# Crystal recombination control by using Ce doped in mesoporous TiO<sub>2</sub> for efficient perovskite solar cells†

Honglin Lu, Jia Zhuang, \* Zhu Ma, \* Weiya Zhou, Haoran Xia, Zheng Xiao, Hua Zhang and Haimin Li

Efficient electron transport layers (ETLs) are the crucial issue for electron transport and hole blocking in organic–inorganic hybrid perovskite solar cells (PSCs). To date, most of the reported effective ETLs have comprised TiO<sub>2</sub>, which exhibits limited electron mobility and numerous defect states and restricts the enhancement of the performance of PSCs. Hence, the investigation of effective tactics for improving the electronic properties of TiO<sub>2</sub> is critical for the fabrication of high-efficiency devices. In this study, a cerium doping method was adopted in mesoporous TiO<sub>2</sub>, which was prepared *via* a traditional one-step hydrothermal process, to improve its electron transport properties by recombining nanocrystals and optimizing the negative flat band potential of TiO<sub>2</sub>. Continuous, aligned and regulated recombined crystals of mesoporous TiO<sub>2</sub> were obtained with optimized pathways of electron transport from the ETL to the FTO layer. Moreover, a small amount of Ti<sup>4+</sup> ions was replaced by Ce<sup>4+</sup> ions in the TiO<sub>2</sub> lattice, which led to deformation of the TiO<sub>2</sub> lattice and influenced the growth process of TiO<sub>2</sub> grains. With an optimized mole proportion of Ce element in the TiO<sub>2</sub> precursor, the power conversion efficiency (PCE) of perovskite solar cells was typically boosted to 17.75% in comparison with 15.92% in the case of undoped TiO<sub>2</sub>.

## Introduction

In recent years, numerous works have focused on organic–inorganic hybrid perovskite solar cells (PSCs) owing to their strong photovoltaic properties and low cost of manufacture. Their photoelectric conversion efficiency (PCE) has increased enormously from 3.8% in 2009 to 23.3% in 2018.<sup>1–3</sup> Owing to the untiring efforts of researchers, PSCs will have great potential as replacements for silicon-based solar cells. In typical PSCs, a perovskite absorber layer, either with or without a mesoporous scaffold, is sandwiched between the electron transport layer (ETL) and the hole transport layer (HTL).<sup>4,5</sup> The ETL has a significant function in transporting electrons and blocking holes.<sup>6–8</sup>

To date, various metal oxide films have been employed as ETLs, such as TiO<sub>2</sub>, ZnO, SnO<sub>2</sub>, CeO<sub>2</sub>, BaSnO<sub>3</sub>, Nb<sub>2</sub>O<sub>5</sub>, SrTiO<sub>3</sub> and In<sub>2</sub>S<sub>3</sub>,<sup>9–17</sup> of which TiO<sub>2</sub> has been the most frequently used material. In comparison with compact TiO<sub>2</sub> (c-TiO<sub>2</sub>), mesoporous TiO<sub>2</sub> (m-TiO<sub>2</sub>) is usually used as a scaffold over c-TiO<sub>2</sub> to

enhance the electron transport, light absorption and environmental stability of PSCs.<sup>18,19</sup> At present, most high-efficiency PSCs are based on m-TiO<sub>2</sub>. However, m-TiO<sub>2</sub> suffers from many problems, such as the surface and internal oxygen vacancies in m-TiO<sub>2</sub>, low conductivity, and multiple defect state densities, which lead to the loss of performance in PSCs.<sup>20,21</sup>

Surface passivation is considered to be an efficient method of boosting electron transport in silicon-based solar cells and PSCs from the absorption layer to the electrodes or ETLs and reducing electron recombination, which further increases the PCE of the device. Many groups have focused on the interfacial engineering of ETLs to increase the PCE of cells. For instance, Jia *et al.* introduced CsI as an interfacial modification layer between MAPbI<sub>3</sub> and m-TiO<sub>2</sub>, which could improve the surface morphology of m-TiO<sub>2</sub>, reduce the work function of TiO<sub>2</sub>, and reduce the surface defect density.<sup>22</sup> Zheng *et al.* reported an easy strategy whereby the deposition of both aminocaproic acid and caproic acid between mesoporous TiO<sub>2</sub> and an MAPbI<sub>3</sub> layer achieved a significant increase in PCE, which could contribute to the accelerated extraction and transfer of electrons *via* interfacial modification.<sup>23</sup> Although the surface passivation of m-TiO<sub>2</sub> can notably increase the PCE of devices, this additional modification process is contrary to the requirement for a simple fabrication process for the industrialization of PSCs. Therefore, it is important to search for a cost-effective and easy

manufacturing method for processing high-quality and efficient m-TiO<sub>2</sub> ETLs.

Recently, an ion doping method has been used to replace this additional modification process and moreover improve the optoelectronic properties of m-TiO<sub>2</sub> ETLs. At present, many researchers have reported the ion doping of ETLs to increase the PCE of devices. For example, in the case of tungsten-doped TiO<sub>2</sub> it was demonstrated that the conduction band (CB) of TiO<sub>2</sub> was shifted downward, which is beneficial for electron transport because of the optimized energy level matching between the lowest unoccupied molecular orbital (LUMO) of an MAPbI<sub>3</sub> layer and the CB of TiO<sub>2</sub>.<sup>24</sup> Su *et al.* demonstrated that niobium (Nb)-doped TiO<sub>2</sub> was manufactured *via* a one-step spin-coating process and the PCE of a cell increased from 14.9% to 16.3%, which was attributed to the increased charge density and conductivity of the TiO<sub>2</sub> ETL.<sup>25</sup> Chen *et al.* reported that in PSCs based on lithium-doped TiO<sub>2</sub> the density of electron trap states can be increased.<sup>26</sup> Moreover, aluminum, cesium and cadmium have been doped into TiO<sub>2</sub> ETLs to improve the performance of PSCs by controlling the carrier dynamics in TiO<sub>2</sub>.<sup>27–29</sup> Thus far, the aim of doping ions into TiO<sub>2</sub> has mainly been to enhance the electronic properties of ETLs, which is mainly attributed to the high conductivity of the doped metal itself and the improved alignment of energy levels. However, few researchers have proposed schemes for the improvement of electronic properties by optimizing the morphology of TiO<sub>2</sub> films by ion doping, which promotes electron transport in ETLs and decreases electron recombination.

In this study, a crystal recombination phenomenon was observed after cerium element was doped into mesoporous TiO<sub>2</sub>, which was prepared using a one-step hydrothermal method. The regulated crystal recombination provided optimized transport pathways for the extraction and transport of electrons. PSCs exhibited a maximum PCE of 17.75% with an increased open-circuit voltage ( $V_{OC}$ ), short-circuit current density ( $J_{SC}$ ), and fill factor (FF) in comparison with undoped cells. The overall enhancement in performance was ascribed to the excellent electronic properties of the ETL.

## Results and discussion

Fig. 1a shows a schematic flow chart of the fabrication process of mesoporous TiO<sub>2</sub>. Compact TiO<sub>2</sub> was prepared by spin coating, and mesoporous TiO<sub>2</sub> was fabricated by a hydrothermal method. SEM images of mesoporous TiO<sub>2</sub> and mesoporous TiO<sub>2</sub> doped with 2% Ce are presented in Fig. 1b and c, respectively. As seen in Fig. 1b and c, we obtained nanoparticle-shaped TiO<sub>2</sub> by a hydrothermal method, whereby mesoporous TiO<sub>2</sub> doped with 2% Ce exhibited recombined crystalline grains with a greater diameter and a smoother nanodrusse surface than undoped m-TiO<sub>2</sub>. The morphology of Ce-doped m-TiO<sub>2</sub> promoted the transport and penetration of electrons from the MAPbI<sub>3</sub> absorption layer into the mesoporous ETL, which possessed planar and mesoporous characteristics.<sup>30,31</sup> Fig. 1d shows the diameter distribution of crystalline grain agglomerates, which further demonstrates that the diameter of

crystalline grain agglomerates was larger when 2% Ce ions were doped into mesoporous TiO<sub>2</sub>.

High-resolution transmission electron microscopy (HRTEM) was used to elucidate the reason for the lattice deformation that occurred when 2% Ce was doped into m-TiO<sub>2</sub> (Fig. 2a and b). The lattice spacing measured from an HRTEM image was 0.35 nm (inset of Fig. 2a), which corresponded to the (101) crystallographic planes of the anatase form of titanium dioxide. Doping 2% Ce into TiO<sub>2</sub> led to lattice deformation and a decrease in the spacing (0.31 nm) between the (101) crystallographic planes of the anatase form of titanium dioxide. This result shows that Ce element penetrated into the TiO<sub>2</sub> lattice. Because the ionic radius of Ce<sup>4+</sup> ions is greater than that of Ti<sup>4+</sup> ions, the extrusion effect of ion replacement caused the lattice spacing to decrease. Fig. 2c illustrates the reason why mesoporous TiO<sub>2</sub> doped with 2% Ce had a greater diameter of crystalline grain agglomerates when Ce<sup>4+</sup> ions were doped into the TiO<sub>2</sub> lattice.<sup>32,33</sup> (A study showed that the critical temperature for the valence state from Ce<sup>3+</sup> ion to Ce<sup>4+</sup> ion is 200 °C. The experimental temperature was 500 °C, indicating that the conversion to valence state is credible.) Ce atoms have higher bond energies than Ti atoms, which could enable substitution doping when Ce<sup>4+</sup> ions were doped into the TiO<sub>2</sub> lattice.<sup>32</sup> The incomplete match between the geometric features of the two elements led to slight deformation and strain in the TiO<sub>2</sub> lattice. The greater diameter of recombined crystalline grains of TiO<sub>2</sub> nanoparticles that was observed can be attributed to the occurrence of lattice deformation and strain induced by the substitution of larger Ce<sup>4+</sup> ions (94 pm) in the positions of Ti<sup>4+</sup> ions (68 pm). Lattice deformation caused by substitution doping leads to larger crystal particles, improves the regularity of the crystal structure, decreases the number of irregular holes, and provides more channels and opportunities for electron transport. Frank *et al.* reported that a decrease in film porosity was beneficial for electron transport in an m-TiO<sub>2</sub> film.<sup>34</sup> High porosity implies longer electron transport pathways, which indicates that electrons will spend a longer time in the m-TiO<sub>2</sub> network before being collected.<sup>34,35</sup> This result will cause more electron recombination. m-TiO<sub>2</sub> doped with 2% Ce (Fig. 1c) exhibited lower porosity than undoped m-TiO<sub>2</sub> (Fig. 1b), which was beneficial for improved electron transport and further increased the PCE of cells.

Fig. 3a and b show elemental maps of the elemental compositions of undoped and 2% Ce-doped mesoporous TiO<sub>2</sub> ETLs, respectively. Tin element originated from FTO glass, and Ti element originated from c-TiO<sub>2</sub> and m-TiO<sub>2</sub>. The presence of cerium element and its uniform distribution demonstrate that Ce was successfully doped into mesoporous TiO<sub>2</sub> by doping cerium nitrate pentahydrate into the hydrothermal precursor solution.<sup>36</sup> To further confirm the presence and intrinsic effect of cerium element in TiO<sub>2</sub>, XPS (the carbon peak correction was carried out) was used to determine the chemical compositions and chemical states of undoped mesoporous TiO<sub>2</sub> and mesoporous TiO<sub>2</sub> doped with 2% Ce.<sup>37</sup> The full XPS spectra can be seen in Fig. 3c, which shows the presence of Ti, O, and C elements in undoped mesoporous TiO<sub>2</sub> and mesoporous TiO<sub>2</sub> doped with 2% Ce. The presence of a C 1s peak is ascribed to

Fig. 1 (a) Schematic flow chart of the fabrication of compact TiO<sub>2</sub> and mesoporous TiO<sub>2</sub>, (b) and (c) SEM images of FTO/c-TiO<sub>2</sub>/m-TiO<sub>2</sub> and FTO/c-TiO<sub>2</sub>/2% Ce-doped m-TiO<sub>2</sub>, (d) diameters of crystalline grain agglomerates of mesoporous TiO<sub>2</sub>.

adsorbed hydrocarbons on the TiO<sub>2</sub> surface. However, the presence of Ce element is not directly indicated in Fig. 3c owing to its low concentration, but its characteristic peak can

influence shifts in other peaks of mesoporous TiO<sub>2</sub>, which could confirm the presence of Ce indirectly. Fig. 3d shows the O 1s peaks of undoped mesoporous TiO<sub>2</sub> and mesoporous TiO<sub>2</sub>

Fig. 2 HRTEM images of (a) TiO<sub>2</sub> and (b) 2% Ce-TiO<sub>2</sub> and (c) 3D model diagram of Ce<sup>4+</sup> ions replacing Ti<sup>4+</sup> ions in the TiO<sub>2</sub> lattice.

Fig. 3 EDX elemental images of (a) FTO/c-TiO<sub>2</sub>/m-TiO<sub>2</sub> and (b) FTO/c-TiO<sub>2</sub>/2% Ce-doped m-TiO<sub>2</sub>. XPS measurements of TiO<sub>2</sub> and Ce-doped TiO<sub>2</sub> mesoporous ETLs: (c) survey spectrum, (d) O 1s spectrum, and (e) Ti 2p spectrum.

doped with 2% Ce. The Ti 2p spectra in Fig. 3e show that mesoporous TiO<sub>2</sub> doped with 2% Ce exhibited a peak shift from 463.4 eV to 463.6 eV in comparison with undoped mesoporous TiO<sub>2</sub>, *i.e.*, a shift of 0.2 eV. The shifts in the peaks of Ti 2p and O 1s are assigned to the different coordination environments and chemical environments that resulted when Ce<sup>4+</sup> ions were doped into mesoporous TiO<sub>2</sub>. The shifts in the peaks of O 1s and Ti 2p are ascribed to the changes in the charge densities of O and Ti atoms, which could be caused by electron transfer from O 1s orbitals and the 2p orbitals of Ti atoms to Ce 4f orbitals. This result influenced the nucleation and crystallization of m-TiO<sub>2</sub> when Ce was doped into m-TiO<sub>2</sub>, which further improved the morphology of m-TiO<sub>2</sub>. The characterization *via* EDS and XPS shows that Ce element was successfully doped into mesoporous TiO<sub>2</sub> and was uniformly distributed.

Surface SEM images of perovskite films based on undoped mesoporous TiO<sub>2</sub> and mesoporous TiO<sub>2</sub> doped with 2% Ce are shown in Fig. 4a and b, respectively. When Ce was added to mesoporous TiO<sub>2</sub>, there was no observable change in the morphology of the perovskite film in comparison with pure mesoporous TiO<sub>2</sub>. This result shows that the decrease in porosity when Ce was doped into m-TiO<sub>2</sub> had no influence on the morphology of the perovskite layer. The perovskite films deposited onto mesoporous TiO<sub>2</sub> and Ce-doped mesoporous TiO<sub>2</sub> ETL substrates exhibited uniform film-forming abilities, which is important for producing high-efficiency PSCs. Fig. 4c

shows the XRD patterns of perovskite thin films deposited on mesoporous TiO<sub>2</sub> and 2% Ce-doped mesoporous TiO<sub>2</sub> ETLs, which demonstrate that the addition of cerium nitrate did not influence the crystal structure of MAPbI<sub>3</sub> and a perovskite film structure was formed. UV-vis absorption spectra (Fig. 4d) show that the CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3</sub> film based on a 2% Ce-doped TiO<sub>2</sub> ETL exhibited a stronger absorption peak due to the CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3</sub> film within the range of 400–450 nm than the CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3</sub> film based on an undoped TiO<sub>2</sub> ETL, and hence the absorption of visible light by the perovskite layer was further improved. This result further shows the improvement in the PCE of cells after Ce was doped into m-TiO<sub>2</sub>.

We manufactured a perovskite solar cell with a cell structure of FTO/c-TiO<sub>2</sub> (70 nm)/m-TiO<sub>2</sub> (300 nm)/MAPbI<sub>3</sub> (500 nm)/spiro-OMeTAD (150 nm)/Ag (100 nm) (Fig. 5a), and a corresponding cross-sectional SEM image is shown in Fig. 5b. The reverse and forward current–voltage (*J*–*V*) characteristics of solar cells with and without 2% Ce dopant are shown and summarized in Fig. 5c and Table 1, respectively. The undoped TiO<sub>2</sub> cell exhibited a *J*<sub>SC</sub> value of 22.80 mA cm<sup>-2</sup>, a *V*<sub>OC</sub> value of 1.020 V, and an FF of 68.50%, with a PCE of 15.92% under reverse scanning (10.11% under forward scanning), whereas the 2% Ce-TiO<sub>2</sub> PSC exhibited a PCE of 17.75% (*V*<sub>OC</sub> = 1.048 V, *J*<sub>SC</sub> = 23.61 mA cm<sup>-2</sup>, FF = 71.70%) under reverse scanning and a PCE of 13.81% under forward scanning. A decrease in the hysteresis index (to 0.22) was demonstrated for the cell based on

Fig. 4 (a) and (b) Top-view SEM images of MAPbI<sub>3</sub> films based on mesoporous TiO<sub>2</sub> and 2% Ce-doped mesoporous TiO<sub>2</sub> ETLs, (c) XRD patterns of MAPbI<sub>3</sub> films (♦ represents FTO), and (d) UV-vis absorption spectra of MAPbI<sub>3</sub> films based on mesoporous TiO<sub>2</sub> and 2% Ce-doped mesoporous TiO<sub>2</sub> ETLs.

2% Ce-m-TiO<sub>2</sub> as the ETL (in comparison with the hysteresis index of 0.36 for the undoped device), which can be ascribed to the improved morphology and increased conductivity of m-

TiO<sub>2</sub>. From Table S1,<sup>†</sup> we can demonstrate that the  $J_{SC}$  and  $V_{OC}$  values and FF of Ce-doped cells increased in comparison with the undoped TiO<sub>2</sub> cell when the concentration was 1% and 2%.

Fig. 5 (a) Cell model diagram, (b) cross-sectional SEM image of PSC (FTO/compact TiO<sub>2</sub>/mesoporous TiO<sub>2</sub>/CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3</sub>/spiro-OMeTAD/Ag), (c)  $J$ - $V$  curves, (d) histogram of PCE, and (e) and (f) error bars of PCE and FF.

Table 1 Photovoltaic performance of PSCs based on TiO<sub>2</sub> and 2% Ce–TiO<sub>2</sub> ETLs

ETL	V <sub>OC</sub> (V)	J <sub>SC</sub> (mA cm <sup>-2</sup> )	FF (%)	PCE (%)	Hysteresis index
TiO <sub>2</sub> reverse	1.020	22.80	68.50	15.92	0.36
TiO <sub>2</sub> forward	0.852	22.51	52.70	10.11	
2% Ce–TiO <sub>2</sub> reverse	1.048	23.61	71.70	17.75	0.22
2% Ce–TiO <sub>2</sub> forward	0.931	23.32	63.60	13.81	

When the dopant concentration was 4%, the  $J_{SC}$  and  $V_{OC}$  values and FF of the cell declined rapidly. Ce<sup>4+</sup> ions doped into m-TiO<sub>2</sub> could produce a new impurity energy level, which may help charge capture and separation and may also serve as a recombination center for carriers. Obviously, doping with 4% Ce<sup>4+</sup> ions provided m-TiO<sub>2</sub> with recombination centers and further exerted a passive influence on the ETL. Therefore, Ce<sup>4+</sup> ions were added to increase the  $J_{SC}$  and  $V_{OC}$  values and FF, which further led to an increase in the PCE at a certain concentration. The statistical distribution of the PCEs of undoped and 2% Ce-doped devices is shown in Fig. 5d, from which the PCEs of cells based on 2% Ce–TiO<sub>2</sub> were concentrated around 15% and 16% in comparison with 13% and 14% in the case of undoped devices. The error bars (Fig. 5e, f and S1†) show that the 2% Ce-doped TiO<sub>2</sub> cells exhibited higher  $V_{OC}$  and  $J_{SC}$  values and FFs than the undoped devices, which further illustrates that doping with Ce was effective for improving cell performance.

In order to get an insight into the relationship between the performance of devices and the properties of Ce-doped mesoporous TiO<sub>2</sub>, different tactics were used. Fig. 6a shows the UV-vis absorption spectra of undoped and 2% Ce-doped mesoporous TiO<sub>2</sub>. The absorption spectrum of Ce-doped TiO<sub>2</sub> displays a red shift in the band gap (small image in Fig. 6a). The transformed Kubelka–Munk spectra (Fig. 6b) of undoped and 2% Ce-doped TiO<sub>2</sub> were recorded to determine the optical band gap. The optical band gap of TiO<sub>2</sub> decreased from 3.25 to 3.20 eV when 2% Ce(NO<sub>3</sub>)<sub>3</sub> was doped into the TiO<sub>2</sub> precursor solution. This could be attributed to the formation of a Ti–O–Ce bond structure in Ce-doped m-TiO<sub>2</sub> owing to the partial substitution of Ti by Ce, which caused the red shift in the band gap of TiO<sub>2</sub>. The decrease in the band gap can promote an increase in the force of charge injection from the ETL to the FTO glass layer, as shown by the increased  $J_{SC}$  value of the device. Fig. 6c shows the Mott–Schottky curves for undoped and 2% Ce-doped mesoporous TiO<sub>2</sub>. The flat band potential ( $V_{fb}$ ) is the external voltage and corresponds to the intercept with the x-axis. A shift in the  $V_{fb}$  value is related to the position of the conduction band of m-TiO<sub>2</sub>.<sup>37</sup> Fig. 6c shows that the  $V_{fb}$  value was negatively shifted from -0.601 V to -0.621 V, whereas the negative shift in the  $V_{fb}$  value implies that the quasi-Fermi level was higher (Fig. 6d). These results further led to an upward shift in the conduction band, which resulted in an increase of 15 mV in the  $V_{OC}$  value. The increase of 28 mV observed in the  $V_{OC}$  value of the device was much greater than the increase of 15 mV in the  $V_{OC}$  value due to the shift in the conduction band, which may be ascribed to the improved morphology and increased conductivity of m-TiO<sub>2</sub>. Fig. 6e shows the EIS spectra of devices based on undoped

and 2% Ce-doped TiO<sub>2</sub> as ETLs, which were recorded with an amplitude of 7.5 mV and a measurement frequency ranging from 1 to 100 kHz.<sup>38,39</sup> The model in the inset of Fig. 6e shows the fitted equivalent circuit. Table 2 shows the values used for fitting. The arc at high frequencies is attributed to the contact resistance of the interface between the perovskite layer and the ETL, whereas that at low frequencies originated from the recombination resistance ( $R_{rec}$ ). The arc at high frequencies shows that doping with 2% Ce had little influence on electron transfer from the perovskite layer and ETL in comparison with the undoped device. The larger semicircle in the curve is generally related to the recombination of electrons. Obviously, the PSC based on mesoporous TiO<sub>2</sub> doped with 2% Ce as the ETL exhibited a higher recombination resistance (8535 Ω) than the undoped cell (5420 Ω), which indicated that a lower recombination loss occurred when Ce element was doped into meso-TiO<sub>2</sub>. This result led to increases in the FF and  $V_{OC}$  value of PSCs. Fig. 6f shows a 3D map of electron transport from MAPbI<sub>3</sub> to the ETL. The higher PCE of the device based on 2% Ce–TiO<sub>2</sub> as the ETL decreased the recombination of electrons owing to the optimized morphology of mesoporous TiO<sub>2</sub>, the decreased  $V_{fb}$  value and the increased conductivity in comparison with the undoped device.

PL (Fig. 7a) and TRPL (Fig. 7b) measurements were used to assess whether charges could be efficiently extracted from the MAPbI<sub>3</sub> layer to the mesoporous TiO<sub>2</sub> layer.<sup>40,41</sup> Fig. 7a shows the steady-state PL spectra of PSCs with the structures FTO/compact TiO<sub>2</sub>/mesoporous TiO<sub>2</sub>/perovskite and FTO/compact TiO<sub>2</sub>/2% Ce-doped mesoporous TiO<sub>2</sub>/perovskite. From the PL peak at about 775 nm, the CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3</sub> perovskite film deposited on 2% Ce-doped mesoporous TiO<sub>2</sub> exhibited more evident PL quenching in comparison with the pristine mesoporous TiO<sub>2</sub> film, which demonstrated an enhanced charge extraction ability. Furthermore, the time constants  $\tau_e$  were determined by fitting the TRPL curves (Fig. 7b) to calculate the extraction lifetimes for perovskite layers on mesoporous TiO<sub>2</sub> with and without a Ce dopant as the ETL. As a result, the fitted time constants  $\tau_e$  were calculated by a biexponential decay function as follows:

$$\tau_{ave} = \frac{\sum_i^n a_i \tau_i^2}{\sum_i^n a_i \tau_i} \quad (1)$$

The results for the  $\tau_e$  values (Table 3) were 37.40 ns for the doped cell and 51.93 ns for the undoped cell, respectively. Thus,

Fig. 6 (a) UV-vis absorption spectra of  $\text{TiO}_2$  and 2% Ce-doped mesoporous  $\text{TiO}_2$  ETLs, (b) band gap map of  $\text{TiO}_2$ , (c) Mott-Schottky curves for  $\text{TiO}_2$  and Ce-doped mesoporous  $\text{TiO}_2$  ETLs, (d) electronic density of states for meso- $\text{TiO}_2$  ETLs including the densities of conduction band states ( $D_{\text{CB}}$ ), trap states ( $D_{\text{T}}$ ), and valence band states ( $D_{\text{VB}}$ ) and the decrease in the density of surface trap states due to doping with Ce, (e) EIS spectra of perovskite solar cells based on  $\text{TiO}_2$  and 2% Ce-doped mesoporous  $\text{TiO}_2$  as ETLs, and (f) 3D map of electron transport from  $\text{MAPbI}_3$  to the ETL.

the PL decay for the cell based on 2% Ce-doped  $\text{TiO}_2$  was approximately 27.98% faster in comparison with the PSC based on pristine mesoporous  $\text{TiO}_2$ , which showed that the time taken for electron injection from the perovskite layer to 2% Ce-doped mesoporous  $\text{TiO}_2$  was shorter. The enhanced electron extraction ability was probably due to the optimized morphology of mesoporous  $\text{TiO}_2$  and the decrease in the  $V_{\text{fb}}$  value, which further resulted in the increase in the PCE of the cell.

We introduced Ce element as an effective doping agent into mesoporous  $\text{TiO}_2$  to increase the PCE of perovskite solar cells. It was shown that doping of mesoporous  $\text{TiO}_2$  with Ce improved the optoelectronic properties of the ETL owing to the optimized morphology of mesoporous  $\text{TiO}_2$  and the decreased  $V_{\text{fb}}$  value. The PCE of a cell increased to 17.75% in comparison with the PCE of an undoped device of 15.92%. The increases in the values of  $J_{\text{SC}}$  and  $V_{\text{OC}}$  are ascribed to the increase in the force of electron transport from the ETL to the FTO layer and the rise in the quasi-Fermi energy level. The increase in the FF is attributed

to the increase in the value of  $R_{\text{rec}}$  after Ce was doped into the mesoporous  $\text{TiO}_2$  ETLs. This study shows that ion doping is an effective strategy for producing high-efficiency perovskite solar cells.

## Experimental section

### Materials and reagents

Chlorobenzene (99.9%), *N,N*-dimethylformamide (DMF, 99.9%), titanium isopropoxide (99.999%), and acetonitrile (99.9%) were obtained from Sigma-Aldrich. Cerium(III) nitrate hexahydrate and isopropanol were obtained from Aldrich. 2,2',7,7'-Tetrakis(*N,N'*-di-*p*-methoxyphenylamino)-9,9'-spirobifluorene (spiro-OMeTAD, 99.5%),  $\text{PbI}_2$  (99.99%), lithium bis(trifluoromethanesulfonyl)imide (Li-TFSI, 99.9%),  $\text{CH}_3\text{NH}_3\text{I}$  (99.5%), and 4-*tert*-butylpyridine (tBP, 96%) were obtained from Xi'an Polymer Light Technology Company. Glass substrates coated with fluorine-doped tin oxide (FTO) ( $15 \Omega \text{ sq}^{-1}$ ) were

bought from OPV Tech New Energy Co. All the materials and reagents were used without further purification.

### Solar cell fabrication

The FTO substrates were ultrasonically cleaned with an abstergent, acetone, deionized water, and ethanol for 15 min in each case. The conductive substrates were dried with a nitrogen gun and post-treated with UV–ozone for 15 min. A c-TiO<sub>2</sub> layer was coated on the cleaned FTO substrates by spin coating with the titanium precursor solution at 2000 rpm for 30 s. The as-prepared c-TiO<sub>2</sub> was post-annealed at 150 °C for 15 min and then heated at 500 °C for 30 min in a muffle furnace. Then, we started to prepare the mesoporous TiO<sub>2</sub> precursor solution, and 15 mL hydrochloric acid was mixed with 15 mL deionized water under magnetic stirring for 10 min. Then, 0.75 mL tetra-*n*-butyl titanate with or without different amounts of cerium(III) nitrate pentahydrate (Ce(NO<sub>3</sub>)<sub>3</sub>·5H<sub>2</sub>O) as a dopant was added to the abovementioned mixed solution, and then the solution was vigorously stirred for 30 min to obtain a clarified solution. Afterwards, the clear solution was transferred into a reaction kettle equipped with compact TiO<sub>2</sub>/FTO substrates. The sealed reaction kettle was placed in a laboratory oven at 170 °C for 1 h. After the autoclave was cooled to room temperature naturally, the substrate was taken out, rinsed with deionized water and ethanol twice to remove residual reactants, and finally dried with a nitrogen gun and then annealed at 500 °C for 30 min in a muffle furnace. An MAPbI<sub>3</sub> layer was spin-coated on c-TiO<sub>2</sub>/m-TiO<sub>2</sub>/FTO glass at 3000 rpm for 55 s. CB (80 μL) was washed onto

the substrate during the spin-coating method about 10 s before the beginning of the procedure, and the substrate was then annealed at 100 °C for 20 min. An HTL film was manufactured by spin-coating a spiro-OMeTAD solution on a perovskite film at 3000 rpm for 30 s. Finally, an Ag electrode was deposited onto the spiro-OMeTAD layer by a sputtering technique to finish the manufacture of the cell.

### Characterization

The current–voltage characteristics of perovskite solar cells were determined using an electrochemical workstation under AM 1.5 simulated solar illumination (CEL-S500, Beijing, China). Mott–Schottky plots were recorded by employing an electrochemical workstation with a standard three-electrode configuration with Ag/AgCl as the reference electrode in saturated Na<sub>2</sub>SO<sub>4</sub> and a Pt sheet as the counter electrode in deionized water. The morphology and composition of mesoporous TiO<sub>2</sub> films were investigated using a scanning electron microscope (SEM; Zeiss EVOMA15) equipped with an energy-dispersive X-ray spectroscopy (EDX) detector. X-ray diffraction (XRD, DX-2700, Dandong) patterns were recorded from 22° to 58° with Cu K $\alpha$  radiation ( $\lambda = 0.15406$  nm) at a scanning rate of 4° min<sup>−1</sup>. X-ray photoelectron spectroscopy (XPS) measurements were carried out with an X-ray photoelectron spectrometer (Kratos Axis Ultra DLD) with a monochromated Al K $\alpha$  X-ray source ( $h\nu = 1486.6$  eV, 200 W). HRTEM images were recorded with a Hitachi HT-7700 transmission electron microscope (Hitachi Limited, Tokyo, Japan) at a voltage of 100 kV. UV-vis absorption spectra were recorded by a UV-vis spectrometer (Varian Cary 5000). Time-resolved photoluminescence (TRPL) spectra were recorded at 765 nm with an Edinburgh Instruments FLS 980 spectrometer with a pulsed diode laser at 485 nm (with an intensity of 0.12 mW cm<sup>−2</sup>) at a pulse frequency of 1 MHz. Incident photocurrent conversion efficiency (IPCE) spectra were recorded using an IPCE system (PVE 300, Bentham, Inc.) as a function of the wavelength from 300 to 800 nm. The active area of the perovskite solar cells was fixed at 0.16 cm<sup>2</sup> using a mask.
