Preparation of S–N co-doped CoFe$_2$O$_4$@rGO@TiO$_2$ nanoparticles and their superior UV-Vis light photocatalytic activities

Fengyu Wei, * Hui Wang, Wei Ran, Tao Liu and Xueting Liu

A S–N co-doped CoFe$_2$O$_4$@rGO@TiO$_2$ (CFGT-S/N) nanocomposite was successfully synthesized via a facile vapor-thermal method. XRD, XPS, FT-IR and FETEM results confirmed that N and S were co-doped into the lattice of TiO$_2$. Photocatalytic tests indicated that CFGT-S/N exhibited excellent UV-Vis photocatalytic activity for decompositions of different organic dyes, including methyl orange (MO), rhodamine B (RhB) and methylene blue (MB). Particularly, the photocatalytic degradation rate of MO was about 33% higher than that when using P25 under visible light irradiation. The higher UV-Vis light photocatalytic activity of CFGT-S/N can be attributed to the synergetic effects of the strong absorption of visible light, the narrow band gap, improved separation of photo-generated electron/hole pairs, and the enhancement of the enrichment of pollutant dye molecules by S, N co-doping, CoFe$_2$O$_4$ and rGO. Moreover, this photocatalyst was superparamagnetic, which enables it to be easily recovered by an external magnetic field, and maintained stable photocatalytic efficiency over five cycles. Hence, CFGT-S/N with its highly efficient, recoverable and stable photocatalytic properties shows great potential for environmental treatment.

1 Introduction

Titanium dioxide (TiO$_2$) is a conventional photocatalyst widely used for the degradation of organic pollutants in wastewater, because of its powerful oxidizing power, high benefit-to-cost ratio, nontoxicity, and its extended stability against photo- and chemical corrosion. However, TiO$_2$ can be activated only under UV-light irradiation due to its wide bandgap (E$_g$ = 3.2 eV for anatase TiO$_2$), which might hinder its practical application. To improve the utilization of solar light, a lot of researchers have shown that doping TiO$_2$ with non-metal elements such as C, N, F, S and B could be an effective strategy. In order to further achieve photocatalytic activity, co-doping TiO$_2$ with two or three non-metal elements has attracted much attention, as well as N, F, S, N and C, and so on. Density functional theory (DFT) calculations have shown that the doping S, N elements could lower the band gap of TiO$_2$ effectively. Our previous work also proved that a S–N co-doped anatase nanosized TiO$_2$ photocatalyst exhibited a high activity for the decomposition of methyl orange under both UV-light and Vis-light irradiation comparing to S-doped TiO$_2$ and undoped TiO$_2$ due to the synergetic effects induced by N and S co-doping.

In recent years, graphene has attracted much attention because it is an ideal electron acceptor for nanocomposites during the photocatalytic process, which can slow the recombination of photoexcited electron–hole pairs, increasing the charge transfer rate of electrons. What is more, the high surface area of graphene based on nanocomposites can provide more active sites to adsorb reactant molecules. Many researchers have indicated that graphene–TiO$_2$ hybrid materials exhibited enhanced photoactivity over bare TiO$_2$ during decomposition of organic dyes in water.

Although the photocatalytic performance of graphene–TiO$_2$ nanocomposites has improved, separation and recycling is still a major bottleneck for their application. To solve the separation of the catalyst, a method to integrate graphene–TiO$_2$ with magnetic nanocomposites, such as Fe$_3$O$_4$, CoFe$_2$O$_4$, ZnFe$_2$O$_4$, and so on, was proposed, which enables recycling and removal of the magnetic particles by an external magnetic field. Wherein, cobalt ferrite (CoFe$_2$O$_4$) with a spinel crystallographic structure and a narrow band-gap exhibited a superior magnetic behavior and visible light response. But these TiO$_2$ and magnetic nanoparticles loaded on the surface of graphene sheets may have the defects of detachment and could not effectively prevent photodissolution and recombination of electron–hole pairs, which decreases their photocatalytic activity. Recently, Yang et al. synthesized a ternary nanocomposite with TiO$_2$ nanoparticles anchored on reduced graphene oxide (rGO)-encapsulated Fe$_3$O$_4$ spheres (Fe$_3$O$_4$@rGO@TiO$_2$) by an electrostatic layer-by-layer method.
The results showed that the three components of Fe₃O₄@rGO@TiO₂ possessed synergistic effect, and the catalyst exhibited enhancing catalytic activity for the degradation of MB. However, its preparation was more complicated, and visible light activity was high only in the presence of H₂O₂.

Recently, our group has prepared a magnetic CoFe₂O₄@rGO core–shell nanocomposite as an efficient adsorbent for removal of organic pollutants, which had excellent adsorption properties and selectivity. On this basis, we provided a facile and feasible way to synthesize S and N co-doped CoFe₂O₄@rGO@TiO₂ composites, which possessed excellent photocatalytic activity under both ultraviolet and visible light irradiation. Physical and chemical characterizations of catalysts were conducted, and the photocatalytic activity was evaluated in the photocatalytic degradation of organic dyes. This work may be helpful for preparing novel UV-light and Vis-light photocatalysts with good performance and recoverable ability.

2 Experimental

2.1 Materials and chemicals

Graphite powder, ethylene glycol (EG), polyethylene 2000 (PEG 2000), anhydrous ferric chloride (FeCl₃), cobalt(II) chloride hexahydrate (CoCl₂·6H₂O), sodium acetate (NaAc), tetraethylammonium (TBOT), thiourea, methylene blue, methylene orange, rhodamine B and other reagents were purchased from Sinopharm Group Chemical Reagent Co (China). All chemicals used were analytical grade and were used without further purification.

2.2 Preparation of the S, N co-doped CoFe₂O₄@rGO@TiO₂ nanocomposite

Graphene oxide was prepared by a modified Hummers method. The preparation of the binary core–shell composites CoFe₂O₄@rGO (CFG) using a one-step hydrothermal method has been reported by our laboratory. The S–N co-doped CoFe₂O₄@rGO@TiO₂ nanocomposite was synthesized via the vapor-thermal method with minor modifications. Briefly, 0.8 mL of TBOT and 60 mg of thiourea were added into 10 mL ethanol, and then the beaker was placed in an ultrasonic bath to completely dissolve the resulting mixture. After that, 50 mg of the as-prepared CFG was added into the above clear solution with the help of ultrasound for two hours, and then the suspension was transferred into a 25 mL beaker, which was placed into a 100 mL stainless steel autoclave with a Teflon-liner filled with de-ionized water. The autoclave was heated to 180 °C and kept for 36 h. During the reaction, the de-ionized water vaporized and led to TBOT hydrolysis. At the end of the reaction, the autoclave was cooled to ambient temperature, and the precipitate obtained was repeatedly washed with de-ionized water and ethanol, and then dried at 60 °C in a vacuum oven for 8 h. Furthermore, undoped CoFe₂O₄@rGO@TiO₂ (CFG) was synthesized as above without thiourea.

2.3 Characterization

X-ray powder diffraction (XRD) was used to characterize the phase structures and particle sizes of the as-prepared samples, using a Rigaku D/max 2500 pc X-ray diffractometer with Cu Kα radiation (λ = 1.54056 Å) at a scan rate of 0.02° s⁻¹. The morphology and structure of the catalysts were examined by field emission transmission electron microscopy (HRTEM, JEM-2100F, Japan). Fourier transform infrared (FT-IR) spectra on KBr pellets of the samples were recorded on a PE-100 FT-IR spectrometer at a resolution of 4 cm⁻¹. Diffuse reflectance spectra (DRS) of samples were obtained using a Varian Cary 5000 spectrometer equipped with a Cary Labsphere DRA-CA-301 DR accessory. Photocurrent density was measured by a CHI electrochemical analyzer (CHI 660e, China) in a standard three-electrode configuration, with the working electrode (an effective area of 2 cm²), a platinum foil as the counter electrode, and a saturated calomel electrode (SCE) as the reference electrode. Na₂SO₄ (0.01 M) was used as the electrolyte. X-ray photoelectron spectroscopy (XPS) was conducted with an ESCALAB250 (Vacuum Generators) spectrometer using monochromatized Al K X-rays (150 W). The magnetic properties of the samples were determined by a vibrating sample magnetometer (VSM, Lake Shore 7410, USA) at a temperature of 300 K.

2.4 Photocatalytic experiments

The photocatalytic performance of the as-prepared samples was evaluated by measuring the decomposition of a 5 mg L⁻¹ organic dyes aqueous solution. UV-light photocatalytic experiments were carried out in a homemade jacketed reactor under a 25 W low-pressure mercury lamp as the UV-light source, and the light intensity was 80 μW cm⁻². 0.18 g of the as-prepared sample was dispersed in 900 mL of the aqueous dye solution. The Vis-light photocatalytic experiments were carried out in a 250 mL jacketed reactor under a 300 W Xe lamp with a filter to remove light of wavelengths below 420 nm as the Vis-light source, and the light intensity was 240 mW cm⁻². 0.08 g of the as-prepared sample was dispersed in 100 mL of the aqueous dye solution. Prior to photocatalytic experiments, the catalysts were settled in suspension for 30 min in the dark for the adsorption equilibrium. The concentration of the organic dye solution was quantified by a Shimadzu UV-2550 (Japan) spectrophotometer at the maximum absorption wavelength of different dyes (λmax (MO) = 464 nm, λmax (MB) = 663 nm and λmax (RhB) = 554 nm). To evaluate the photocatalyst stability, CFGT-S/N were magnetically separated, washed, dried, and reused for the next cycle under the same conditions. The used CFGT-S/N after five cycles was named CFGT-S/N-5. The quenching tests of the active species for the photoreaction were carried out by using different scavengers. The photocatalytic reaction rate constants (k) used the pseudo-first-order model as expressed as eqn (1)

\[ \ln(C/C_0) = -kt \]  

(1)

where C and C₀ were the actual and initial concentrations of the MO solution, respectively, and k was the apparent reaction rate constant.
constant. To ensure the accuracy of the experiment, each experiment was carried out three times.

3 Results and discussion

3.1 XRD analysis and FT-IR measurements

The XRD patterns of CFG, CFGT, CFGT-S/N and CFGT-S/N-5 are shown in Fig. 1(a). It can be easily found that the diffraction peaks of CFG at 2θ = 30.0°, 35.4°, 43.5°, 57.2° and 62.7° matched the reflections of (220), (311), (400), (511) and (440), respectively, corresponding to the cubic spinel structure of CoFe2O4 [JCPDS #79-1744].

No apparent diffraction peaks of GO were observed. This was because the crystal growth of the (001) dihedral site CoFe2O4 between the interlayer of GO destroyed the regular layer stacking, leading to the exfoliation of GO and the disappearance of the (001) diffraction peak during the hydrothermal reaction. After coating with a TiO2 layer, a new crystalline phase of anatase TiO2 (JCPDS #21-1272) occurred in the CFGT. However, the diffraction peaks of CoFe2O4 were weakened, which suggested that most of the CoFe2O4 NPs were coated with a TiO2 layer. For the co-doped TiO2 NPs (CFGT-S/N), the main diffraction peak at 2θ = 35.4° of CoFe2O4 almost disappeared, suggesting that its saturation magnetization may be decreased. The unit cell volumes of CFGT and CFGT-S/N determined by the Debye–Scherrer equation were 0.1317 and 0.1359 nm3, which indicated that S and N had been successfully co-doped into the TiO2 lattice.

As shown in Fig. 1(a), P25 mainly responded to the ultraviolet region. However, the absorption of TiO2-SN (T-SN) in the visible light region was significantly increased due to co-doping with N and S elements. CoFe2O4 (CF) had broad and obvious absorption ranging in a wide region from 300 to 800 nm owing to its narrow bandgap.

Compared with CFG, the absorption intensity of CFGT decreased slightly, which can be attributed to the mixing effect of the two semiconductors introducing defect levels. Furthermore, it was found that CFT showed a relatively lower absorption in the visible light region (550–800 nm) than CFGT. After co-doping, the absorption of CFGT-S/N in the visible region improved, hence enhancing the photocatalytic activity. The plots of the transformed Kubelka–Munck function versus the energy of light were shown in Fig. 2(b). The band gap values of P25, T-SN, CF, CFG, CFT, CFGT and CFGT-S/N were 3.29, 3.08, 1.55, 1.45, 2.33, 2.21 and 2.15 eV, respectively. The results indicated that S, N co-doping,

3.2 UV-Vis DRS spectra analysis

To further investigate the optical properties of the prepared catalysts, the UV-Vis DRS spectra were recorded (Fig. 2). As shown in Fig. 2(a), P25 mainly responded to the ultraviolet region. However, the absorption of TiO2-SN (T-SN) in the visible light region was significantly increased due to co-doping with N and S elements. CoFe2O4 (CF) had broad and obvious absorption ranging in a wide region from 300 to 800 nm owing to its narrow bandgap. CFG NPs showed a stronger light absorption than CF, implying that the introduction of rGO can enhance the visible light absorption. Compared with CFG, the absorption intensity of CFGT decreased slightly, which can be attributed to the mixing effect of the two semiconductors introducing defect levels. Furthermore, it was found that CFT showed a relatively lower absorption in the visible light region (550–800 nm) than CFGT. After co-doping, the absorption of CFGT-S/N in the visible region improved, hence enhancing the photocatalytic activity.
CoFe$_2$O$_4$ and rGO can enhance the visible light absorption of CFGT-S/N.

3.3 Morphology and structure analysis

The morphological structure of CFGT-S/N was further verified by FETEM observation. As can be seen in the inset of Fig. 3(a), binary CFG nanoparticles with a core–shell structure can be observed. After TiO$_2$-S/N coating, CFGT-S/N nanocomposites had a spherical morphology and their grain sizes were 160–220 nm in diameter. From the HRTEM image of the CFGT-S/N hybrid (Fig. 3(b)), two different lattices were observed with $d$ spaces of 2.54 and 3.50 Å, corresponding to the (311) plane of CoFe$_2$O$_4$ and the (101) plane of anatase TiO$_2$, respectively, which were similar to the literature values.

3.4 XPS analysis

In order to determine the surface chemical compositions, XPS analysis was carried out. As shown in Fig. 4(a), CFGT contained Fe, Co, C, Ti and O, while CFGT-S/N not only contained Fe, Co, C, Ti, and O, but also S and N, which indicated that S and N had been co-doped into the CFGT-S/N hybrids. As shown in Fig. 4(b), the XPS spectrum of Fe 2p depicted two main broad peaks, 710.9 eV for Fe 2p$_{3/2}$ and 724.0 eV for Fe 2p$_{1/2}$, and a small peak at 714.3 eV for Fe 2p$_{3/2}$, which could be due to the contributions from Fe$^{3+}$ ions. From Fig. 4(c), the peaks of 779.0 eV, 781.0 eV and 794.2 eV were associated with Co$^{2+}$ ions.

3.5 Magnetic characterization

To evaluate the magnetic separation capacity, the magnetic hysteresis loops of CFG, CFGT and CFGT-S/N nanoparticles were measured at room temperature, as shown in Fig. 5. The saturation magnetization ($M_s$) values of the CFG, CFGT and CFGT-S/N were 32.74, 2.95 and 1.73 emu g$^{-1}$, respectively. It can be found that the non-magnetic coating TiO$_2$ layer affected the magnetic properties of the CoFe$_2$O$_4$ particles. Fortunately, the maximum saturation magnetization of 1.73 emu g$^{-1}$ was strong enough to separate CFGT-S/N from solution with the help of an external magnetic force. The magnetic separability was tested by placing a magnet near a glass bottle. The black product was rapidly attracted toward the magnet in a short period (the inset of Fig. 5), demonstrating the high magnetic sensitivity of the CFGT-S/N nanocomposites.

3.6 Photocatalytic activities

3.6.1 Photodegradation of MO. The photocatalytic activities of CFT, CFGT, CFGT-S/N, P25, and CoFe$_2$O$_4$ were tested.
using the degradation of MO under UV- and Vis-light irradiation and the results were displayed in Fig. 6. From Fig. 6(a), it can be seen that CF displayed poor UV-light photocatalytic activity and P25 exhibited the highest photocatalytic activity. For CFT, MO degradation rate was only 74% within 150 min, while for CFGT, 100% of MO was degraded due to the rGO acting as an acceptor of the electrons generated in the TiO$_2$ particles, suppressing the recombination of charges. After S, N co-doping, CFGT-S/N exhibited an improved photocatalytic activity compared to CFGT, and it took around 120 min to decompose MO completely. Furthermore, Fig. 6(b) illustrates that the photocatalytic reaction rate constants ($k$) onto CF, CFT, CFGT, CFGT-S/N and P25, were in turn 0.0009, 0.0081, 0.0133, 0.0192 and 0.1014 min$^{-1}$. Due to the lower content of TiO$_2$ in CFGT-S/N at the same dosage of catalysts, its rate constant $k$ was lower than that of P25. As shown in Fig. 6(c), almost no degradation of MO over bare CF and CFT was observed under visible light irradiation. Although CFGT exerted facile MO adsorption, it displayed less photocatalytic activity. Notably, CFGT-S/N exhibited better catalytic activity, and the degradation rate of MO reached 100% within 6 h. For P25, only 72% of MO was removed within 6 h. It can be seen from Fig. 6(d), the $k$ of CF, CFT, CFGT, CFGT-S/N and P25 was 0, 0, 0.0003, 0.0052 and 0.0039 min$^{-1}$, respectively. The $k$ of CFGT-S/N was 33% higher than that of P25 under visible light irradiation. It indicated that the prepared CFGT-S/N displayed an excellent photocatalytic activity no matter which light source (UV or Vis) was used.

3.6.2 Photodegradation of various dyes. The photodegradation of the different organic dyes on CFGT-S/N was further studied under UV- and Vis-light irradiation. Two kinds of anionic dyes (RhB and MB) were selected as other pollutants. To confirm whether dyes were not photodegraded by itself, a blank test was also carried out. As shown in Fig. 7(a), CFGT-S/N exhibited excellent UV-light photocatalytic activity, and it only
took 120 min to decompose various pollutants molecules completely. Under Vis-light illumination, the photocatalytic degradation rates of pollutants were still lower than those under UV-light illumination as shown in Fig. 7(b). Overall, the CFGT-S/N showed no selectivity to photocatalytic degradation for most organic pollutants, which was of great importance to practical applications.

### 3.6.3 Cycling photodegradation of MO

As a recyclable photocatalyst, high stability and facile separation of catalysts were also important for the photocatalytic nanomaterial in water remediation. Recycling photocatalytic experiments of CFGT-S/N were conducted, and the results are represented in Fig. 8(a and b). A 3-5 cycles, the degradation rates of MO were 96% and 92% of that for the first cycle under UV- and Vis-light illumination, respectively. This result implied that the as-prepared catalysts had an excellent chemical stability and could be recycled in the organic dyestuff wastewater purification.

### 3.7 Photocatalytic mechanism

To better understand the separation efficiency of the photo-generated electrons and holes of CFGT-S/N, we investigated its photoinduced charge transfer properties. Fig. 9(a) shows the photocurrent density variations of the P25, CFG, CFT, CFGT and CFGT-S/N electrodes with measured potential in Na2SO4 solution. The dark current densities in all cases can be negligible. Upon irradiation, a significant increase in the photocurrent density was observed throughout the potential window at the CFGT-S/N electrode. The saturated photocurrent density of the CFGT-S/N electrode was about 0.71 mA cm−2, higher than those of the CFGT (0.08 mA cm−2), CFT (0.05 mA cm−2), CFG (0.05 mA cm−2) and P25 (0.06 mA cm−2) electrodes by a factor of 11.8, 14.2, 14.2 and 8.9, respectively. This demonstrated that the separation rate of photo-generated electrons and holes increased because of the co-doping of S and N in the TiO2 network.

Furthermore, to verify the role of the reactive species under UV-Vis light irradiation over CFGT-S/N, different scavengers were employed in this study. They were benzoquinone (0.1 mM BQ) for the superoxide radical (O2•−), tert-butyl alcohol (0.1 mM TBA) for the hydroxyl radical (·OH), AgNO3 (0.01 mM) for photogenerated electrons (e−) and disodium ethylenediaminetetraacetate (0.1 mM EDTA) for photo-generated holes (h+). As shown in Fig. 9(b), upon the addition of BQ and EDTA, the degradation rates were greatly suppressed to 23% and 48%, respectively. After the addition of AgNO3, the photodegradation rate of MO decreased from 100% to 68%, indicating that e− was definitely produced and transferred from TiO2-SN to rGO in the photocatalytic reaction, which was consistent with the literature reports. Besides, a significant change was observed in the presence of TBA, displaying that ·OH as an oxidation species was also indeed photogenerated on catalyst surfaces. The results suggested that O2•−, h+, e− and ·OH were the main active species in the MO photocatalytic oxidation process.

On the basis of the above experimental results, a possible photocatalytic mechanism for CFGT-S/N under UV-Vis irradiation was proposed and is illustrated in Scheme 1. Upon UV-Vis irradiation, CoFe2O4 (1.55 eV) with a narrow bandgap energy...
could be easily excited from the valence band (VB) to the conduction band (CB), inducing the generation of electron–hole pairs (eqn (2)). Notably, the introduction of CoFe2O4 with superparamagnetic behavior was conducive to catalyst recyling. For TiO2, the co-doping of nitrogen and sulfur into the TiO2 lattice led to the formation of mid-gap energy levels such as N 2p and S 2p between the valence band (VB) of O 2p and the conduction band (CB) of Ti 3d and narrowed the bandgap energy to 3.08 eV, thereby TiO2-S/N can be excited easily by the photons (eqn (3)). The photoinduced electrons (e\textsuperscript{-}) from TiO2-S/N can be quickly transferred to the huge π–π network of rGO due to their excellent electron accepting and transporting properties, and then rGO (e\textsuperscript{-}) reacted with dissolved O2 to generate O2\textsuperscript{-} radicals (eqn (4) and (5)). This process can restrain effectively the electron–hole recombination on TiO2-S/N. Moreover, the h\textsuperscript{+} on the VB of TiO2-

---

**Fig. 7** Photodegradation of various dyes in the presence of CFGT-S/N under (a) UV- and (b) Vis-light irradiation.
TiO$_2$-S/N can be transferred to the VB of CoFe$_2$O$_4$ due to the lower potential energy of the VB of CoFe$_2$O$_4$, which can facilitate efficiently interface charge separation and hamper carrier recombination.\textsuperscript{44-51} As a result, these highly reactive oxygen species (ROS, such as O$_2$\textsuperscript{-}, h\textsuperscript{+} and ·OH) can effectively degrade MO adsorbed on CFGT-SN (eqn (7)). According to the above analysis, the relevant reactions on the surface of nanocomposite can be expressed as follows:

\begin{align}
\text{CoFe}_2\text{O}_4 + h\nu & \rightarrow \text{CoFe}_2\text{O}_4 (h^+ + e^-) \\
\text{TiO}_2\text{S/N} + h\nu & \rightarrow \text{TiO}_2\text{S/N} (h^+ + e^-) \\
\text{e}^- + \text{rGO} & \rightarrow \text{rGO} (\text{e}^-) \\
\text{rGO} (\text{e}^-) + \text{O}_2 & \rightarrow \text{O}_2^- \\
h^+ + \text{H}_2\text{O} & \rightarrow \text{H}^+ + \cdot\text{OH} \\
\text{MO} + \text{ROS} & \rightarrow \text{CO}_2 + \text{H}_2\text{O}
\end{align}

4 Conclusions

In summary, we have presented a simple and controllable way to synthesise magnetically separable S, N co-doped
Furthermore, the presence of CoFe₂O₄ in the hybrid helped the synthesized CFGT-S/N can be used as a composite photocatalyst were easily separated from the catalytic solution. Therefore, the catalyst particles to acquire ferromagnetic properties, and they were easily separated from the catalytic solution. Therefore, the synthesized CFGT-S/N can be used as a composite photocatalyst for the elimination of organic pollutants from waste water.
