obtained using a JEOL JEM 2200 FS. All the TEM samples were prepared by dropping 10 mL of diluted methanol suspension onto carbon-coated TEM grids followed by solvent evaporation under ambient conditions.

Electrospray ionization quadrupole time-of-flight mass spectrometry

5 μL of the sample (optical density 1 in ACN), diluted further 1:5 using ddH_2O /acetonitrile (CAN, HPLC grade) 50/50 v/v, were injected *via* direct infusion into an ESI-Q-TOF mass spectrometer (maXis, Bruker Daltonik) coupled to an UHPLC (Dionex Ultimate 3000, Thermo Scientific). As an eluent

ddH_2O + 0.1% formic acid (FA, HPLC grade)/ACN + 0.1% FA 50/50 v/v was used with a flow rate of 200 μL min⁻¹. MS-spectra were recorded in positive ion mode with a mass range of 800–5000 Da and a spectra rate of 1 Hz. The capillary voltage was set to 4500 V, the source temperature to 200 °C, the nebulizer pressure to 3.0 bar and the drying gas to 8.0 L min⁻¹.

Liquid chromatography electrospray ionization quadrupole time-of-flight mass spectrometry

5 μL of the same sample were injected into an UHPLC system (Dionex Ultimate 3000, Thermo Scientific) coupled to an ESI-Q-TOF mass spectrometer (maXis, Bruker Daltonik). For separation the compounds were loaded onto a reversed phase separation column (Extend C18, 1.8 μm, 2.1 × 50 mm, Agilent Technologies) and a linear gradient with ddH_2O + 0.1% FA (buffer A) and ACN + 0.1% FA (buffer B) as mobile phase and a flow rate of 300 μL min⁻¹ was applied. In the beginning the concentration of buffer B was set to 50% and was increased to 95% within 30 minutes, kept constant for two minutes, was decreased to 50% within 3 minutes and finally kept constant for five minutes. MS spectra were recorded in positive ion mode with a mass range of 800–5000 Da and a spectra rate of 1 Hz. The capillary voltage was set to 4500 V, the source temperature to 200 °C, the nebulizer pressure to 3.0 bar and the drying gas flow to 8.0 L min⁻¹.

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry

1 μL of the same sample were mixed with 1 μL of MALDI matrix (2,5-dihydroxybenzoic acid, 20 mg mL⁻¹ in ddH_2O /ACN 70/30 v/v and 0.1% TFA) and the mixture was spotted and dried on a MALDI groundsteel target. The target was injected into a MALDI-TOF-TOF mass spectrometer (UltrafleXtreme, Bruker Daltonik) and MS spectra were recorded in positive ion mode with a mass range of 500–5040 Da, a laser intensity of 27% and 1000 laser shots per spectrum in partial sample mode. Ion source 1 voltage was set to 20 kV, ion source 2 voltage to 17.85 kV, lens voltage to 8.8 kV, reflector 1 voltage to 21 kV and reflector 2 voltage to 11 kV.

To obtain MS/MS spectra the ions of interest were isolated and fragmented using MALDI-LIFT-MS/MS. MS/MS spectra were recorded in positive ion mode, with a laser intensity of 29–35% and 9000 laser shots per spectrum in partial sample mode. Ion source 1 voltage was set to 7.5 kV, ion source 2 voltage to 6.85 kV, lens voltage to 3.5 kV, reflector 1 voltage to 29.5 kV, reflector 2 voltage to 13.85 kV, LIFT 1 voltage to 19.00 kV and LIFT 2 voltage to 3.2 kV.

Results and discussion

On the basis of known procedures^{13,15} a modified approach for the synthesis of Au_{25} NCs with the formula $[\text{Au}_{25}(\text{TPP})_{10}(\text{PET})_5\text{X}_2]^{2+}$ was established. Initially, polydisperse 1–3 nm sized Au_n TPP-stabilized NPs were synthesized, followed by size focusing through thiol etching, which produced

the desired Au₂₅ NC. Finally, ultra-pure Au₂₅ NCs were obtained by separation from major inorganic byproducts. Fig. 1A shows UV-Vis optical spectra of aliquots taken at different times during the thiol-etching step, showing how large, polydisperse Au_n NPs are converted to Au₂₅ NCs (crystal structure shown in Fig. 1A inset). Before size focusing, the rather featureless optical spectrum is typical of Au_n NPs smaller than 2.5 nm.²² As the particle size distribution narrows over time, distinct and gradually sharpening peaks appear. The peak at 670 nm corresponds to the HOMO to LUMO transition with a wave function localization around the vertex position. Higher excitations are partially due to HOMO-*n* to LUMO+*n* transitions (*n* > 0) in the Au₁₃ sub-units comprising the Au₂₅ NC.¹⁴

The increasing intensity of these peaks serves as convenient markers to monitor the etching process. Plotted in Fig. 1B is the height of both peaks as a function of etching duration, which respectively were measured from the peak maximum to minimum at shorter wavelength. It becomes evident that after an initial decrease, the peak height at 415 nm increases and levels off at an extinction value between 0.07 and 0.09 (100 μL withdrawn aliquot diluted to 3 mL). This is the highest possible extinction value demonstrating the termination of the size focusing process. Furthermore, as indicated by the error bars, the necessary etching duration can fluctuate and should be monitored by UV-VIS spectroscopy.

We propose that the variation in the duration of the thiol etching step is due to residual water, accidentally transferred during the aqueous phase to organic phase transfer of the Au compound. As an increased amount of water was observed to prevent or delay the white clouding upon TPP addition and thus AuTPPX formation (starting material), it is obvious that residual water impacts the NaBH₄ (reduction agent) mediated reduction step and thus the particle size distribution. Therefore, a detailed description is provided in the Experimental section on how to successfully carry out a quasi water-free phase transfer. After the reaction ended the suspension was purified through DCM/hexane redissolution/precipitation for multiple times and extracted with methanol (abbreviated as DCM/Hex/MeOH), resulting in an optical spectrum of the “purified” Au₂₅ NC with sharp, molecule-like optical transitions at 415 and 670 nm, shown in black in Fig. 1A.

The present method is designed to be lossless and convenient in two ways: first, purification typically employed before thiol-etching is instead performed afterwards, ensuring a larger fraction of Au_n-TPP NPs to be loss-free and available for the conversion to Au₂₅ NCs. Second, an adjustment of the Au:thiol molar ratio through thermo gravimetric analysis (including drying and combustion of 5–10 mg NPs) can be bypassed, and the suggested thiol volume can be considered as constant. Combining an optimized reaction time derived from the optical spectrum, proper handling of water residues, and finally a loss-free transfer of polydisperse Au NPs by omitting purification in between of synthesis steps, the synthetic yield of “purified” Au₂₅ NCs has been raised to 35 mg NCs per 100 mg chloroauric acid (40% in respect to elemental Au).

Various analytic and imaging techniques were applied to further investigate the properties and quality of the Au₂₅ NC suspension. Transmission electron microscopy (TEM) and high resolution TEM (shown in Fig. 1C and inset) reveal well separated nm sized crystals, with no aggregates or larger particles observed. By means of high-resolution electrospray ionization (ESI) MS, shown in Fig. 1E, three modifications of the [Au₂₅(TPP)₁₀(PET)₅X₂]²⁺ NC are identified, giving rise to signals at *m/z* 4151.60, 4174.08 and 4196.05, corresponding to X₂ = Cl₂, BrCl or Br₂ respectively. The solubility of Au₂₅ NCs in solvents of varying polarities, from methanol to toluene, makes their separation from residual organic synthesis byproducts challenging. This topic is not covered sufficiently in previous reports, which lack ³¹P or ¹H NMR spectra.^{13,14,23–25} Through these methods, we identified a large amount of TPP and the ionic and organic soluble phase transfer agent tetraoctylammonium (TOA⁺) as major organic residues. The DCM/Hex/MeOH purification sequence thoroughly removed loose TPP, resulting in exclusively surface-bound TPP giving rise to a signal at 53 ppm in the ³¹P NMR spectrum (Fig. 1D). In addition, a remarkably low concentration of residual TOA⁺, identified by the small integral of the signal at 3.15 ppm in the ¹H NMR spectrum (Fig. S1†) is achieved.

Since organic byproducts were thoroughly removed as evidenced by the NMR analysis, a deeper insight into colloidal impurities of inorganic nature was necessary. Their presence can be clearly recognized from the UV-Vis optical spectra. Comparing the UV-Vis optical spectra of Au₂₅ NC suspensions prepared by different groups a remarkable difference is evident (Fig. 2). The extinction offset compared to the black curves is clearly visible below 460 nm. An offset in this spectral region could originate from NCs of a similar or smaller core

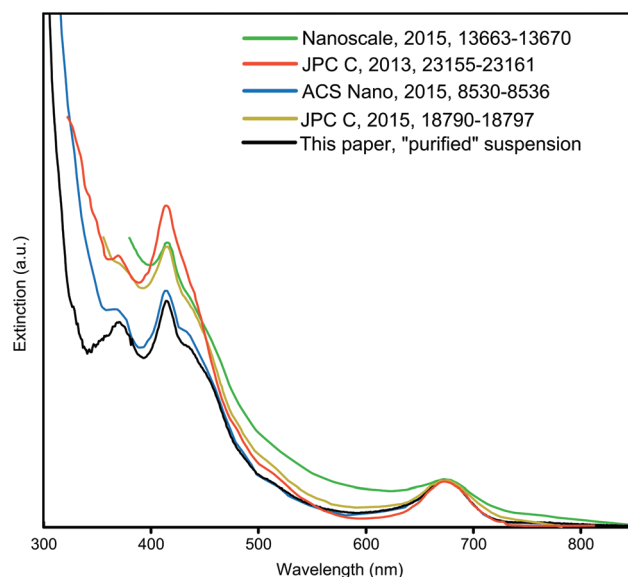

Fig. 2 Optical spectra reported for [Au₂₅(TPP)₁₀(PET)₅X₂]²⁺ NCs illustrating clear differences in the relative intensities of the peaks and the expression of the fine structure. All data were digitized from the cited source and normalized to 675 nm (HOMO to LUMO transition).

size than Au₂₅. However, distinct spectral signatures of such NCs were not apparent in the corresponding optical or mass spectra. Consequently, plasmonic absorption or scattering by large Au NPs cause the increased extinction and broaden the 415 nm optical feature of the Au₂₅ NC. Removal of these by the established DCM/Hex/MeOH purification sequence and especially proper reaction control, including an optimized reaction time, were identified in the present work to be crucial for obtaining a Au₂₅ NC suspension free of large NPs and an extinction spectrum as shown in black in Fig. 2.

As apparent from the blue curve in Fig. 2, an extinction offset to the black curve can also rise only below 380 nm. This indicates that instead of Au NPs, unreacted starting material AuTPPX¹³ or, despite their absence in the reported MS spectrum, small few gold-atoms comprising complexes are present. To this day, mass spectra of products from thiol etching synthesis as applied for Au₂₅ and for many other NCs are usually not shown below *m/z* 1200, although the formation of byproducts including few gold-atoms containing complexes is known giving rise to signals in that mass range. A 2011 report from the Jin group shed light on the dark: the Au₂ complex with the formula [Au₂TPP₂PET]⁺ was crystallized from a Au₂₅ NC suspension.¹⁵ Although crystals of this major byproduct could be mechanically separated, it did not become clear whether a significant level of purity of the Au₂₅ NC suspension could be achieved since a mass spectrum covering the whole mass range was not reported. Therefore, the present study focused on a comprehensive MS analyses including the mass range below *m/z* 1200 and removal of all inorganic byproducts, including the few gold-atoms comprising complexes.

High performance liquid chromatography (HPLC) proved to be a useful tool for a preparative separation of Au NCs covered with different ligands and of varying size.^{26,27} Combined with high resolution electrospray ionization (ESI)-MS, a chromatographic separation of the Au₂ complex from Au₂₅ NCs was targeted. With the established HPLC method, three distinct fractions could be observed, as indicated by the base peak chromatogram (BPC) in Fig. 3A. The first fraction solely includes the above mentioned [Au₂TPP₂PET]⁺ complex (*m/z* 1055) followed surprisingly by a third single positive charged compound with a mass of *m/z* 1409, whose simulated spectrum is shown in the inset. After about 25 min, all three modifications (with X₂ = Cl₂, ClBr or Br₂) of the Au₂₅ NC are eluted, along with a compound already present in the blank measurement. The corresponding BPC of the blank measurement as well as extracted ion chromatograms (EICs) are shown in Fig. S2.†

Since a gold-complex with a mass of 1409 has not yet been reported, matrix assisted laser desorption/ionization (MALDI)-MS was applied to analyze the peak at *m/z* 1409 in more detail. A MALDI-MS spectrum in the range of *m/z* 500–5040 of the Au₂₅ NC sample is shown in Fig. 3B. In accordance to the HPLC-ESI-MS results, the compounds with masses of 1409 and 1055 give rise to a signal and a fragment at *m/z* 721. All three compounds were further fragmented and analyzed by means of MALDI-MS/MS (Fig. 3C). Indicating a similar molecular structure, the compounds at *m/z* 1409 and 1055 fragment

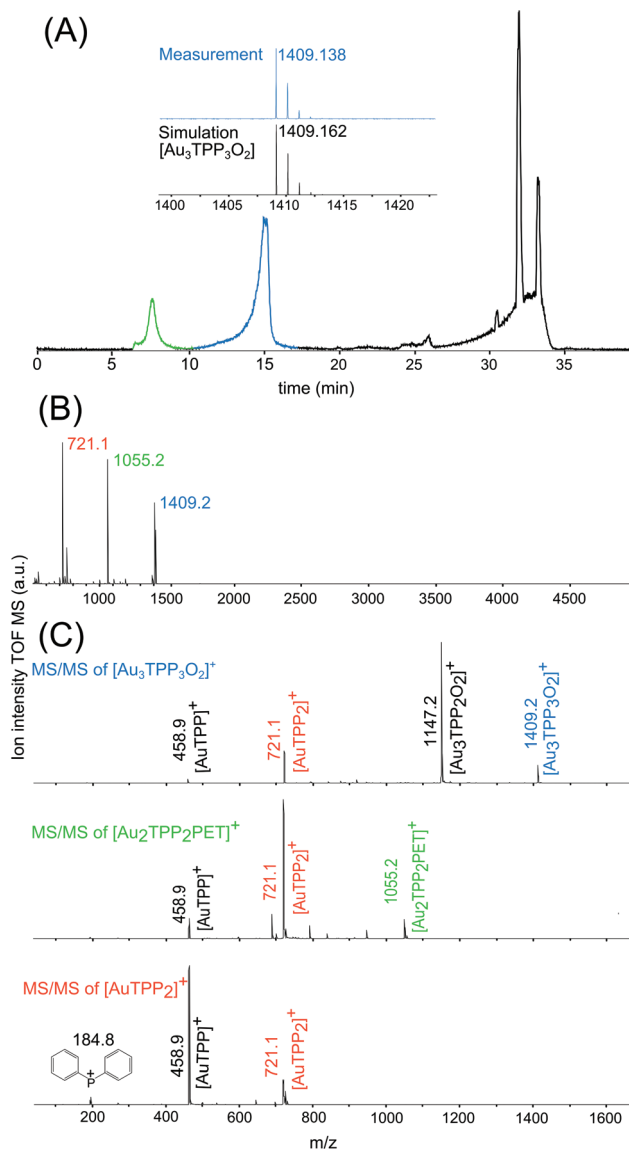

Fig. 3 MS analysis of [Au₂₅(TPP)₁₀(PET)₅X₂]²⁺ and contained byproducts. (A) Base peak chromatogram of Au₂₅ NCs measured with ESI-MS. (B) MALDI-MS of Au₂₅ NCs. (C) MALDI-MS/MS analysis of components present in (B). Same color in different figures indicates the same compound or the same fragment.

in a similar way to fragments at *m/z* 721 and 458, which are suggested to be [AuTPP₂] and [AuTPP], respectively. In addition, the MS/MS spectrum of the peak at *m/z* 1409.2 compound shows a fragment at *m/z* 1147, which can be assigned to [Au₃TPP₂O₂]. Based on this fragment and the well matching simulated spectrum (inset in Fig. 3A) the newly found compound at *m/z* 1409 is proposed to be a [Au₃TPP₃O₂] complex, which has not been reported to this day.

Having identified the residual inorganic byproducts including the Au₂ and Au₃ complexes, we proceeded to remove them. In addition to the chromatographic separation, two practical methods are presented to obtain Au₂₅ NCs satisfying different application purposes. The first method is based on a known

procedure and involves the crystallization of the Au_{25} NCs whose microscope image is shown in Fig. 4B. However, in accordance with a previous report,¹⁵ a mass spectrum indicating the exclusive presence of Au_{25} NCs could not be obtained from the redissolved crystals. Conclusively, the mechanical separation of Au_2/Au_3 complexes from the Au_{25} appeared to be useful only when few single crystals are required (*e.g.* single crystal analysis) but not as a purification method for the suspension.

The second method is based on a classical selective precipitation method. Starting with the “purified” Au_{25} NC suspen-

sion with an UV-Vis optical spectrum shown in Fig. 4A in black, the dry material is mixed with a methanol/water (2/8 vol%) mixture resulting a colorless liquid phase and a residual black solid. The optical spectrum of the liquid phase is shown in red in Fig. 4A. Two of four sharp optical features, located at 266 and 273 nm are directly assigned to the $[\text{Au}_2\text{TPP}_2\text{PET}]^+$ complex¹⁵ whereas two residual features at 254 and 260 nm are believed to stem from absorption of the $[\text{Au}_3\text{TPP}_3\text{O}_2]$ complex. The residual black solid is redissolved in methanol resulting in an optical spectrum, shown in blue in Fig. 4A, indicative of Au_{25} NCs. The spectrum of the obtained Au_{25} NCs gives rise to two new sharp transitions and rises moderately below 300 nm, while the starting materials and Au_2/Au_3 spectra rise much steeper. As the black spectrum appears to be a superposition of the red Au_2/Au_3 spectrum and the blue Au_{25} spectrum (indicated by the inset), the UV-Vis spectral data suggests that Au_{25} NCs are successfully separated by selective precipitation from its major byproducts. The results from the UV-Vis spectroscopy are supported by ESI-MS recorded before and after selective precipitation in the range of m/z 800 to 5000, shown in Fig. 4C. It becomes clear that “purified” Au_{25} NCs are present in vanishingly small quantities compared to the Au_2 complex. However, after selective precipitation, all aforementioned byproducts are removed and solely Au_{25} NCs remain in the suspension.

Conclusion

The present work demonstrates the necessity of monitoring the Au nanoparticle etching process by UV-VIS spectroscopy, and the importance of proper purification and selective precipitation to obtain ultra-pure Au_{25} NCs. The above spectra show that despite the classically applied and herein advanced DCM/Hex/MeOH purification techniques, Au_{25} NCs prepared by both, the present and previous methods mainly contain the Au_2 complex. The key component was a thorough MS analysis, including a discussion of the mass region below m/z 1200, which was not covered in previous reports. An HPLC method was established, which serves as a starting point for a preparative chromatographic separation leading to ultra-pure Au_{25} NC fractions. The preparative HPLC and selective precipitation methods established here, are believed to be directly applicable to the purification of other Au NCs. Similar byproducts might occur in the synthesis of highly fluorescent $\text{Ag}_x\text{Au}_{25-x}$, single atom-doped Au_{24}Pd , Au_{25} NCs’ big brother Au_{37} , and many other mix-ligand stabilized charged Au NCs. Due to the size focusing mechanism, the formation of these small gold-containing byproducts is unavoidable.²⁸ Their removal, along with that of organic residues, is key to obtaining high purity required for using Au NCs in applications.

Conflicts of interest

There are no conflicts to declare.
