A biomimetic magnetosome: formation of iron oxide within carboxylic acid terminated polymersomes†

Jennifer Bain,‡ Christopher J. Legge,‡ Deborah L. Beattie,‡ Annie Sahota,‡ Catherine Dirks,‡ Joseph R. Lovett and Sarah S. Staniland*

Bioinspired macromolecules can aid nucleation and crystallisation of minerals by mirroring processes observed in nature. Specifically, the iron oxide magnetite (Fe₃O₄) is produced in a dedicated liposome (called a magnetosome) within magnetic bacteria. This process is controlled by a suite of proteins embedded within the liposome membrane. In this study we look to synthetically mimic both the liposome and nucleation proteins embedded within it using preferential orientation polymer design. Amphiphilic block co-polymers self-assemble into vesicles (polymersomes) and have been used to successfully mimic liposomes. Carboxylic acid residue-rich motifs are common place in biomineralisation nucleating proteins and several magnetosome membrane specific (Mms) proteins (namely Mms6) have a specific carboxylic acid motifs that are found to bind both ferrous and ferric iron ions and nucleate the formation of magnetite. Here we use a combination of 2 diblock co-polymers: Both have the hydrophobic 2-hydroxypropyl methacrylate (PHPMA) block with either a poly(ethylene glycol) (PEG) block or a carboxylic acid terminated poly(2-methacryloyloxyethyl phosphorylcholine) (PMPC) block. These copolymers (PEG₁₁₃-PHPMA₄₀₀ and (PMPC₂₈-PHPMA₄₀₀) respectively) self-assemble in situ to form polymersomes, with PEG₁₁₃-PHPMA₄₀₀ displaying favourably on the outer surface and PMPC₂₈-PHPMA₄₀₀ on the inner lumen, exposing numerous acidic iron binding carboxylates on the inner membrane. This is a polymersome mimic of a magnetosome (PMM₂₈) containing interior nucleation sites. The resulting PMM₂₈ were found to be 246 ± 137 nm in size. When the PMM₂₈ were subjected to electroporation (5 pulses at 750 V) in an iron solution, iron ions were transported into the PMM₂₈ polymersome core where magnetic iron-oxide was crystallised to fill the core; mimicking a magnetosome. Furthermore it has been shown that PMM₂₈ magnetopolymersomes (PMM₂₈Fe) exhibit a 6 °C temperature increase during in vitro magnetic hyperthermia yielding an intrinsic loss power (ILP) of 3.7 nHm² kg⁻¹. Such values are comparable to commercially available nanoparticles, but, offer the added potential for further tuning and functionalisation with respect to drug delivery.

Introduction

Biological iron oxide precipitation

The presence of iron oxide particles has been found in various species of birds and dolphins.¹,² While the true function and mechanism of action of these particles has never been properly explained, it is widely believed that in most cases they play an essential role in navigation by acting as “internal compasses”. The formation of such particles is the result of biomineralization. Biomineralization involves precipitation of an inorganic material within or around living organisms.³ These minerals typically fulfil a specific function, such as forming a protective shell or a structural skeleton.² Biomaterials often possess highly controlled size, shape and crystal structure compared to the equivalent synthetic materials.⁴ This level of structural control can be difficult to achieve in the laboratory because most biomineralization processes are governed by a complex suite of proteins, usually embedded within templating membranes.⁴

Precipitation of magnetite in magnetotactic bacteria

Magnetotactic bacteria are the smallest organisms that are known to perform biomineralization. Most strains precipitate pure magnetite nanoparticles (MNPs) within internally formed vesicular organelles, known as “magnetosomes”. Precise mag-
netite crystallisation within the magnetosome is controlled by various proteins that are responsible for specific stages of the overall process, from recruitment of soluble iron species into the magnetosome lumen through transmembrane iron-transporter proteins\textsuperscript{5,6} to its nucleation and subsequent controlled crystal growth. The resulting magnetite nanoparticles are well known for their precise mono-dispersed size and morphology.

**Nucleation biomineralisation proteins for iron oxide precipitation**

Some common mechanistic feature are exhibited across a range of biomineralisation processes. One such example is the concentration of metals ion and nucleation of the mineral on a nucleation protein. The common features of these proteins are the large proportion of carboxylic acid residues\textsuperscript{7} available to bind and accumulate metal cations (such as iron or calcium). For example, approximately a third of all the amino acid residues in the bone mineralising protein osteopontin are the two carboxylic acids aspartic (D) or glutamic (E) acid.\textsuperscript{8} The integral nature these amino acids have on biomineralisation has further been elegantly demonstrated with chiral glutamic and aspartic acids producing chiral vaterite (CaCO\textsubscript{3}) minerals.\textsuperscript{9} Magnetosomes also contain acidic nucleation proteins. Mms6 is a small acidic magnetosome membrane specific (Mms) protein 6 kDa in size located on the magnetosome interior. It was found strongly bound to the magnetite crystal when the magnetosome membrane was removed,\textsuperscript{10} and the purified protein has been shown to control magnetite particle formation in vitro.\textsuperscript{10,11} The C-terminus of the protein (predicted to be on the interior and thus exposed to the forming magnetite) has a large number of acidic residues believed to play a key role as a nucleation site for the biomineralisation of magnetite.\textsuperscript{12-15} A DEEVE motif, has been shown to change conformation on binding ferrous ion\textsuperscript{12,16} while ferric ion have been shown to bind readily and less specifically to multiple acidic residues on the C-terminus.\textsuperscript{12,14,15} Like many other nucleation proteins, Mms6 protein is known to aggregate to display a surface of carboxylate groups on the inner lumen of the magnetosome membrane that promotes magnetite nucleation.\textsuperscript{12} A similar acidic region is a common feature of several Mms proteins in the magnetosome including Mms7 and MmsF, strongly suggesting that magnetite biomineralization is aided by carboxylic acid-functionalization on the inner lumen on the vesicle.\textsuperscript{11,17,18}

**Bioinspired iron oxide precipitation in polymersomes**

**Applications of magnetopolymersomes.** The incorporation of MNPs into vesicles can introduce multi-functionality into established vesicular drug delivery systems undergoing clinical trials worldwide.\textsuperscript{19-21} Functionalisation of these vesicles with MNPs can allow steering with a magnetic field enabling drug targeting. Further, simultaneous imaging during drug delivery through magnetic resonance imaging (MRI) can be achieved, allowing for in situ monitoring of therapeutic delivery. Furthermore, and perhaps most extensively researched, MNPs can provide alternative or additional hyperthermic heating therapies. Application of an alternating magnetic field can cause localised heating of tissue known as magnetic hyperthermia, destroying diseased tissue or sensitising the local area to further therapeutics. The ability of MNP materials to heat can be quantified by the specific absorption rates (SAR), which is the heating power. The measure of heating power normalised to the magnetic field and frequency is the intrinsic loss power (ILP) parameter. ILP values between 1.6 & 5 nHm$^{-2}$ kg$^{-1}$ have been extensively reported for various synthetic magnetopolymersomes and are shown to be functional for hyperthermic therapies.\textsuperscript{22}

However, magnetosomes have a much larger magnetic heat loss than comparably sized synthetic magnetite nanoparticles at lower fields\textsuperscript{23} with SAR from 600 W g$^{-1}$ to 960 W g$^{-1}$ reported (depending on the magnetic field strength and frequency) and with a the very high ILP of 23.4 nHm$^{-2}$ kg$^{-1}$.\textsuperscript{24,25} Control of MNP precipitation within a vesicle has a direct effect on the heating achieved during in vivo hyperthermic application\textsuperscript{26} and bioinspired routes to precipitation offer the potential to tightly control precipitation leading to increased levels of monodispersity which could vastly improve current nanomedical materials.\textsuperscript{27,28}

**Creating a polymersome nanoreactor.** A synthetic vesicle can provide a perfect analogue to the biologically formed magnetosome. There are many examples of polymer vesicles (or polymersomes) being used to mimic liposomes. Ideally, we would mimic a magnetosome using a polymersome with a basic core as a nanoreactor for magnetite precipitation by importing iron ions across the membrane into the alkaline core. However, our previous attempts to use a diblock polymersome to mimic a magnetosome have resulted in MNPs precipitated within the polymer membrane\textsuperscript{29} and a triblock polymersome yielded MNPs again mainly within the membrane with some precipitation within the core.\textsuperscript{30}

**Iron transport via electroporation.** We and others have previously shown that the application of an electric field can cause a polymersome membrane to porate (form pores) and enable synthetic intravesicular diffusion, a process known as electroporation.\textsuperscript{23,31-33} Electroporation is a technique widely used in biology for the transformation of DNA into cells by electrically permeabilising a cell membrane through application of a pre-determined voltage.\textsuperscript{31,32,34,35} The mechanism by which the membrane is permeated has been widely explored, but as yet has not been fully understood.\textsuperscript{33,36} Electroporation is the method we exploit to import soluble iron ions into the polymersomes in our previous studies resulting in iron oxide precipitation mainly within the membrane.\textsuperscript{29,30} We conclude that without specific internal nucleation sites, iron oxide will precipitate indiscriminately in an uncontrolled fashion.

**Mimicking membrane/protein surface of the magnetosome.** The inner lumen of the magnetosome membrane contains a range of biomineralisation proteins. Importantly, carboxylic acid rich nucleation proteins such as Mms6, which display a negatively charged surface for iron ion binding to nucleate magnetite formation. In this work we have advanced our pre-
vicious polymersomes by designing and creating a new di-block co-polymersome that will better mimic the magnetosome. Specifically, we have designed one copolymer to include a short hydrophilic block that displays carboxylic groups, while the other will instead include a longer neutral block. Due to the curvature of the polymersome we predict that steric factors will orientate the shorter acidic copolymer on the interior, dis- tinguishing proteins on the inner membrane (Fig. 1).

PEG-PHPMA/PMPC-PHPMA polymersomes

Poly(2-(methacryloyloxy)ethyl phosphorylcholine)-poly(2-hydroxypropyl methacrylate) (PMPC-PHPMA) is a vesicle-forming diblock copolymer that has a terminal carboxylic acid group situated on the hydrophilic PMPC block. In principle, addition of such groups should mimic the iron binding sites found in the Mms6 protein (mimicked by the COOH end group) within the magnetosomes liposome (lipid mimicked by the phosphorylcholine). It should be noted that carboxybetaine zwitterionic groups similar to phosphorylcholine have been shown to not interact with calcite mineralisation, to the extent they are not incorporated into calcite mineral whereas COOH groups alone do, so interaction with the negative charge on zwitterionic phosphorylcholine is improbable. Moreover, preferential location of these carboxylic acid liposome-mimicking groups on the polymersome inner leaflet should create a synthetic mimic of a nucleation protein within the magnetosome membrane (Fig. 1). In practice, this is achieved using a binary mixture of the PMPC-PHPMA chains with a second diblock copolymer, poly(ethylene glycol)-poly(2-hydroxypropyl methacrylate) (PEG-PHPMA). The two weakly hydrophobic PHPMA blocks have the same mean degree of polymerisation and co-assemble to form the vesicle membrane. However, the PMPC and PEG chains are thermodynamically incompatible. Hence microphase separation occurs across the vesicle membrane, with the shorter PMPC block being preferentially expressed at the inner leaflet, while the longer PEG block is located mainly at the outer leaflet. It is well known that amphiphilic diblock copolymers undergo spontaneous self-assembly in water. Traditionally diblock copolymers are prepared in a solvent with ideal solubility for both blocks before being transferred into water. Such copolymers can assemble into spheres, worms or vesicles depending on the relative volume fractions of each block. More recently several groups have utilised polymerisation-induced self-assembly (PISA) to prepare nano-objects in situ. More specifically, a soluble homopolymer is chain-extended with a monomer which when polymerised forms the insoluble core-forming block. For example, a poly(ethylene glycol) macromolecular chain transfer agent (PEG macro-CTA) has been prepared via end-group derivatization and sub-sequently chain-extended with HPMA via reversible addition-fragmentation chain transfer (RAFT) aqueous dispersion polymerization. By varying the degree of polymerization (DP) of the core-forming PHPMA block and also the copolymer concentration, pure spheres, worms or polymersomes could be prepared in concentrated aqueous solution. Similarly, chain-extending a PMPC macro-CTA with HPMA enabled the synthesis of a similar series of PMPC-PHPMA nano-objects. In both cases, PISA syntheses had to be conducted at relatively high copolymer concentration (20–25% w/w) in order to produce a pure polymersome phase. According to Gonzato and co-workers, using a binary mixture comprising a short macro-CTA and a long macro-CTA should produce low-poly-dispersion polymersomes, whereby the short macro-CTA chains are mainly located within the inner lumen, while the long macro-CTA chains are preferentially expressed at the outer surface of the polymersomes. In the present work, we have explored the use of a relatively long PEG macro-CTA in conjunction with a relatively short PMPC macro-CTA to polymerize HPMA via RAFT aqueous dispersion polymerization (Fig. 2). Microphase separation of these two steric stabilizer blocks across the membrane was anticipated, not least because Blanazs and co-workers have shown that PEG and PMPC homopolymers are enthalpically incompatible. Moreover, judicious selection of a carboxylic acid-functionalized RAFT agent for the synthesis of the PMPC macro-CTA enables the construction of polymersomes in which the acid end-groups on this stabilizer block are mainly located within the lumen. Thus such polymersomes mimic the structure of naturally occurring bacterial magnetosomes containing the Mms6 protein. Following the work of Chambon et al., such poly-
Polymersomes can be covalently stabilized by addition of a bifunctional cross-linker at high HPMA conversions (>99%). PEG-PHPMA/PMPC-PHPMA vesicles assemble as part of the polymer synthesis process. Therefore, it is not possible to encapsulate base during rehydration. Instead, we report the novel methodology of soaking pre-formed polymersomes in NaOH. Using this di-block system we have designed and are able to produce synthetic polymersomes that mimic magnetosomes (PMM28).

Materials and methods

Materials

All solutions used were degassed and sparged with N₂ prior to use and all experiments were carried out under an inert atmosphere to minimise iron oxidation. 2-(Methacryloyloxy)ethyl phosphorylcholine (MPC; >99%) was donated by Biocompatibles Ltd (Farnham, UK). 2-Hydroxypropyl methacrylate (HPMA) was purchased from Alfa Aesar, 2,2′-azobis[2-(2-imidazolin-2-yl)propane] dihydro-chloride (VA-044) was purchased from Wako Pure Chemical Industries (Japan), ethylene glycol dimethacrylate (EGDMA) was purchased from Sigma Aldrich. All other chemicals were purchased from Sigma Aldrich, unless otherwise stated. All other chemicals were purchased from Sigma Aldrich, unless otherwise stated.

Polymersome synthesis

PMM28 was prepared and reported elsewhere.⁴⁷ A typical protocol for the synthesis of PMM28 polymersomes (self-assemblies of 70% PEG113-PHPMA400 and 30% PMPC28-PHPMA400) is as follows: PEG113 macro-CTA (0.0735 g, 1.4 × 10⁻⁵ mol), PMPC28 macro-CTA (0.0516 g, 6.0 × 10⁻⁶ mol); VA-044 initiator (0.00187 g, 6.7 × 10⁻⁷ mol), [combined CTA]/[VA-044] molar ratio = 5.0 and HPMA monomer (1.12 g, 8.0 × 10⁻³ mol, target DP = 400) were dissolved in degassed water to generate a 20% w/w solution. The pH of the solution was adjusted to pH 6.8 using 0.1 M NaOH. This solution was then purged with nitrogen for 30 minutes. The flask was sealed using a rubber septum and immersed in an oil bath at 50 °C. When the polymerisation had proceeded for 4 hours, the reaction was quenched by exposure to air and cooling to 20 °C. Cross-linked polymersomes, were synthesised as described above, but, after 4 hours degassed EGDMA (0.158 g, 8 × 10⁻⁴ mol) was added under N₂, and left to stir for 12 hours at 50 °C.

¹H NMR

¹H NMR was used to calculate conversion in the synthesis of 70% PEG113-PHPMA400, 30% PMPC28-PHPMA400 to form PMM28. Spectra were acquired using a Bruker Avance III HD 400 spectrometer. Samples were prepared by dissolving 100 µL polymersomes solution in CD₃OD (3 mL).

Electroporation of polymersomes

PMM28 polymersomes were incubated in 10 mM NaOH, then cleaned up using a size exclusion chromatography (SEC) column. A 1 : 2 Fe(m)/Fe(m) stock iron solution was prepared by mixing 1 ml of 10 mM FeCl₃·6H₂O solution (0.019 g, 1.00 × 10⁻⁵ mol, 10 mL, dissolved in degassed water) with 2 ml of 10 mM FeCl₂·6H₂O solution (0.027 g, 1.00 × 10⁻⁴ mol, 10 mL, dissolved in degassed water). The PMM28 polymersomes with new basic cores were electroporated using a BioRad Micropulser™. 100 µL of basic PMM28 were incubated with 100 µL of mixed valence iron solution (in a 1 : 1 v/v ratio), before being electroporated at a maximum volume of 800 µL. 5 pulses were applied at a voltage of 750 V, to facilitate transport of the iron ion solution as previously published.³⁰ SEC Cleaned electroporated PMM28 were visualised unstained using TEM (Fig. 4).

Dynamic light scattering (DLS)

5 µl of the vesicle samples were diluted in 1 ml of MilliQ water before analysis in a disposable DLS cuvette using a scattering angle of 173° on a Zetasizer Nano (Malvern Instruments). Samples were scanned three times at a standard temperature of 25 °C, with each scan having 10–14 runs; data were analysed using Malvern Zetasizer software.

Transmission electron microscopy (TEM)

Transmission electron microscopy (TEM) was used to visually assess the polymersomes size, shape and integrity pre and post electroporation. The size and location of the iron oxide precipitation associated with the vesicle was assessed post-electroporation and selected area electron diffraction was used to assess crystallinity of the iron oxide. 5 µl of the polymersome sample (diluted 1 : 1000% v/v) was applied to a carbon film grid and left to stand for approximately 1 minute, before blotting off excess liquid. Grids were then dried at ambient temperature. All post-electroporation samples were imaged unstained. Control samples assumed not to contain dense iron minerals were subsequently stained (0.75% uranyl formate) prior to imaging, before blotting off after a 12 seconds staining period. Samples were imaged using a Tecnai F20 and images processed using ImageJ.
Inductively coupled plasma emission spectrometry (ICP-ES)

Inductively coupled plasma emission spectrometry, (Spectro-Ciros-Vision Inductively Coupled Plasma Optical Emission Spectrometer) was used to determine iron concentrations in the PMM$_{28}$Fe samples. ICP-ES samples were prepared for detection of iron concentration, by dissolving a known volume of magnetopolymersomes sample (100 µl) in aqua regia to a total volume of 5 ml (4 parts water to 1 part acid). The iron content was detected and measured against calibration standard of known concentrations.

Magnetic hyperthermia measurements

PMM$_{28}$ magnetopolymersomes were analysed for their use as agents in magnetic hyperthermia, using a Nanotherics MagneTherm®. Measurements were taken using a 17 turn coil with a frequency of 636 kHz, an applied voltage of 19.0 V creating a current of 5.2 A across the coil. The field within the coil was calculated to be 7.2 kA m$^{-1}$. A grant recirculating water bath, maintained a constant base temperature of 10 °C around the coil. A 200 µl 1.0% w/v aqueous dispersion of PMM$_{28}$Fe polymersomes was made up to 1 ml with ultrapure water (0.11 mg ml$^{-1}$ of iron) and the temperature measured in the alternating field over a period of 10 minutes, using a single channel fibre optic thermometer (Lambda Photometrics Ltd). Control measurements of the blank polymersomes of the same concentration in PBS solution were taken and subtracted from the PMM$_{28}$Fe data. The data was used to extract the SARs and ILP values, analysed using software from Resonant Circuits Limited, with consideration of all parameters that can skew the data.$^{51}$ The SAR and the ILP are defined by equations 1 & 2 below, where $\Delta T/\Delta t$ is the initial gradient of the change in temperature over time, $c$ is the heat capacity of water, $M_{Fe}$ is the mass of iron per ml, $H$ is the magnetic field and $f$ is the frequency of the alternating field.

$$\text{SAR} = \frac{\Delta T}{\Delta t} \frac{c}{M_{Fe}}$$

$$\text{ILP} = \text{SAR} \frac{H}{f}$$

Results and discussion

Polymersome synthesis

PMM$_{28}$ were prepared by PISA via RAFT aqueous dispersion polymerisation of HPMA at pH 6.5 with a 70% : 30% ratio of PEG$_{113}$-PHPMMA$_{500}$ to PMPC$_{28}$-PHPMMA$_{400}$. $^1$H NMR studies indicated high monomer conversions (>99%) after 4 hours at 50 °C, indicated by the loss of the vinyl group peaks at 5.5 ppm (ESI 1†). To obtain a high pH (basic) PMM$_{28}$ core, PMM$_{28}$ were soaked in NaOH to diffuse into the core. TEM confirms that this process did not affect the appearance of the vesicles. TEM imaging shows a mixture of spherical and elongated PMM$_{28}$ vesicles with a relatively disperse size population (Fig. 3a) with the sizes being maintained in hydrated conditions when imaged using cryo-TEM (Fig. 3b). This is reflected in grainsize analysis of the polymersomes, giving a high polydispersity of 224 ± 209 nm (Fig. 3c). The grainsizing analysis from the TEM images also correlates well with the DLS analysis, showing a stable size across the pH range from 2–10, maintaining an average vesicle diameter of 246 nm (ESI 2†). Zeta potential decreases as the pH is increased from 2–9 with the hydrophilic surface of polymersomes becoming negatively charged at pH’s above 3.5 (ESI 2†), indicating that the vesicles will maintain a negatively charged surface through deprotonation of the carboxylic acid through each stage of the iron oxide precipitation experiment.

PMM$_{28}$ iron oxide precipitation through electroporation to form PMM$_{28}$Fe

PMM$_{28}$ with a basic core (through NaOH soaking) were added to a mixed valence iron salt solution (1 : 2, Fe(II):Fe(III)) but no precipitation was observed. After several days only a small amount of precipitation of electron dense iron oxide on the outer membrane of polymersomes was observed but no or negligible internal iron oxide precipitation (ESI 3†), suggesting the membrane is impermeable to iron ions and only limited quantities of OH$^-$ seep out after several days. Thus an iron ion transport mechanism is required such as electroporation.

Therefore, basic PMM$_{28}$ were subjected to our previously published method of electroporation to import iron ions into the NaOH PMM$_{28}$ core to induce iron oxide precipitation.$^{29,30}$ Here, we improve on our previous method, as PMM$_{28}$ offers carboxylic acid iron nucleation sites inside the core which should promote more iron oxide inside the polymersome rather than in the membrane.

Electroporation of PMM$_{28}$ basic polymersomes in an iron solution was successful, with the polymersomes showing distinct electron dense cores (attributed to precipitation of iron oxide) consistent across all the PMM$_{28}$Fe sample (Fig. 4) which
tron dense cores, attributed to the precipitation of magnetic iron oxide.

A permanent magnet) and selected area electron diffraction image confirmed to 5.54 ± 0.55 nm (ESI 4†). The size of these isolated particles was determined across the whole population and are also smaller with a narrower size distribution (212 ± 79 nm). The filled cores are made up of aggregates of smaller MNPs of iron oxide, with some discreet particles visible nearer the membrane as the density of iron oxide reduces radially from the centre (Fig. 5a). The size of these isolated particles was determined to 5.54 ± 0.55 nm (ESI 4†). Furthermore, the iron oxide loaded polymersomes were found to be magnetic (attracted to a permanent magnet) and selected area electron diffraction confirms that the precipitation visible in the polymersome core was crystalline, indicating the iron oxide core is crystalline magnetite or maghemite (Fig. 5b). ICP elemental analysis gave an approximate 5-fold minimal increase in quantity of elemental iron compared with both the tri-block and di-block. 29,30 This strongly indicates that the COOH groups promote more internal nucleation of larger MNPs.

**Effect of crosslinking PMM28**

There is not seen in the PMM28 prior to electroporation (compare Fig. 4 with ESI 3†).

The electroporated PMM28Fe are visibly more spherical uniformly across the whole population and are also smaller with a narrower size distribution (212 ± 79 nm). The filled cores appear to be made up of aggregates of smaller MNPs of iron oxide, with some discreet particles visible nearer the membrane as the density of iron oxide reduces radially from the centre (Fig. 5a). The size of these isolated particles was determined to 5.54 ± 0.55 nm (ESI 4†). Furthermore, the iron oxide loaded polymersomes were found to be magnetic (attracted to a permanent magnet) and selected area electron diffraction confirms that the precipitation visible in the polymersome core was crystalline, indicating the iron oxide core is crystalline magnetite or maghemite (Fig. 5b). ICP elemental analysis gave an approximate 5-fold minimal increase in quantity of elemental iron compared with both the tri-block and di-block. 29,30 This strongly indicates that the COOH groups promote more internal nucleation of larger MNPs.

**Comparison to other magnetopolymersomes**

This is the first example of the precipitation of magnetic iron-oxide densely concentrated into the core of a polymersome (Fig. 5a). Our previous work utilising electroporation to produce magnetopolymersomes was conducted on poly(butadiene)-poly(ethylene oxide) (PBD-PEO) diblock co-polymersomes. PBD-PEO polymersome possess no functional nucleation sites and as a result the MNPs simply form in the membrane where the two reagents (iron ions and NaOH) meet in the pores opened by the electroporation process (Fig. 5c). 22 Similarly we have demonstrated electroporation can be used to produce magnetopolymersomes from Tri-block co-polymers by precipitate MNPs within an ABA Tri-block co-polymersome composed of PMOXA-PDMS-PMOXA (where PMOXA = poly(2-methyloxazoline) & PDMS = poly(dimethylsiloxane)) (Fig. 5d). 30 Again, there are no functional nucleation sites on this polymer and while we believe there may be more internal MNPs in this example (possibly due to the different structural configuration of pore formation for a tri-block under electroporation conditions), the size of particles formed in both these two previously reported examples is ~2.6 nm. This contrasts with this current study which shows a two-fold increase in the particle size (5.5 nm) and the overall quantity and quality of precipitation within the PMM28Fe core. ICP elemental analysis shows an approximate 5-fold minimal increase in quantity of elemental iron compared with both the tri-block and di-block. 29,30 This strongly indicates that the COOH groups promote more internal nucleation of larger MNPs.

**Fig. 4** Unstained TEM images of (a) PMM28Fe. The PMM28 sample was soaked in NaOH (10 mM) before electroporation at 750 V (5 pulses) in the presence of excess FeCl2·4H2O. The polymersomes show dark electron dense cores, attributed to the precipitation of magnetic iron oxide.

**Fig. 5** (a) Unstained TEM image of electroporated PMM28Fe polymersomes showing precipitation on the outer leaflet of the polymersome as well as in the vesicle core. (b) A selected area electron diffraction image of the same electroporated polymersome confirming the presence of a crystalline substance within the polymersome. (c) Cryo-EM micrograph of PEO-PBD polymersomes from the first reported use of the electroporation method 29 and (d) show comparison of use of the electroporation method on PMOXA-DMS-MOXA tri-block polymersomes. 30
duced with and without the EGDMA crosslinker. If anything there is less MNP precipitated in the core of the EGDMA cross-linked PMM$_{28}$. We can thus conclude flipping of the PMPC$_{28}$-PHPMA$_{100}$ block onto the outer surface post formation is not the dominant reason for surface iron oxide precipitation. Thus it is clear that either some of the carboxylic acid groups mis-orientation to the exterior during polymersome formation, or the precipitation on the surface is simply due to some NaOH leaking out during electroporation and is bound at the external membrane pore site.

Hyperthermic heating effect of PMM$_{28}$Fe magnetopolymersomes

The biomedical hyperthermia treatment potential of PMM$_{28}$Fe magnetopolymersomes was investigated. PMM$_{28}$Fe were exposed to an alternating magnetic field to determine their potential for magnetic hyperthermia by assessing their heating power (over a 10 minutes period). A control of the blank PMM$_{28}$ polymersome in PBS (ESI 6†) was subtracted from the final heating power of the magnetopolymersomes (Fig. 6). A temperature increase of 6 °C was observed over a 10 minutes period. A SAR value of 122 W g$^{-1}$ and an ILP of 3.7 nHm$^2$ kg$^{-1}$ was thus calculated. In principle, such localized heating can sensitize surrounding tissue towards a therapeutic payload that could be delivered within the same polymersomes.

Conclusions

In this work we have successfully designed and synthesized an asymmetric polymersome with a selectively orientated smaller acidic block copolymer (PMPC$_{28}$-PHPMA$_{400}$) in the interior and a larger PEG$_{113}$-PHPMA$_{400}$ block copolymer forming the exterior of the vesicle to create a polymersome mimic of a magnetosome (PMM$_{28}$). Similar to our previous work producing magnetopolymersomes, we used electroporation to allow iron ion transport across the membrane and into the core of the vesicle to precipitate iron oxide. Unlike our pre-vious work, here we have been successful in precipitating dense, magnetic, crystalline iron oxide within the core of the vesicle (closer to resembling a magnetosome) due to iron ion binding and iron-oxide nucleation capacity of the COO$^-$ functional groups exposed on the inner leaflet in the core.

The iron oxide core of PMM$_{28}$Fe is not a single crystal but an aggregation of 5.5 nm sized MNPs of high density in the centre, with discreet MNP being visible near the membrane. The addition of the acidic nucleation sites have not only targeted the MNP precipitation into the core of PMM$_{28}$ but has also lead to larger MNP within the magnetopolymersome. A small amount of exterior surface iron oxide precipitation is seen which was not reduced by cross-linking the PMM$_{28}$ during formation.

Finally, PMM$_{28}$Fe magnetopolymersomes were found to have advantageous properties with respect to potential future magnetic hyperthermia treatments, achieving a 6 °C heat increase in 10 minutes. In principle, such magnetite-loaded polymersomes can sensitize tissue for the in vivo delivery of a therapeutic payload or serve as a contrast agent for MRI diagnostic applications. Furthermore, the use of polymersomes enable greater ability to design in multiple responsive functionalities for novel bioinspired smart nanomedical materials.
