Fabrication of Ag/AgBr/Ag₃VO₄ composites with high visible light photocatalytic performance

Wenxue Li,^a Qianlin Chen,^{id} *^{ab} Xianyu Lei^a and Shang Gong^a

Herein, Ag/AgBr/Ag₃VO₄ composites were synthesized by a simple continuous precipitation method. The obtained composites were characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM), energy dispersive spectrometry (EDS), X-ray photoelectron spectroscopy (XPS), UV-vis diffuse reflectance spectroscopy and photoluminescence spectroscopy (PL). Photocatalytic performance of the composites was assessed by the degradation of methyl orange (MO) and tetracycline hydrochloride (TC) under visible light, and the effects of different nominal mass ratios of AgBr and Ag₃VO₄ on the photocatalytic activity were investigated. The results showed that after 20 min of visible light irradiation ($\lambda > 420$ nm), the removal rate of MO in the presence of a 5 : 1 sample reached 98.6%. The EIS and photocurrent results demonstrated that the enhancement of the visible light photocatalytic activity was attributed to the efficient electron–hole pair separation. In addition, the scavenging reactions conducted via the addition of different scavengers confirmed that h^+ and $\cdot O_2^-$ were the main active species in the reaction. The present study offers potential for the degradation of contaminants.

1. Introduction

With the gradual development of industry and technology, serious environmental pollution and the scarcity of clean energy have become the most urgent problems. Various forms of organic wastewater are discharged into the environment every year; this has caused serious pollution to the environment. Moreover, the compound structure of organic pollutants is quite stable in water, difficult to decompose, and resistant to biodegradation.^{1–4} Some advanced oxidation processes, such as the Fenton oxidation,⁵ photocatalytic oxidation⁶ and photo-electro-catalytic technology,^{7,8} have been developed to solve the problem of wastewater pollution. Photocatalytic oxidation has the advantages of mild reaction conditions, no secondary contamination, and low energy consumption in the reaction process and thus has become one of the best green environmental protection technologies to be developed.^{9–11} To date, the most commonly used photocatalyst is TiO₂ that has excellent chemical stability and is abundant, non-toxic, and low-cost.^{12,13} However, TiO₂ is a photocatalyst with a wide band gap (3.2 eV), and its low solar energy utilization and quantum yield limit its practical application.^{14–16} Researchers have tried to develop a variety of photocatalytic materials with effective visible light responses, which has already been a key problem in the field of photocatalysis. In the past few years, many studies have been conducted on

silver-based photocatalysts, including Ag₂O,¹⁷ Ag₃PO₄,¹⁸ Ag₂CO₃,¹⁹ AgX (X = Cl, Br, I),²⁰ and Ag₆Si₂O₇,^{21,22} with excellent properties in the degradation of organic pollutants.

AgBr is a traditional photosensitive material whose properties of light decomposition greatly limit its application as a photocatalyst.^{23,24} Studies have shown that AgBr can reduce its surface component Ag⁺ to Ag⁰ under illumination to form Ag/AgBr, and the photocatalytic activity of Ag/AgBr is improved because Ag⁰ exhibits a high efficiency plasmon resonance effect (SPR) in the visible region.²⁵ Since the electron–hole pairs of AgBr rapidly combine, AgBr is generally mixed with other materials to improve its photocatalytic performance. Chen *et al.*²⁶ synthesized a AgBr@rGO composite by coating AgBr on graphene nanosheets *via* a precipitation method; this increased the separation rate of the photogenerated charges. Upon further loading AgBr onto the graphene hydrogel to form a 3D network structure with good adsorption performance, bisphenol A rapidly degraded under the synergistic effect of adsorption and photocatalytic degradation. Lin *et al.*²⁷ studied the decoration of nano Ag@AgBr particles on flower-like Bi₂WO₆ using an oil-in-water self-assembly method to form Ag@AgBr/Bi₂WO₆ composites, whose degradation rate for MB was 1.29 times that of Ag@AgBr. In summary, it can be clearly concluded that the AgBr-based composite materials show better photocatalytic activity in the degradation of organic pollutants.

Ever since Konta *et al.*²⁸ have conducted a pioneering study on Ag₃VO₄ and found that Ag₃VO₄ can split H₂O into O₂ and H₂, the narrow band gap monoclinic scheelite Ag₃VO₄ (~2 eV) has attracted wide attention of researchers. Due to its special band structure, the electron–hole recombination rate of pure Ag₃VO₄

^aSchool of Chemistry and Chemical Engineering, Guizhou University, Guiyang, 550025, China. E-mail: cq1018@163.com

^bInstitute of Advanced Technology, Guizhou University, Guiyang, 550025, China

is higher.²⁹ Many researchers have further modified its photocatalytic properties by combining it with a large number of materials such as WO_3 ,³⁰ BiVO_4 ,³¹ ZnO ,³² $\text{g-C}_3\text{N}_4$,³³ and BiOBr .³⁴ In general, the construction of a heterojunction photocatalyst is a method that can effectively improve the performance of a single photocatalyst. Zhu *et al.*³⁵ have reported the initial combination of Ag_3VO_4 and AgBr materials; however, investigation of the ideal ratio of each material is still worth further exploration; in addition, the preparation of a composite photocatalyst of the system by a continuous precipitation method and the development of the composite $\text{Ag/AgBr/Ag}_3\text{VO}_4$ for the degradation of MO and TC have not been reported to date.

In this study, a series of $\text{Ag/AgBr/Ag}_3\text{VO}_4$ photocatalysts with different AgBr masses were synthesized by a simple continuous precipitation method. The visible light catalytic performance of the photocatalyst in the degradation of MO and TC was investigated. The effects of different active substances during the degradation of MO were also studied by introducing various scavengers into the photocatalytic reaction system. The separation efficiency of electron-hole pairs has been discussed by investigating the electrochemical properties, and the possible mechanism of the photocatalytic processes has been proposed.

2. Experimental

2.1. Chemicals

Silver nitrate (AgNO_3) was purchased from Sinopharm Chemical Reagent Co., Ltd (Shanghai, China). Potassium bromide (KBr) was purchased from Chengdu Jinshan Chemical Reagent Co., Ltd. Sodium vanadate (Na_3VO_4) was purchased from Cool Chemistry (Beijing, China). Methyl orange (MO) was purchased from Chengdu Jinshan Chemical Reagent Co., Ltd. Tetracycline hydrochloride (TC) was purchased from Aladdin (Shanghai, China). All reagents were of analytical grade and used without further purification.

2.2. Synthesis of the $\text{Ag/AgBr/Ag}_3\text{VO}_4$ photocatalyst

A series of $\text{Ag/AgBr/Ag}_3\text{VO}_4$ composites were prepared through a continuous precipitation route. In a typical synthetic procedure, a certain amount of AgNO_3 (7.6, 6.7, 6.3, 6.1 mmol) was added to 50 mL of deionized water followed by stirring to obtain a uniform clear solution, labeled as solution A. Then, 5.3 mmol of KBr was dissolved in 20 mL of deionized water and marked as solution B. A certain amount of Na_3VO_4 (0.76, 0.46, 0.33, 0.25 mmol) was added to another 20 mL of deionized water and labeled as solution C. The solution B was gradually added dropwise to the solution A *via* a dropping funnel under vigorous stirring. After 30 min, Ag^+-AgBr was obtained. Then, solution C was continuously added to the above mentioned mixture in the same manner, and magnetic stirring was further continued for another 4 h to obtain the $\text{AgBr/Ag}_3\text{VO}_4$ composites. After this, the mixture solution was reduced under visible light for 20 minutes to produce a portion of Ag^0 . The final product was obtained by filtration, rinsed three times with deionized water and placed in an oven at 60 °C for 24 h. The nominal mass ratios

of AgBr to Ag_3VO_4 were 3 : 1, 5 : 1, 7 : 1, and 9 : 1, and the corresponding samples were denoted as S1, S2, S3, S4. In brief, pure Ag/AgBr was prepared by precipitation of 3 mmol AgNO_3 with 3 mmol KBr followed by photoreduction for 20 minutes. Ag_3VO_4 was obtained by precipitation of 6 mmol AgNO_3 with 2 mmol Na_3VO_4 .

2.3. Evaluation of the photocatalytic performance

The photocatalytic reactions occurred in a 200 mL reactor at room temperature, and a 300 W Xe lamp (CEL-HXF300) equipped with a 420 nm cut-off filter was used as the light source for the reaction process. Typically, 50 mg photocatalyst was added to 100 mL of MO (10 mg L^{-1}) solution (or 50 mg photocatalyst was added to 100 mL of TC (10 mg L^{-1}) solution), and the mixture was stirred in the dark for 30 min to ensure an adsorption-desorption balance. Then, the light source was turned on for photocatalysis experiments, and timing was initiated. During the reaction, quantitative samples were obtained at given time intervals under light irradiation. The sample was centrifuged at 10 000 rpm for 5 min to separate the catalyst from the solution. Analysis of the absorbance of the supernatant at each of the abovementioned intervals was performed using a UV-vis spectrophotometer. The role of various active species in the photocatalytic system was investigated by adding different active species capture agents, including 0.2 g ammonium oxalate (AO), 3 mL isopropanol (IPA) and 8 mg benzoquinone (BQ), to the solution.

2.4. Characterization of the as-prepared samples

To discriminate the phase composition and purity of the materials, X-ray diffraction (XRD) analysis of the samples was conducted using the D8 ADVANCE diffractometer with $\text{Cu K}\alpha$ radiation. The morphology and constituent elements of the composites were investigated by scanning electron microscopy (S-4800, accelerating voltage 200 kV) and energy dispersive spectroscopy (EDS) analysis, respectively. The elemental composition and the chemical state of the composites were obtained by X-ray photoelectron spectroscopy (ThermoFisher K-Alpha). UV-vis diffuse reflectance spectra (DRS) were obtained by a spectrophotometer (UV2700, Shimadzu, Japan) in the wavelength range of 200–800 nm. Photoluminescence (PL) spectra of the samples were obtained by the Cary Eclipse fluorescence spectrophotometer (Agilent Technologies). Electrochemical impedance spectroscopy (EIS) was conducted using an electrochemical workstation (CHI760E Shanghai). The Pt electrode, the calomel electrode and the sample electrode played the role of a counter electrode, a reference electrode and a working electrode, respectively, and were placed in a 0.1 M Na_2SO_4 electrolyte for measuring the photocurrent.

3. Results and discussion

The $\text{Ag/AgBr/Ag}_3\text{VO}_4$ composite was prepared by a simple continuous precipitation method. As shown in Fig. 1, the synthetic route is described as follows: at first, KBr was added dropwise to the AgNO_3 solution, and Br^- in the solution reacted

Fig. 1 Schematic of the synthesis route of the Ag/AgBr/Ag₃VO₄ composites.

with Ag⁺ to form AgBr. Then, Na₃VO₄ was added to the solution, and Ag⁺ that had been immobilized further reacted with VO₄^{3−} to form Ag₃VO₄ and covered the surface of AgBr. Finally, Ag/AgBr/Ag₃VO₄ was generated after illumination.

3.1. XRD analysis

The XRD spectra of Ag/AgBr, Ag₃VO₄ and Ag/AgBr/Ag₃VO₄ composites are shown in Fig. 2. The peaks of Ag/AgBr and Ag₃VO₄ well-matched with those of cubic AgBr (JCPD no. 06-0438) and monoclinic Ag₃VO₄ (JCPDS no. 43-0542), respectively. For AgBr, the sharp diffraction peaks at 30.96°, 44.35° and 55.04° corresponded perfectly to the crystal planes of (2 0 0), (2 2 0) and (2 2 2). This shows that its crystallinity is good and there are no other impurities. For pure Ag₃VO₄, the diffraction peaks at 30.86°, 32.33° and 35.07° corresponded to the crystal planes of (−1 2 1), (1 2 1) and (3 0 1); this indicated that the prepared Ag₃VO₄ was pure and had no second phase. A fairly weak intensity peak can also be observed in the XRD pattern of Ag/AgBr/Ag₃VO₄; since the intensity of the peak of Ag₃VO₄ in the composite is much weaker than that of AgBr and their peak positions are relatively close at around 31°, the peak of Ag₃VO₄ may be covered by the peak of AgBr.³⁶ As the AgBr content increases, the peak of Ag₃VO₄ becomes weaker until it is barely visible. The results of XRD suggest that the composites have been successfully prepared by a continuous precipitation method. In addition, the reason why the characteristic diffraction peak of Ag⁰, which is expected to occur, is not observed in the spectrum may be that the content of Ag⁰ is low.

3.2. XPS analysis

To acquire the elemental composition of the composite and the chemical states of the measured elements, sample S2 was selected for X-ray photoelectron spectroscopy (XPS). As shown in Fig. 3, the high-resolution spectrum is composed of Ag 3d, Br 3d, V 2p and O 1s with no other impurities. Moreover, two peaks with the binding energies of 368.25 eV and 374.22 eV were observed in the Ag 3d spectra (Fig. 3b), which were consistent with Ag 3d_{5/2} and Ag 3d_{3/2} of Ag⁺ for AgBr and Ag₃VO₄, respectively, and further confirmed that the Ag species mainly existed in the form of Ag⁺. Moreover, there were two weak peaks at the binding energies of 369.16 eV and 375.02 eV, which corresponded to Ag 3d_{5/2} and Ag 3d_{3/2}, indicating that Ag also existed in the form of metallic Ag⁰.³⁷ The reason for the occurrence of this phenomenon is that under light, Ag⁺ is partially reduced to Ag⁰ and attached to the surface of the composite photocatalyst. Moreover, two distinct peaks at the binding energies of 68.85 eV and 69.6 eV were observed in the Br 3d spectra (Fig. 3c), which were attributed to Br 3d_{5/2} and Br 3d_{3/2} and indicated that Br existed as Br[−].³⁸ The peaks of V 2p_{1/2} and V 2p_{3/2} at 516.85 eV and 524.35 eV confirmed that V existed as V⁵⁺ (ref. 39) (Fig. 3d). The peak of O 1s (Fig. 3e) at 530.08 eV corresponded to hydroxyls (−OH), and the other peak at 531.87 eV confirmed the existence of oxygen in Ag/AgBr/Ag₃VO₄. All these results further showed that the composites consisted of Ag/AgBr and Ag₃VO₄.

3.3. SEM analysis

The morphologies and composition of Ag₃VO₄, Ag/AgBr, and Ag/AgBr/Ag₃VO₄ were investigated by SEM and EDS, respectively

Fig. 2 (a) XRD patterns of Ag/AgBr and Ag/AgBr/Ag₃VO₄ composites and (b) pure Ag₃VO₄.

Fig. 3 (a) Survey XPS spectra of the S2 sample; (b, c, d and e) high-resolution XPS data of Ag 3d, Br 3d, V 2p, and O 1s for S2, respectively.

(Fig. 4). As shown in Fig. 4a, fine particles of Ag/AgBr having an average particle diameter of more than 1 μm can be observed. Fig. 4b shows the prepared Ag_3VO_4 with nanometer-sized particles. Both Ag/AgBr and Ag_3VO_4 prepared by the continuous precipitation method are irregular small particles, and the particle size of Ag_3VO_4 is much smaller than that of Ag/AgBr. The composite Ag/AgBr/ Ag_3VO_4 also exhibited irregular particles, and the surface of the large particles was occupied by many small particles (Fig. 4c). The abundant content of AgBr in the composite material made a significant impact on the formation of its final morphology, and the particle size of the composite was similar to that of AgBr. Moreover, the composite exhibits good dispersibility (Fig. 4d), and the close contact between AgBr

and Ag_3VO_4 will enhance the transfer and separation of photogenerated charges;⁴⁰ one of the advantages of a Ag/AgBr/ Ag_3VO_4 composite is that it has more active sites, and the photogenerated electron-hole pairs can be rapidly transferred; this is very beneficial to the degradation of MO by the photocatalyst.⁴¹ The EDS spectra of Ag/AgBr and S2 are shown in Fig. 4e and f, respectively. Pure AgBr consisted of Ag and Br elements, whereas the Ag/AgBr/ Ag_3VO_4 composite material was confirmed to contain Ag, Br, V and O elements. Based on the results of the abovementioned XRD, SEM and EDS data, the preparation of the Ag/AgBr/ Ag_3VO_4 composite was successfully confirmed.

Fig. 4 SEM images of (a) pure Ag/AgBr, (b) pure Ag₃VO₄, and (c and d) S2 sample; (e and f) EDS spectra of pure Ag/AgBr and S2 sample, respectively.

3.4. The optical property analysis

The optical properties of the prepared samples were investigated via a UV-vis spectrophotometer. The light absorption characteristic of the composite material can be analyzed from Fig. 5. All samples exhibited absorbance in the visible region, and AgBr caused a significant absorption band in the sample curve due to the surface plasmon resonance effect (SPR) of Ag⁰, which was derived from the collective oscillation of free electrons.^{27,42} With a change in the AgBr content in the composite, the edge absorption band value of the composite appears to increase in a regular way. As the absorption edge value of the sample becomes larger, the response of the sample to visible light is enhanced. The band gap width of the composite materials was obtained by the

equation $(\alpha h\nu) = A(h\nu - E_g)^{n/2}$, where E_g , ν , h , A and α are the band gap energy of the semiconductor, light frequency, Planck's constant, a constant value and the absorption coefficient, respectively.^{19,34} The relationship between $(\alpha h\nu)^2$ and $h\nu$ was obtained as shown in Fig. 5b, and the E_g value was acquired by estimating the intercept of the tangent of the curve. In this study, the band gap values of Ag/AgBr, Ag₃VO₄, and sample S2 were calculated to be 2.43 eV, 2.01 eV, and 2.64 eV, respectively, which were consistent with the previously reported values.^{31,43,44}

3.5. Charge separation analysis

In general, PL spectra can be used to detect the separation and recombination rates of photogenerated charges. A lower PL

Fig. 5 (a) UV-vis diffuse reflectance spectra of Ag/AgBr, Ag₃VO₄ and Ag/AgBr/Ag₃VO₄ composites; (b) Tauc plot of Ag/AgBr, Ag₃VO₄ and S2.

intensity means that the photogenerated electron-hole pairs have high separation efficiency and thus produce high photocatalytic activity.⁴⁵ The photoluminescence spectra of Ag₃VO₄, Ag/AgBr and S2 are shown in Fig. 6. It can be found that the intensities of both pure Ag₃VO₄ and Ag/AgBr in the plot are higher than those in the curve of the S2 sample at different wavelengths; this indicates the reduction of photogenerated electron-hole pair recombination in sample S2.

To further analyze the separation efficiency of photogenerated electron-hole pairs, the EIS and transient photocurrent responses of the photocatalytic samples were investigated. For the EIS, a small arc radius leads to a low charge transfer resistance.¹⁸ Fig. 7a clearly reveals that the Nyquist plots of S2 are smaller than that of Ag/AgBr; this indicates that the photogenerated electron-hole transfer efficiency of S2 is high. In the transient photocurrent response of the samples, a change in the light source causes a sudden change in the photocurrent. A high transient photocurrent response is generally indicative of a high separation efficiency of the photogenerated electron-hole pairs. It can be observed that the photocurrent of S2 is stronger than that of Ag/AgBr; this denotes that S2 has a faster electron-hole separation efficiency (Fig. 7b). This may be due to

the fact that the electron-hole transfer efficiency between interfaces becomes higher after the combination of AgBr and Ag₃VO₄ into a composite material.

3.6. The photocatalytic performance test

To explore the ability of the as-prepared composites to degrade pollutants, the degradation of the common pollutants MO and TC by the composites was studied by the degradation experiments. As shown in Fig. 8a, the negligible self-photolysis of MO under visible light demonstrates that MO has stable chemical properties to light. The adsorption rate in the dark reaction is also low; this indicates that the main cause of MO degradation is visible light irradiation rather than surface adsorption of the photocatalyst. As expected, all the prepared composite photocatalysts have higher photocatalytic activity than Ag/AgBr and Ag₃VO₄ with the ranking of S2 > S3 > S4 > S1 > Ag/AgBr > Ag₃VO₄, proving that AgBr plays an active role in enhancing the photocatalytic activity.⁴⁵ Moreover, as the proportion of AgBr in the composites increases, the degradation of MO first increases and then decreases. Particularly, the removal efficiency of all the composite photocatalysts could reach over 90% after 10 min of illumination. S2 exhibited the most excellent photocatalytic activity, and 98.6% of MO was decomposed after 20 min of irradiation. The findings demonstrate that the composite photocatalyst has a shorter degradation time and higher degradation efficiency than the single photocatalyst. The photocatalytic activity of S3 and S4 in the plot is also lower than that of S2; this may be explained by the recombination of photogenerated electrons and holes that suppresses the photocatalytic efficiency. In addition, for the typical colorless antibiotic TC, S2 exhibited superior photocatalytic activity in the degradation of TC (Fig. 8b). Its degradation efficiency reached 77% after 10 minutes. However, after 4 min, the degradation rate of TC became very low, possibly reaching equilibrium rather than complete degradation.³⁹

The pseudo first-order plots of MO degradation reactions for different samples are shown in Fig. 8c, which have been obtained by processing the data using a pseudo first-order model whose equation is $\ln(C_0/C_t) = kt$. C_0 is the initial concentration of MO before the photoreaction, C_t is the concentration of MO

Fig. 6 PL spectra of pure Ag/AgBr, Ag₃VO₄ and S2 sample.

Fig. 7 (a) Electrochemical impedance spectra of Ag/AgBr and S2 photocatalysts and (b) transient photocurrent response of Ag/AgBr and S2.

after the reaction time t , and k is the reaction rate constant. The degradation rates of MO were calculated to be 0.0026 min^{-1} , 0.1118 min^{-1} , and 0.2509 min^{-1} over the Ag_3VO_4 , Ag/AgBr, and S2 samples, respectively. The degradation rate of S2 is higher than the degradation rate of a single photocatalyst, which is 2.2 and 96.5 times that of Ag/AgBr and Ag_3VO_4 , respectively. This is highly consistent with the results of photocatalytic degradation. These results more accurately demonstrate that the composite

material significantly improves the degradation rate of the pollutants.

The MO solution was taken at a given reaction time, and the change in its TOC content was measured to account for the change of the remaining content of MO in the solution. As shown in Fig. 8d, during the photocatalytic degradation of MO, the TOC gradually decreased to 31% with time. It showed that the composite could effectively remove MO, and MO was mineralized into CO_2 and H_2O .

Fig. 8 (a) The photocatalytic degradation of MO via different as-synthesized photocatalysts; (b) the photocatalytic degradation of TC via different as-synthesized photocatalysts; (c) pseudo first-order plot of the photocatalytic degradation of MO via different as-synthesized photocatalysts; (d) change of TOC removal rate of MO in the presence of the S2 sample.

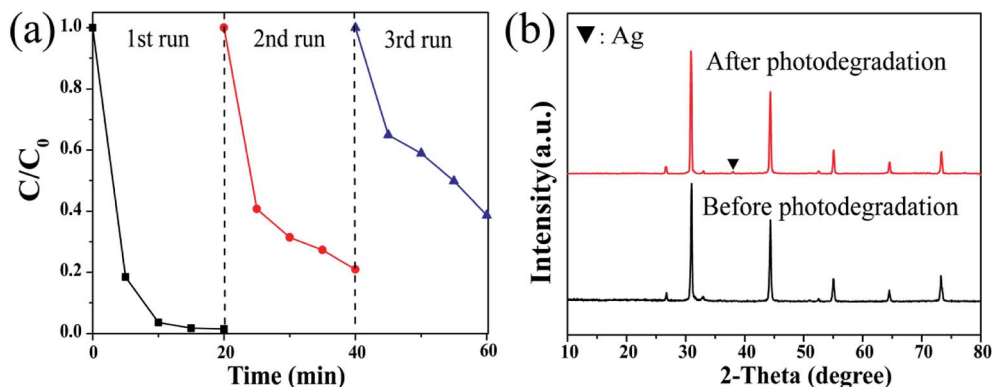

Fig. 9 (a) Reusable performance of S2 and (b) XRD data contrast diagram before and after the use of S2.

To further assess the performance of the photocatalyst, the stability of the photocatalyst was explored through cycling experiments. As shown in Fig. 9a, the catalyst can be subjected to multiple cycling experiments to show that it has good stability; however, after three cycles, the degradation efficiency is reduced, and only 61.3% of the pollutants are degraded. There are two possibilities for explaining this phenomenon: one is that some catalysts are inevitably lost during the experimental operation, and the second is that the catalyst decomposes a part of Ag^0 ; this directly leads to a decrease in the photocatalytic activity. The latter reason could be supported by the XRD comparison data obtained before and after the sample was used. The Ag^0 characteristic diffraction peak was clearly observed in the spectrum of the catalyst recovered after the cycling experiment, and the other structures hardly changed (Fig. 9b).

3.7. Possible photocatalytic mechanism of the $\text{Ag}/\text{AgBr}/\text{Ag}_3\text{VO}_4$ composites

The photocatalysts produce various active substances in the solution such as hydroxyl radicals ($\cdot\text{OH}$), $\cdot\text{O}_2^-$ and h^+ . The active substances produced can oxidize or reduce the pollutants into new non-toxic and harmless substances; thus, the purpose of removing the target pollutants in the solution is achieved. Therefore, experiments to capture the reactive species have been conducted to identify the active species that are primarily catalytically active. Herein, ammonium oxalate (AO), benzoquinone (BQ) and isopropanol (IPA) acted as scavengers to eliminate h^+ , $\cdot\text{O}_2^-$ and $\cdot\text{OH}$, respectively.⁴⁶ As Fig. 10 shows, the degradation rate of MO was 98.6% before the addition of a scavenger, and the removal rate of MO after the addition of AO and BQ was 62% and 21%, respectively. The phenomenon of photocatalytic activity was significantly inhibited; this indicated that h^+ and $\cdot\text{O}_2^-$ might be the main reactive species involved in the photocatalytic degradation process, and $\cdot\text{O}_2^-$ played a dominant role in the reaction. When IPA was added as a scavenger, the degradation rate of MO was still as high as 98%, which was enough to show that $\cdot\text{OH}$ was a partly reactive species in the reaction and had only a weak influence on the degradation process.

Fig. 10 Photocatalytic degradation of MO in an aqueous solution via S2 under different conditions.

Based on the previous analysis, a possible mechanism for the degradation of MO by the composites can be proposed, as shown in Fig. 11. The band gaps of AgBr and Ag_3VO_4 estimated by UV-vis spectroscopy were about 2.43 eV and 2.01 eV, respectively. Through the Mulliken electronegativity theory, we computed the position of the semiconductor band, and the formulas are as follows:

$$E_{\text{CB}} = X - E_{\text{e}} - 0.5E_{\text{g}} \quad (1)$$

$$E_{\text{VB}} = E_{\text{CB}} + E_{\text{g}} \quad (2)$$

where E_{CB} and E_{VB} represent the edge potential of the conduction band (CB) and valence band (VB), respectively, and X stands for the absolute electronegativity of the semiconductor, which is derived from the geometric mean of the electronegativity of the constituent atoms (the X value of AgBr is 4.42,⁴⁷ and the X value of Ag_3VO_4 is 5.64 (ref. 48)). E_{e} is the energy of free electrons in the hydrogen scale (about 4.5 eV). E_{g} is the band gap energy of the semiconductor. It has been determined by calculation that the valence band edges of AgBr and Ag_3VO_4 are located at

Fig. 11 The possible photocatalytic mechanism of the Ag/AgBr/Ag₃VO₄ composites.

1.13 eV and 2.15 eV, and the conduction band edges are located at the positions -1.3 eV and 0.14 eV, respectively. Under visible light irradiation, the energy of light is greater than the energy band gap of AgBr and Ag₃VO₄. Ag⁰, AgBr and Ag₃VO₄ can absorb visible light photons to form electron-hole pairs. Subsequently, the electrons will migrate from the surface of Ag⁰ to the CB of AgBr and, in turn, eventually to the CB of Ag₃VO₄, whereas the holes remain on Ag⁰. The electrons accumulate to a higher concentration in the CB of Ag₃VO₄, and the electrons can be trapped by molecular oxygen in the solution to form a strong oxidizing substance, $\cdot\text{O}_2^-$, and other reactive oxygen species, which can oxidize MO and result in high photocatalytic activity.³⁵ Furthermore, the holes in the VB of Ag₃VO₄ gradually migrate to the VB of AgBr and aggregate. A large number of holes can react with H₂O or $\cdot\text{OH}$ to produce the $\cdot\text{OH}$ radicals, and excess holes can be combined with Br⁻ to reduce it to Br⁰ since Br⁰ is also a kind of active radical species.^{35,38,49} Finally, $\cdot\text{O}_2^-$, h⁺, $\cdot\text{OH}$ and Br⁰ react with MO as oxidants to generate H₂O, CO₂ and other small molecules, resulting in the degradation of MO. The possible mechanism by which Ag/AgBr/Ag₃VO₄ degrades MO can be explained as follows:

On the one hand, the composite material of this structure accelerates the effective separation of photogenerated electrons and holes and reduces the recombination of electron-hole

pairs; on the other hand, Ag⁰ on the photocatalyst surface can absorb more visible light, thus further improving the photocatalytic performance.

4. Conclusions

A series of Ag/AgBr/Ag₃VO₄ composites were synthesized by a simple continuous precipitation method. The degradation rates of the sample S2 for MO and TC were 98.6% and 77%, which were better than those of the single photocatalysts Ag₃VO₄ and Ag/AgBr, indicating that S2 had a better degradation effect on MO and TC in an aqueous solution. In addition, the evidence that h⁺ and $\cdot\text{O}_2^-$ were the main active substances in the degradation process of the pollutant MO was obtained by conducting active group capture experiments. The results of PL, EIS and photocurrent response show that the composite exhibits better charge separation efficiency, and the surface plasmon resonance (SPR) effect of Ag⁰ together improves the photocatalytic performance of the composite. As a highly efficient photocatalyst, Ag/AgBr/Ag₃VO₄ is a promising photocatalyst for wastewater purification.
