Preparation and visible-light photocatalytic properties of the floating hollow glass microspheres – TiO2/Ag3PO4 composites†

Yu An, Pengwu Zheng* and Xiaofei Ma*

A novel floating visible-light photocatalyst (HGMs–TiO2/Ag3PO4) composite was prepared using amino modified low-density hollow glass microspheres (HGMs) as carriers to disperse and support TiO2 and Ag3PO4 photocatalysts. The surface morphology, crystal structure and optical properties of the HGMs–TiO2/Ag3PO4 composites were characterized and the Ag3PO4 content on the surface of the microspheres was determined by atomic absorption spectrometry (AAS). Methylene blue (MB) was chosen to investigate the visible-light catalytic properties of the HGMs–TiO2/Ag3PO4 composites. For HGM composite photocatalysts, when the theoretical mass ratio of TiO2 to Ag3PO4 on the surface of HGMs is 1 : 1.5, the visible-light catalytic activity of the composite is superior to pure Ag3PO4 and a TiO2/Ag3PO4 photocatalyst with a mass ratio of 1 : 1.5 under the same conditions, due to the increased light-contact area and the photocatalytic active sites, since the TiO2 and Ag3PO4 particles can be well dispersed on the surface of the floating HGMs. Furthermore, the deposits of TiO2 and Ag3PO4 on the HGM surface form a heterostructure, facilitating the separation of electron–hole (e− – h+) in the energy band, and elevating the photocatalytic activity and cycle stability of Ag3PO4. This work indicates that floating HGMs–TiO2/Ag3PO4 composites could become a promising photocatalyst for organic dye removal due to the low cost and high visible-light responsiveness.

1. Introduction

With the development of industrialization, the issues of energy shortage and environmental pollution have become increasingly severe. Solar energy, the most abundant clean energy, hitting the earth within one hour is higher than the energy consumed by humans throughout the year. Using renewable solar energy, photocatalytic technology that undergoes redox reactions is a sustainable method to solve environmental problems, especially removing residual dye contaminants in wastewater.

Since Fujishima and Honda used TiO2 electrodes for photocatalytic decomposition of water under ultraviolet light for the first time in 1972, significant advances have been made in the design of Z-scheme photocathodes and research on high-efficiency semiconductor photocatalysts. In recent years, various types of semiconductor photocatalysts, such as In(OH)3, BiVO4, ZnO, CdS, Cu2O, CuO, Fe2O3, Ag2O, Ag3PO4, g-C3N4, MOF, have been reported. TiO2 is one of the most widely used photocatalytic materials in a wide range of semiconductors due to its high chemical inertness, corrosion resistance, non-toxicity, cost effectiveness, and environmental friendliness. However, owing to its wide bandgap (3.0–3.2 eV), TiO2 can only absorb ultraviolet light that accounts for 4% of the total sunlight, which greatly limits its practical application under visible light. Therefore, the study of visible light-driven high-efficiency photocatalysts has become a hot issue in the field of semiconductor photocatalysis.

During the past few decades, Ag-based photocatalysts have been developed as high-efficiency photocatalysts to degrade organic contaminants such as AgX (X = Cl, Br, and I), Ag2O, and Ag2CO3. In 2010, Yi et al. reported the new use of Ag3PO4 in the photooxidation of water and degradation of organic dyes under visible light. The indirect band gap of Ag3PO4 is 2.36 eV, and the direct bandgap is 2.43 eV. Both the large dispersion of the conduction band and the strong inducing effect of PO43− promote the separation of the photo-generated electron–hole pairs (e− – h+) of the Ag3PO4, making it one of the currently promising visible-light catalysts. However, Ag3PO4 will undergo photo-corrosion to produce Ag particles that affect its photocatalytic activity. Therefore, it is critical to develop a novel Ag3PO4-based visible-light photocatalyst with improved photocatalytic activity and stability.

† Electronic supplementary information (ESI) available. See DOI: 10.1039/c8ra08697d
In this paper, low-density hollow glass microspheres (HGMs) were used as carriers, and TiO$_2$ was loaded on the surface of HGMs by hydrothermal method at first, and then floating HGMs–TiO$_2$/Ag$_3$PO$_4$ composites were prepared by ion exchange method with Ag$_3$PO$_4$. The as-prepared floating photocatalyst enlarge the contact area between the photocatalyst and light on the one hand, and on the other hand, both the synergistic effect of TiO$_2$ and Ag$_3$PO$_4$ semiconductor and the formation of surface heterojunction can promote the e$^-$–h$^+$ charge separation, thus the photocatalytic activity and stability of the photocatalyst is further enhanced.

2. Experimental

2.1. Materials

HGMs (density $\rho = 0.26$ g cm$^{-3}$) were obtained from Zhengzhou Holloware Corp (Henan, China). (3-Aminopropyl) triethoxysilane (APTES) was purchased from Shanghai Aladdin Chemistry Corp (China). All of the other reagents were analytical grade and purchased from Tianjin Chemical Company (China).

2.2. Preparation of amino modified HGMs

10 g of HGMs were added into 50 mL of deionized water in which 40 $\mu$L APTES was dissolved under stirring. The floating product (aminated modified HGMs) was washed several times with distilled water and absolute ethanol and dried at 60 °C for 8 h.

2.3. Fabrication of HGMs–TiO$_2$ composite

2 g amino modified HGMs was dispersed in the mixed solution of 1.28 mL titanium butoxide (Ti(OC$_4$H$_9$)$_4$) and 20 mL absolute ethanol with stirring. Then, 40 mL 50% ethanol–water solution was added to the above HGMs suspension through a constant pressure dropping funnel. The mixture was transferred into a 100 mL Teflon-lined stainless-steel autoclave and heated at 120 °C for 5 h. After cooling down to the room temperature, the obtained floating product was washed with distilled water and ethanol for three times and dried at 60 °C for 8 h. The sample was placed in a muffle furnace at 300 °C for 2 h, and taken out after the furnace chamber temperature was lowered to 60 °C. The theoretical TiO$_2$ loading of the obtained sample was 0.15 g g$^{-1}$ HGMs, labeled as HGMs-1 : 0. At the same time, the same method was used to prepare pure TiO$_2$ powder without adding HGMs.

2.4. Preparation of HGMs–TiO$_2$/Ag$_3$PO$_4$ composite

1.15 g HGMs-1 : 0 was dispersed in 100 mL AgNO$_3$ solution and stirred for 5 h. Then, 100 mL Na$_3$PO$_4$ solution was slowly added dropwise to the above mixture solution and stirred for 30 min. The obtained floating product was washed with distilled water to remove unreacted ions and dried at 60 °C for 8 h. HGMs–TiO$_2$/Ag$_3$PO$_4$ composites with different theoretical loadings of Ag$_3$PO$_4$ (0.150, 0.225 and 0.300 g g$^{-1}$ HGMs) were prepared by adjusting the concentration of AgNO$_3$ and Na$_3$PO$_4$ aqueous solution and maintaining the stoichiometry of AgNO$_3$ and Na$_3$PO$_4$ to 3 : 1. According to the theoretical loading mass ratio of TiO$_2$ and Ag$_3$PO$_4$, the obtained samples were labeled as HGMs-1 : 1, HGMs-1 : 1.5 and HGMs-1 : 2, respectively. At the same time, pure Ag$_3$PO$_4$ was prepared without adding HGMs-1 : 0, and TiO$_2$/Ag$_3$PO$_4$ composite with mass ratio of 1 : 1.5 was synthesized by the same preparation method as HGMs–TiO$_2$/Ag$_3$PO$_4$ without adding HGMs.

The fabrication process of the photocatalyst was exhibited in Fig. 1.

2.5. Characterization

The morphology of HGMs–TiO$_2$/Ag$_3$PO$_4$ composite fixed on the sample holder with conducting resin and subjected to gold spray treatment was observed with a Hitachi S-4800 scanning electron microscope. The qualitative analysis of the elemental distribution on the surface of obtained composites was determined by energy dispersive spectrometer (EDS) in conjunction with SEM at an accelerating voltage of 3 kV. The X-ray diffraction (XRD) patterns of photocatalyst composites were recorded in reflection mode in the range of 10–80° (2θ) at a scanning rate of 0.067° s$^{-1}$ with a D/MAX-2500 operated at a CuK$\alpha$ wavelength of 1.542 Å. The ultraviolet-visible diffuse reflectance spectra (DRS) were characterized with UV-2450 spectrophotometer in the range of 200 to 800 nm by using BaSO$_4$ as the reflectance standard material, and measured by the standard Kubelka-

Fig. 1  Schematic illustration of the fabrication process of floating HGMs–TiO$_2$/Ag$_3$PO$_4$ composite. (Inset: digital photos of HGMs (a), aminated HGMs (b), HGMs–TiO$_2$ (c) and HGMs–TiO$_2$/Ag$_3$PO$_4$ (d)).
2.6. Photocatalytic activity testing

The photocatalytic property of HGMs–TiO2/Ag3PO4 composites was evaluated by organic dye methylene blue (MB) as the target of photodegradation under simulated sunlight. 0.12 g obtained photocatalyst was dispersed in 60 mL 5 mg L\textsuperscript{−1} MB solution. Before the photocatalytic test began, the photocatalyst was stored in the dark for 60 min to reach adsorption–desorption equilibrium. Then, the photocatalyst-containing MB solution was vertically irradiated with a 300 W xenon lamp and the equilibrium. Then, the photocatalyst-containing MB solution was evaluated by the cycling degradation experiments of MB (663 nm) with distilled water as reference solution. A 1800 spectrophotometer at the maximum absorption wavelength of MB solution. At the end of each cycle, the floating composite was separated and dried at 60 °C for 4 h.

3. Results and discussion

3.1. Synthesis process of HGMs–TiO2/Ag3PO4 photocatalysts

Fig. 1 depicted the fabrication process of HGMs–TiO2/Ag3PO4 composites. The first I step was the amino modification of HGMs. HGMs were modified by the hydrolysis of silane coupling agent APTES to introduce –NH\textsubscript{2} groups on HGMs. Aminated HGMs (Fig. 1b) look the same as raw materials HGMs (Fig. 1a) and are all white powder. The second II step was to prepare HGMs–TiO2 from aminated HGMs by hydrothermal synthesis. The outer electron arrangement of Ti4+ in titanium butoxide (Ti(OC\textsubscript{4}H\textsubscript{9})\textsubscript{4}) was 1s\textsuperscript{2}2s\textsuperscript{2}2p\textsuperscript{6}3s\textsuperscript{2}3p\textsuperscript{2}, and the 3d orbital was completely empty. The nitrogen atom in –NH\textsubscript{2} of aminated HGMs had the lone pair electrons that can be filled in its empty 3d orbit and the positively charged Ti\textsuperscript{4+} was adsorbed to the surface of aminated HGMs by electrostatic interaction. With the hydrothermal reaction of Ti(O\textsubscript{3}C\textsubscript{3}H\textsubscript{5})\textsubscript{4} and the dehydration of intermediates Ti(OH)\textsubscript{4}, TiO\textsubscript{2} was loaded onto the surface of the HGMs. The obtained HGMs–TiO2 was also white powder (Fig. 1c). The third III step was to prepare HGMs–TiO2/Ag3PO4 by ion reaction (Ag\textsuperscript{+} + PO\textsubscript{4}\textsuperscript{3−} = Ag3PO4) on the surface of HGMs–TiO2. TiO\textsubscript{2} is an amphoteric oxide with super-hydrophilicity, and its surface easily adsors water to form hydroxyl groups. When HGMs–TiO2 was dispersed in Ag\textsuperscript{+} solution, the main species on the surface of the TiO\textsubscript{2} particles was negatively charged O\textsuperscript{−} anion,\textsuperscript{22} which can adsorb positively charged Ag\textsuperscript{+} by electrostatic attraction. With Ag\textsuperscript{+} adsorbed, the reaction of Ag\textsuperscript{+} and PO\textsubscript{4}\textsuperscript{3−} took place on the surface of TiO\textsubscript{2} and the color of the floating HGMs–TiO\textsubscript{2} gradually changed from the original white to yellow (Fig. 1d), indicating the formation of Ag3PO4/TiO2 heterostructure onto HGMs.

3.2. Characterization of the composites

The morphologies of the composites were observed in Fig. 2. HGMs–TiO2 (Fig. 2a and b) had an uneven surface compared to the originally smooth HGMs (inset in Fig. 2a). From the higher magnification of Fig. 2b, it can be clearly seen that the surface of the HGMs was coated with a layer of TiO\textsubscript{2} particles. These indicated that TiO\textsubscript{2} was successfully coated on the HGMs. Fig. 2c showed the HGMs–1 : 1.5 was coated with more particles than Fig. 2b, and was enlarged to 500 nm as shown in Fig. 2d with an average particle size less than 50 nm [similar SEM images of HGMs–1 : 1 and HGMs–1 : 2 in Fig. S1†]. Fig. 2e and f were SEM images of TiO\textsubscript{2} with an average particle size of 30 nm and 1 : 1.5 TiO\textsubscript{2}/Ag3PO\textsubscript{4} with a particle size less than 50 nm, respectively.

The main component of the hollow glass microspheres is soda lime borosilicate.\textsuperscript{23} It can be clearly seen from Fig. 3 that the elements of HGMs–1 : 1.5 sample contained B, O, Na, Ca, Si originally contained in the HGMs. In addition, it also contained the C and N elements form the added APTES and the existence of Ti, Ag and P elements is verified. The EDS mapping qualitatively indicated that the particles supported on the HGMs contain Ti, Ag, and P elements, and the loadings of Ag and P elements were high.

The X-ray diffraction pattern of the raw material HGMs (Fig. 4a) has broad and weak diffraction peaks at 15–40°, but no characteristic diffraction peaks. The diffraction peak of TiO\textsubscript{2} (Fig. 4b) is the same as that of anatase TiO\textsubscript{2} in the JCPDS (No. 21-1272) standard spectrum library,\textsuperscript{24} and the XRD pattern of HGMs–TiO\textsubscript{2} (Fig. 4c) shows the coexistence of HGMs and anatase TiO\textsubscript{2} diffraction phase, indicating the formation of HGMs–TiO\textsubscript{2} composites. The crystal sizes of the (101) diffraction peak of TiO\textsubscript{2} and HGMs–TiO\textsubscript{2} obtained from the Scherrer formula were 34.7 nm and 24.3 nm, which were in good agreement with the observation by SEM. The smaller particle size of TiO\textsubscript{2} supported on HGMs, in comparison with that of unsupported TiO\textsubscript{2}, may be attributed to the pre-adsorption of Ti\textsuperscript{4+} onto the aminated HGMs surface via the electrostatic attraction with –NH\textsubscript{2} by lone pair of electrons to limit the growth of TiO\textsubscript{2} particles. The X-ray diffraction peak of pure Ag3PO4 (Fig. 4g) was matched with body-centered cubic Ag3PO4 crystal [JCPDS No. 06-0505].\textsuperscript{25} As shown in Fig. 4h, the XRD spectrum contained all the characteristic diffraction peaks of Ag3PO4, but only contained a characteristic diffraction peak of the anatase TiO\textsubscript{2} (101) face, which might be due to the fact that TiO\textsubscript{2} was an inner layer coated with Ag3PO4, and the intensity of other characteristic diffraction peaks was weak. Therefore, the XRD pattern of 1 : 1.5 TiO\textsubscript{2}/Ag3PO\textsubscript{4} composite was basically expressed as the spectrum of Ag3PO4. The XRD patterns of
HGMs-1 : 1 (Fig. 4d), HGMs-1 : 1.5 (Fig. 4e) and HGMs-1 : 2 (Fig. 4f) show the coexistence of HGMs and $\text{Ag}_3\text{PO}_4$ diffraction phases, indicating that $\text{Ag}_3\text{PO}_4$ was loaded on the surface of HGMs. Compared with the XRD pattern of 1 : 1.5 TiO$_2$/Ag$_3$PO$_4$ composite (Fig. 4h), the TiO$_2$ diffraction peak was weaker and the diffraction peak of TiO$_2$ (101) plane in the three ratios of HGMs–TiO$_2$/Ag$_3$PO$_4$ composites could be covered by 15–40° wide diffraction peaks of the raw material HGMs. In summary, Ag$_3$PO$_4$ had been coated on the surface of HGMs–TiO$_2$.

The optical properties of HGMs, HGMs–TiO$_2$, TiO$_2$, HGMs–TiO$_2$/Ag$_3$PO$_4$ composites and pure Ag$_3$PO$_4$ were determined by UV-visible diffuse reflectance spectroscopy (Fig. 5). HGMs (Fig. 5a) had a certain UV absorption at wavelengths below 400 nm and almost no absorption in the visible wavelength range. Pure TiO$_2$ (Fig. 5c) absorbed ultraviolet light at wavelengths less than 385 nm, consistent with previous reports. HGMs–TiO$_2$ (Fig. 5b) can absorb ultraviolet light less than 350 nm, which has a certain blue shift relative to TiO$_2$, which may be related to carrier HGMs. And pure Ag$_3$PO$_4$ (Fig. 5g) absorbed visible light less than 530 nm, which is equivalent to a band gap energy of 2.5 eV, in good agreement with the literature. The three ratios of HGMs–TiO$_2$/Ag$_3$PO$_4$ composites (Fig. 5d, e and f) showed characteristic absorption peaks of pure TiO$_2$ in the ultraviolet wavelength range of less than 350 nm and a certain intensity absorption in the visible region, indicating the as-prepared HGMs–TiO$_2$/Ag$_3$PO$_4$ composites can be used for visible light photocatalytic reaction.

The actual Ag$_3$PO$_4$ loadings of HGMs–TiO$_2$/Ag$_3$PO$_4$ composites, including HGMs-1 : 1, HGMs-1 : 1.5 and HGMs-1 : 2, were determined by AAS and listed in Table 1.
the reactants increased, the measured Ag₃PO₄ loading increased in the order of HGMs-1 : 1, HGMs-1 : 1.5, and HGMs-1 : 2. However, the actual load rate of Ag₃PO₄ decreased in turn and the degree of decline was not obvious. When TiO₂ was dispersed in silver nitrate solution, the negatively charged surface can adsorb Ag⁺ to the surface by electrostatic attraction, which was beneficial to the increase of Ag₃PO₄ loading rate and form floating HGMs‒TiO₂/Ag₃PO₄ composites. The loading ratios of the three proportional composites are similar, indicating that the titanium dioxide surface provides sufficient active sites to interact with Ag⁺.

3.3. Photocatalytic properties for the degradation of methylene blue (MB) solutions

The effect of different ratios of TiO₂ and Ag₃PO₄ on the photocatalytic activity of floating HGMs‒TiO₂/Ag₃PO₄ photocatalysts was compared by measuring the photodegradation rate of MB under visible light irradiation by simulating sunlight with a xenon lamp. The decolorization rate of MB as a function of time was shown in Fig. 6a. Taking the MB solution without any photocatalyst as a blank control, it can be seen from the figure that the MB solution is difficult to self-pyrolysis under illumination. Prior to illumination, the MB solutions containing raw material HGMs, different ratios of HGMs‒TiO₂/Ag₃PO₄ composites, pure TiO₂ or Ag₃PO₄ or TiO₂/Ag₃PO₄ photocatalyst were placed in the dark for 60 min to achieve the adsorption–desorption equilibrium between the surface of photocatalysts and the MB. In the absence of irradiation, the decrease in the concentration of the MB solution was entirely attributable to the adsorption of the photocatalyst rather than the photodegradation. The raw material HGMs can adsorb about 8% of MB molecules result from the adsorption of dye cations by its surface Si–OH. TiO₂ and HGMs-1 : 0 almost completely adsorbed the MB in the solution without

**Fig. 4** X-ray diffraction patterns of HGMs (a), TiO₂ (b), HGMs‒TiO₂ (c), HGMs-1 : 1 (d), HGMs-1 : 1.5 (e), HGMs-1 : 2 (f), pure Ag₃PO₄ (g) and 1 : 1.5 TiO₂/Ag₃PO₄ (h).

**Fig. 5** UV-Vis diffuse reflectance spectra of HGMs (a), HGMs‒TiO₂ (b), TiO₂ (c), HGMs-1 : 1 (d), HGMs-1 : 1.5 (e), HGMs-1 : 2 (f) and pure Ag₃PO₄ (g).
illumination, because MB is a cationic dye and the negatively charged surface of TiO\(_2\) can adsorb the positively charged MB\(^+\) in the solution to the surface of TiO\(_2\) by electrostatic attraction.\(^{38}\) During the experiment, it was observed that the color of TiO\(_2\) and HGMs-1:0 changed from the original white to blue. In addition, the TiO\(_2\)/Ag\(_3\)PO\(_4\) photocatalyst could also adsorb nearly 80% of MB in the dark, which was also caused by the electrostatic adsorption of TiO\(_2\). The percentages of MB adsorbed by HGMs-1:1, HGMs-1:1.5 and HGMs-1:2 samples in the dark were 35%, 39% and 48%, respectively, and their MB adsorption capacity enlarged with the increasing of Ag\(_3\)PO\(_4\) ratios. After 90 min of exposure to visible light, the degradation of MB was as follows: HGMs-1:1.5 ≈ TiO\(_2\)/Ag\(_3\)PO\(_4\) (96%) > HGMs-1:2 (92%) > HGMs-1:1 (86%) > Ag\(_3\)PO\(_4\) (84%). For the floating HGMs-TiO\(_2\)/Ag\(_3\)PO\(_4\) photocatalysts, the decolorization rate within 90 min was better than that of the single Ag\(_3\)PO\(_4\) photocatalyst. The absorbance of the MB solution added with HGMs after the light was substantially unchanged, indicating that HGMs had no photocatalytic activity for MB. In addition, the floating characteristics of as-prepared HGMs-1:1.5 photocatalyst can be clearly seen from the inset of Fig. 6c, and the 5 mg L\(^{-1}\) MB solution could completely fade to a colorless solution after visible-light irradiation for 90 min, obviously indicating that HGMs-1:1.5 had excellent photocatalytic performance.

Kinetically, when the concentration of MB dye was very low, the kinetic properties of its photocatalytic degradation were in accordance with the Langmuir–Hinshelwood model, which expression is \(v = \frac{dC}{dt} = \frac{k_r K C}{1 + K C}\). In this formula, \(v\), \(k_r\), \(K\) and \(C\) are the reaction rate, reaction rate constant, adsorption coefficient and the reactant concentration, respectively. When \(C\) is very small, \(v = k_r K C = k C\) and \(\ln \frac{C_0}{C} = kt\) is obtained. \(C_0\) and \(C\)

**Fig. 6** (a) Photocatalytic degradation curve of 5 mg L\(^{-1}\) MB, (b) the kinetic fit of the MB degradation by 2 g L\(^{-1}\) HGMs-1 : 0, HGMs-1 : 1, HGMs-1 : 1.5, HGMs-1 : 2, pure Ag\(_3\)PO\(_4\) and TiO\(_2\)/Ag\(_3\)PO\(_4\), (c) digital picture of 60 mL 5 mg L\(^{-1}\) MB dye solution photo-catalytically degraded by 0.12 g HGMs-1 : 1.5 before (left) and after (right) 90 min of visible-light illumination.
are the concentrations of reactant at time 0 and \( t \), and \( k \) is the apparent constant (first order rate). According to Beer–Lambert Law, \( C/C_0 \) is the ratio of the MB solution absorbance at each time interval to the absorbance of initial dye solution. The process of photocatalytic degradation of MB solution follows pseudo-first-order kinetic model. The photodegradation rate \( k \) is fitted by \( \ln(C/C_0) \) versus \( t \) and the slope of the fitted line is the photocatalytic rate \( k \), as shown in Fig. 6b. The apparent rate constant \((k)\) for \( \text{TiO}_2/\text{Ag}_3\text{PO}_4 \) composite was 0.0182 min\(^{-1}\), larger than that of single \( \text{Ag}_3\text{PO}_4 \) catalyst \((k = 0.0131 \text{ min}^{-1})\). The \( k \) of \( \text{HGMs-1:1} \), \( \text{HGMs-1:1.5} \) and \( \text{HGMs-1:2} \) were 0.0170 min\(^{-1}\), 0.0288 min\(^{-1}\), and 0.0240 min\(^{-1}\), respectively. The \( \text{HGMs-1:1.5} \) composite with a mass ratio of \( \text{TiO}_2 \) and \( \text{Ag}_3\text{PO}_4 \) of 1 : 1.5 had the highest rate constant \( k \), which means this photocatalyst had the highest photocatalytic activity. While the \( \text{Ag}_3\text{PO}_4 \) content of floating \( \text{HGMs-1:1.5} \) was less than pure \( \text{Ag}_3\text{PO}_4 \) and \( \text{TiO}_2/\text{Ag}_3\text{PO}_4 \), the photocatalytic properties were better than pure \( \text{Ag}_3\text{PO}_4 \) and \( \text{TiO}_2/\text{Ag}_3\text{PO}_4 \), which could be attributed to the larger light contact area.

The stability of the photocatalyst is one of the important parameters to measure its practicality. It is well-known that the \( \text{Ag}_3\text{PO}_4 \) photocatalyst is easily photo-etched under light conditions and reduced to Ag \((\text{Ag}^+ + e^- \rightarrow \text{Ag}^0)\), which affects its photocatalytic activity. As shown in Fig. 7, after five consecutive cycles to degrade MB, \( \text{Ag}_3\text{PO}_4 \) almost lost its activity, while \( \text{HGMs-1:1.5} \) still maintained a decolorization rate of about 75%, showing higher degradation efficiency and stability than pure \( \text{Ag}_3\text{PO}_4 \) and indicating that the presence of \( \text{HGMs} \) and the formation of heterostructure with \( \text{TiO}_2 \) were beneficial for improving photodegradation efficiency and stability of \( \text{Ag}_3\text{PO}_4 \). The floating \( \text{HGMs-TiO}_2/\text{Ag}_3\text{PO}_4 \) composites as a photocatalyst can not only greatly reduce the input of the \( \text{Ag}_3\text{PO}_4 \) catalyst and cost, but also significantly improve the photodegradation efficiency. In addition, it was easy to recycle in practical applications and had stable photocatalytic activity, indicating that the floating \( \text{HGMs-TiO}_2/\text{Ag}_3\text{PO}_4 \) composite can be used as an effective and promising visible light photocatalyst.

### 3.4. Possible mechanism of the improved photocatalytic activity

Several reasons may account for the enhanced photocatalytic activity of the floating \( \text{HGMs-TiO}_2/\text{Ag}_3\text{PO}_4 \) photocatalysts. Firstly, the \( \text{HGMs-1:1.5} \) photocatalyst exhibited more enhanced visible light photocatalytic efficiency than that of pure \( \text{Ag}_3\text{PO}_4 \) and \( \text{TiO}_2/\text{Ag}_3\text{PO}_4 \) because \( \text{HGMs-1:1.5} \) could float on the dye solution to enlarge the contact area with light, speeding up the excitation of visible light photons under the same test conditions. Secondly, with \( \text{HGMs} \) as the carrier, \( \text{HGMs-TiO}_2/\text{Ag}_3\text{PO}_4 \) composite can be uniformly dispersed on the surface of \( \text{HGMs} \), which can not only enlarge the active surface area of the photocatalyst, but also increase lattice defects to generate new active centers, and improve its photocatalytic performance. Thirdly, \( \text{Ag}_3\text{PO}_4 \) itself had excellent photocatalytic performance due to the high dispersion of the conduction band \((\text{CB}, + 0.45 \text{ V} \text{ vs. NHE})\) and the large negative charge induction effect of \( \text{PO}_4^{3-} \). However, with the prolongation of irradiation time, \( \text{Ag}_3\text{PO}_4 \) was easily reduced to Ag and Ag replaces active sites of original \( \text{Ag}_3\text{PO}_4 \), so the number both of photogenerated electrons \((e^-)\) and holes \((h^+)\) was reduced and the photocatalytic performance was degraded. The combination of \( \text{Ag}_3\text{PO}_4 \) and \( \text{TiO}_2 \) promoted the separation of \( e^- \) and \( h^+ \), and its photocatalytic activity was enhanced. The possible photocatalytic mechanism of \( \text{HGMs-TiO}_2/\text{Ag}_3\text{PO}_4 \) is depicted in Fig. 8. From the electron band structure of \( \text{Ag}_3\text{PO}_4 \) and \( \text{TiO}_2 \), the valence band \((\text{VB})\) potential of \( \text{Ag}_3\text{PO}_4 (+2.9 \text{ eV vs. NHE}) \) is more positive than that of \( \text{TiO}_2 (+2.7 \text{ eV vs. NHE}) \), and the conduction band potential of \( \text{TiO}_2 (-0.3 \text{ eV vs. NHE}) \) is more negative than that of \( \text{Ag}_3\text{PO}_4 (+0.45 \text{ eV vs. NHE}) \), which means that \( e^- \) and \( h^+ \) will be thermodynamically transferred to the CB of \( \text{Ag}_3\text{PO}_4 \) and the VB of \( \text{TiO}_2 \), respectively.\(^{33-35}\) Under visible light irradiation, the \( e^- \) in the VB of \( \text{Ag}_3\text{PO}_4 \) absorbed energy from the photons \((h\nu)\) to the CB and then further migrated to the surface of the \( \text{Ag}_3\text{PO}_4 \) particles, while \( h^+ \) was generated on the VB and rapidly transferred to the \( \text{TiO}_2 \) particles. The separation of \( e^- \) \((\text{in } \text{Ag}_3\text{PO}_4)\) and \( h^+ \) \((\text{in } \text{TiO}_2)\) prevents charge neutralization, and the
close contact between the two semiconductor particles in the HGMs–TiO2/Ag3PO4 composite promotes this interface charge transfer and separation, improving the photocatalytic activity. In addition, when the mass ratio of TiO2 and Ag3PO4 was 1 : 1.5 among the three HGMs–TiO2/Ag3PO4 samples, the photocatalytic activity of the sample reached an optimum value. When the content of Ag3PO4 exceeds this optimum value, the counteraction effect associated with e– – h+ recombination across TiO2/Ag3PO4 interface may mediate carrier transfer to compromise the overall charge separation efficiency and lead to the depressed photocatalytic efficiency of type-II TiO2/Ag3PO4 semiconductor heterostructures.19 At the same time, the oxidizing h+ in VB can directly oxidize the organic dye MB or indirectly oxidize MB by oxidizing H2O molecules adsorbed to the surface of the photocatalyst to form strong oxidizing –OH radicals14,46 in that the VB level of TiO2 is more positive than both 1.99 eV for OH–/–OH and 2.37 eV for H2O/O–/–OH.6 Furthermore, reducing e– in CB can reduce the adsorbed O2 molecules, and generate strong oxidizing reactive oxygen species (ROS, such as ·O2–, HO2·, H2O2, ·OH, etc.) to oxidatively degrade MB. However, the redox potential of the ROS reaction (such as O2/H2O2, +0.67 V) is similar to the potential of Ag3PO4/Ag (+0.45 V), indicating that it will compete with the reduction reaction of Ag3PO4, so the photo-etching of Ag3PO4 semiconductor is still inevitable. Ag3PO4 are dispersed on the surface of HGMs to increase the active sites of photocatalytic reaction and the unique floating property of the photocatalyst enlarge the contact area of the HGMs–TiO2/Ag3PO4 with light. Moreover, the combination of Ag3PO4 and TiO2 on the surface of HGMs promotes the separation of photogenerated e– and h+, enhancing the photocatalytic performance and stability of the floating HGMs–TiO2/Ag3PO4 composite.

4. Conclusions

In this work, the floating HGMs–TiO2 was prepared by hydrothermal synthesis. Since TiO2 only responded to ultraviolet light, Ag3PO4 was loaded into HGMs–TiO2 composite by ion exchange method to form visible light-responsive floating HGMs–TiO2/Ag3PO4 composites. The photocatalyst had the advantages of low density and high dispersion due to the use of micron-sized HGMs as a carrier, which made it float on the surface of the organic dye solution, enlarge the contact area with light and easy to recover. With MB as the photodegradation target, when the mass ratio of TiO2 to TiO2/Ag3PO4 is 1 : 1.5, the photocatalytic activity of the floating photocatalyst was better than that of pure Ag3PO4 and TiO2/Ag3PO4, and its cycle stability was enhanced compared with single Ag3PO4. The floating HGMs–TiO2/Ag3PO4 composites prepared by complexing TiO2 with Ag3PO4 to form a heterojunction have potential application prospects in the photocatalyzed efficient degradation of organic pollutants under the visible-light irradiation, which greatly reduce the cost and enhance the photocatalytic performance.
