**π-Expanded diketopyrrolopyrroles as acceptor building blocks for the formation of novel donor–acceptor copolymers**†

Florian Trilling, Oskar Sachnik and Ullrich Scherf* †

The incorporation of rigid and planar, π-extended diketopyrrolopyrrole (EDPP) units into alternating donor–acceptor copolymers results in a variety of low band gap copolymers with thiophene-based EDPP (EDPPT) as acceptor blocks in combination with donor units as thiophene-2,5-diyi or cyclopentadiithio-
phene-2,7-diyl (CPDT). These copolymers are characterized by a broad absorption range in the UV/Vis/ NIR region and emission features extending into the Near Infrared (NIR) region. Furthermore, the EDPPT-based copolymers show small optical HOMO/LUMO gaps ranging from 1.65 to 1.81 eV. Replacing the terminal thiophene units of the EDPPT building blocks by fluorene moieties (EDPPF) results in the corres-
ponding EDPPF building blocks for the formation of a second set of EDPPF-based copolymers. These copolymers display distinctly increased HOMO/LUMO energy gaps and well-resolved, mirror-symmetrical absorption and emission features with steep absorption edges and small Stokes shifts when compared to 
EDPPT copolymers, thus reflecting electronically only weakly interacting EDPPF structural units.

**Introduction**

Diketopyrrolopyrrole (DPP) derivatives are very stable, electron-poor chromophores that have been extensively used, in com-
bination with electron-rich comonomers, for the construction of various so-called donor–acceptor-type (DA-type) alternating 
copolymers, for applications e.g. in organic field-effect transis-
tors (OFETs) or organic photovoltaic devices (OPV devices). After the application of the first DPP-based donor–acceptor-type copolymer (pBBTDPP2) in OPV devices, with a power con-
version efficiency (PCE) of 4.0%, by Janssen and coworkers, DPP became one of the most frequently used acceptor building 
blocks in the field of organic optoelectronics. Until now, a broad range of DPP-based copolymers have been introduced showing 
PCEs up to 9.4%. Most of them only vary in their donor structural unit, which is combined with thiophene-sub-
stituted DPP moieties, which are N-alkylated with branched alkyl chains for increased solubility. For developing novel 
DPP-based donor–acceptor copolymers also new designs of the 
DPP-based acceptor building blocks are highly desired. Ladder-type, π-extended DPP (EDPP) derivatives prepared by 
bridging the two DPP amide nitrogens with neighboring aryl/ heteroaryl substituents via vinylene bridges have been intro-
duced by Gryko and co-workers and show distinctly bathochro-
mically shifted absorption features. Furthermore, the EDPP building block was previously used for the formation of DAD-type small molecules, showing strong red emission, high two-photon absorption cross-sections and promising applica-
tion potential in cell imaging assays. Thus, EDPP seems to be a highly promising candidate as a novel acceptor block for the generation of DA-type copolymers. The primary goal of this study is to incorporate such π-extended DPP units, namely 
EDPPTs with two terminal thiophene rings or EDPPFs with 
terminal fluorene units, into the corresponding alternating, donor–acceptor copolymers by copolycondensation with suit-
able, preferably electron-rich comonomers.

**Results and discussion**

**Monomer synthesis**

Scheme 1 shows the synthetic pathway towards the thiophene-
based, π-expanded diketopyrrolopyrrole-derivatives 7a and 7b (EDPPT). In contrast to the non-alkylated EDPPTs previously 
reported by Gryko and coworkers, it is mandatory to start from 
alkylated thiophenes (1a and 1b) to ensure an adequate solubility of the corresponding copolymers. First, 1a and 1b were 
liethiated in the 5-position using the sterically hindered 
base lithium diisopropylamide (LDA) followed by formylation 
with dimethylformamidine (DMF), under generation of 
4-alkylthiophene-2-carbaldehydes 2a and 2b in good yields.
The aldehydes were oxidized in the presence of conc. aqueous ammonia and iodine to obtain the nitriles 3a and 3b. The formation of the nitriles can be monitored by 13C-NMR spectroscopy where the aldehyde resonance at 183 ppm is replaced by the nitrile carbon signal at 115 ppm. DPPs 4a and 4b were generated by condensation with diisopropyl succinate (DIPS) under standard conditions. The red-colored solids show very poor solubility in common organic solvents, caused by intermolecular hydrogen interactions of the strong polar DPP cores. However, the addition of trifluoroacetic acid (TFA) inhibits the hydrogen bond interactions and, thus, increases the solubility. Therefore, the bromination of DPP-derivatives 4a and 4b with N-bromosuccinimide (NBS) was carried out in a 1:2 mixture of TFA and chloroform, obtaining 5a and 5b as purple-colored solids. To obtain the final EDPPT building blocks, 5a and 5b were first N-alkylated with bromoacetaldehyde diethyl acetal under alkaline conditions in the presence of tetrabutylammonium bisulfate (TBAHS). The N-alkylated DPP-derivatives 6a and 6b show an improved solubility and a strong yellow fluorescence in solution. Finally, 6a and 6b were cyclized under “super-acidic” conditions, using an excess of trifluoromethanesulfonic acid (TfOH). The solution color immediately turned from deep purple to green after injection of the acid. Monomers 7a and 7b were obtained as blue solids, after work-up and precipitation into methanol, in good overall yields of 24 and 23%, respectively. In addition to the changes in color, the successful implementation of the vinylenic bridge between the aromatic substituent and the amide nitrogen results in the generation of two aromatic doublet resonances at 7.86 and 6.73 ppm in the respective 1H-NMR spectra.

Synthesis of the EDPPT-based copolymers

Previous studies showed that EDPPT derivatives still have a strong electron withdrawing (accepting) character, allowing for the formation of novel DA-type copolymers when polymerized with corresponding π-donor comonomers. For this purpose, 7a and 7b were copolymerized with a variety of frequently used thiophene-based donor monomers (see Fig. 1). The donor blocks differ considerably in their donor strength and in the number of solubilizing groups, and were generated
The copolymers were purified by Soxhlet extraction with methanol, acetone, ethyl acetate, hexane and chloroform. The highest molecular weight fractions were used for further investigations.

The thiophene- (T), bithiophene- (2T) and thienc[3,2-b]thiophene-based (TT) copolymers PEDDPTHD-TT, PEDDPTHD-2T and PEDDPTHD-T were generated from 7a (with bulky 2-hexyl-decyl sidechains) in good to moderate yields of 50, 58 and 31%, respectively. In particular, PEDDPTHD-2T and PEDDPTHD-TT show very poor solubility in chloroform. In the case of PEDDPTHD-TT, the polymer already precipitated during the reaction, thus lowering the yield and molecular weight significantly. PEDDPTHD-T shows the highest number-average molecular weight ($M_n$) of 23.1 kDa, while PEDDPTHD-2T and PEDDPTHD-TT show lower $M_n$ values of 14.6 and 10.4 kDa, respectively. In comparison with conventional DPP-polymers, which can reach molecular weights >50 kDa, the strong $\pi$-$\pi$-stacking tendency of the EDPPT-based polymers may increase the aggregation potential and inhibit the formation of longer polymer chains, even when decorated with bulky 2-hexyldecyl sidechains. To exclude that aggregation effects affect the obtained molecular weight distributions, the $M_n$ of PEDDPTHD-T was crosschecked by the usage of high temperature GPC at 160 °C with trichlorobenzene as the solvent resulting in nearly similar values of $M_n = 22.2$ kDa. Also a change of the polymerization conditions to Pd$_2$(dba)$_3$/PPh$_3$ as a catalyst and toluene/DMF as a solvent did not result in increased molecular weights. Therefore, we further tried to increase the molecular weights of the EDPPT-based copolymers by using other donor building blocks that contain additional solubilizing groups (see Fig. 1, bottom).

Surprisingly, the copolymerization of 7a with alkylated donor comonomers did not increase the molecular weights of the corresponding polymers in comparison with the previously introduced copolymers. The benzodithiophene (BDT)-based copolymer PEDDPTHD-BDT was synthesized in 68% yield, showing a molecular weight of $M_n = 23.3$ kDa, which is comparable to PEDDPTHD-T. The copolymerization of 7a with cyclopentadithiophene- (CPDT) and dithienopyrrole- (DTP)-based comonomers only resulted in the formation of oligomers (PEDDPTHD-CPDT: $M_n = 5.6$ kDa and PEDDPTHD-DTP: $M_n = 2.7$ kDa). In comparison, when using the EDPPT-based monomer 7b with linear alkyl chains, 2-3 times higher molecular weights have been achieved (PEDDPTDo-CPDT: $M_n = 12.6$ kDa and PEDDPTDo-DTP: $M_n = 7.6$ kDa). The higher molecular weights of PEDDPTDo-CPDT and PEDDPTDo-DTP may result from the sterically less demanding situation during coupling with comonomers containing linear alkyl sidechains. Concurrently, linear sidechains may support an intermolecular $\pi$-$\pi$-stacking of the EDPPT-units leading to reduced polymer solubility. Detailed data on molecular weights and yields can be found in the ESL†

The changes in the optical properties, going ahead with the planarization of the $\pi$-system when going from DPP to EDPP and during the incorporation of EDPP into a donor–acceptor copolymer, are illustrated in Fig. 2. The absorption maximum of DPP 4a peaks at 531 nm, while a distinct bathochromic shift to 625 nm is observed after cyclization (7a), accompanied by a color change from red to deep blue in the solid state (see Fig. 3) as a result of an extension of the $\pi$-conjugated system. In the photoluminescence (PL) spectra, the emission maximum of 4a ($\lambda_{\text{max}} = 543$ nm) is also shifted to higher wavelengths after cyclization (7a: $\lambda_{\text{max}} = 634$ nm). The corresponding copolymers show further red-shifted and broadened absorption and PL bands and a slightly increased Stokes shift. As shown for PEDDPTHD-T, the formation of the DA-type
The optical properties of the EDPPT-based copolymers are depicted in Fig. 4. For a better overview, only one polymer of each backbone type (HD or Do sidechain, in each case the copolymer with the higher molecular weight) is further discussed. UV/vis and PL solution spectra were recorded in chloroform; solid state UV/vis spectra were obtained from spin-coated polymer films (spin coating from 8 mg ml\(^{-1}\) solutions in chloroform) on quartz glass plates. All copolymers show absorption and fluorescence features that are extended into the NIR region, with absorption maxima (in solution) in a range from 683 nm (PEDDPT\(_{\text{HD-T}}\)-BDT) up to 776 nm (PEDDPT\(_{\text{HD-T}}\)). Moreover, more intense absorption features also appear in the UV range at around 400 nm in comparison with the monomers (7a and 7b). For those copolymers bearing no additional solubilizing alkyl groups at the donor units, strong aggregation behavior in solution is observed, as evident from the appearance of additional low energy absorption bands, not only in the film absorption spectra. Even at low concentrations, the less soluble PEDDPT\(_{\text{HD-T}}\) and PEDDPT\(_{\text{HD-T}}\) copolymers show only minor differences in the shape and position of the absorption spectra between the solid state and solution spectra as indication of the high tendency for π-π-interactions and aggregation of the EDPPT moieties already in solution. Beside the T- and 2T-based copolymers, all other copolymers show the additional bathochromically shifted and broadened absorption features only in the solid state. In particular, the absorption maximum of PEDDPT\(_{\text{HD-T-DTP}}\) is red-shifted from 740 to 771 nm with an absorption onset at >950 nm.

The emission maxima of the EDPPT-based copolymers range from 700 to 800 nm. In addition, all polymers show a broad emission shoulder (vibrational progression) at a higher wavelength. Again, PEDDPT\(_{\text{HD-BDT}}\) shows the highest energy PL maximum (723 nm), while the emission maximum of PEDDPT\(_{\text{HD-CPDT}}\) is red-shifted to 800 nm, most probably

copolymer results in the expansion of absorption into the NIR region, with a broad absorption range from 500 up to 900 nm. The long wavelength absorption band peaks at 776 nm, with an intense shoulder at 724 nm. Furthermore, the absorption in the lower wavelength region (\(\lambda_{\text{max}} = 399\) nm) is strongly increased in comparison with that of 4a and 7a. The emission maximum of PEDDPT\(_{\text{HD-T}}\) is shifted towards the NIR region (\(\lambda_{\text{max}} = 764\) nm, with a shoulder around 840 nm). No fluorescence is visible to the human eye (see Fig. 3). In comparison with a non-bridged DPP copolymer with a similar backbone structure (PDPPP3T),\(^{12}\) the absorption and emission features are blue shifted probably due to the lower molecular weight of PEDDPT\(_{\text{HD-T}}\) (longest wavelength absorption maximum for PEDDPT\(_{\text{HD-T}}\): 780 nm vs. 830 nm for PDPPP3T). The wider bandgap value (1.69 eV for PEDDPT\(_{\text{HD-T}}\) vs. 1.33 eV for PDPPP3T) is reflected in the corresponding HOMO and LUMO energy levels: HOMO: for PEDDPT\(_{\text{HD-T}}\): −5.00 eV vs. −5.30 eV for PDPPP3T; LUMO: for PEDDPT\(_{\text{HD-T}}\): −3.31 eV vs. −3.74 eV for PDPPP3T. The photoluminescence of PEDDPT\(_{\text{HD-T}}\) is weak as known for related DPP-derivatives.

caused by the stronger electron-donating character of the CPDT-unit thus increasing the donor–acceptor character of the copolymer. The Stokes shifts of the EDPP-based copolymers are increased in comparison with those of the monomers 7a and 7b, and range from 21 nm (PEDDPT_{10-2T}) to 70 nm (PEDDPT_{10-CPDT}). Exceptions are observed for PEDDPT_{10-T} and PEDDPT_{10-CPDT}. Due to the strong aggregation in solution, the determined “negative” Stokes shift is virtually caused by the fact that the emitting species are not the aggregates causing the longest wavelength absorption band. All in all, the EDPPP-polymers show attractive optical properties with absorption and emission features shifted into the NIR region if compared to most of the previously published, “conventional” DPP-polymers.18

The electronic energy levels, namely the energetic position of the HOMO/LUMO levels, of the polymers are depicted in Fig. 5. All polymers can be described as low bandgap polymeric semiconductors with optical bandgaps below 2 eV. The smallest HOMO/LUMO gap is observed for PEDDPT_{10-DTP} (1.60 eV). Furthermore, PEDDPT_{10-DTP}, PEDDPT_{10-CPDT} and PEDDPT_{10-BDT} show nearly similar HOMO values of −5.18, −5.19 and −5.21 eV, respectively. For these polymers, the position of the LUMO level seems to be mainly determined by the EDPPT acceptor moiety. Increasing the donor strength of the electron-rich comonomer building blocks from BDT to DTP results in an increased HOMO energy level with a decreased HOMO/LUMO gap. A similar clear trend could not be observed for the T-, 2T- and TT-based copolymers, maybe due to differences in the molecular weights, and thus in the lengths of effectively conjugated segments.

**EDPPP-based copolymers**

In addition to the previously presented DA-type copolymers, two other copolymers were synthesized from a fluorene-based EDPP monomer (EDPPP) (see Fig. 6). Monomer 8 was synthesized according to a literature procedure.15 With a total number of ten annulated rings, monomer 8 is a π-expanded DPP derivative with a fully planar structure and was copolymerized with distannylated BDT and CPDT comonomers in Stille-type couplings, as already described for the EDPPT-based copolymers, to afford PEDPPP-BDT and PEDPPP-CPDT in moderate yields of 56 and 44% with comparably high \( M_\text{n} \) values of 23.4 and 16.2 kDa, respectively. Surprisingly, the EDPPP-based copolymers show significant differences in their optical properties when compared to their EDPPT-based counterparts (see Fig. 7). The absorption maximum of PEDPPP-BDT (645 nm) is only slightly red-shifted (by 15 nm) if compared to that of monomer 8, still showing distinct vibronic progressions with sharp absorption and emission edges, strong red fluorescence in solution and a small Stokes shift (10 nm). Similar findings apply for PEDPPP-CPDT with an absorption maximum at 665 nm. This behavior suggests a less pronounced π-conjugation, both on intra- and intermolecular scales, most probably caused by a significant distortion at the EDPPP-BDT or PEDPPP-CPDT single bond linkages. It is expected that the EDPPP-based copolymers show no or very weak push–pull (charge transfer) interactions between donor and acceptor units (EDPPP). Furthermore, the HOMO/LUMO gaps of the EDPPP-based copolymers are much larger (see Table 1) than those of the EDPPT-based copolymers.
Conclusions

In summary, we have successfully synthesized the first EDPPT-based, alternating donor–acceptor copolymers with $M_n$'s up to 23.3 kDa (PEDDPT$_{10}$BDT). All copolymers show broad absorption regions from 500 to 900 nm, with absorption and emission features extended into the NIR region. In combination with small bandgaps and strong aggregation tendency already in solution, features extended into the NIR region. In combination with small absorption and emission edges and small Stokes shifts point to a distinctly reduced donor–acceptor interaction and mirror the optical properties of isolated EDPPF chromophores.
