## Sonochemistry-enabled uniform coupling of $\text{SnO}_2$ nanocrystals with graphene sheets as anode materials for lithium-ion batteries†

 Xiaoyan Han, <sup>a</sup> Ran Li, <sup>b</sup> Shengqiang Qiu, <sup>b</sup> Xiaofang Zhang, <sup>a</sup> Qing Zhang <sup>\*ac</sup> and Yingkui Yang <sup>abc</sup>

$\text{SnO}_2$ /graphene nanocomposite was successfully synthesized by a facile sonochemical method from  $\text{SnCl}_2$  and graphene oxide (GO) precursors. In the sonochemical process, the  $\text{Sn}^{2+}$  is firstly dispersed homogeneously on the GO surface, then *in situ* oxidized to  $\text{SnO}_2$  nanoparticles on both sides of the graphene nanosheets (RGO) obtained by the reduction of GO under continuous ultrasonication. Graphene not only provides a mechanical support to alleviate the volume changes of the  $\text{SnO}_2$  anode and prevent nanoparticle agglomeration, but also serves as a conductive network to facilitate charge transfer and  $\text{Li}^+$  diffusion. When used as a lithium ion battery (LIB) anode, the  $\text{SnO}_2$ /graphene nanocomposite exhibits significantly improved specific capacity ( $1610 \text{ mA h g}^{-1}$  at  $100 \text{ mA g}^{-1}$ ), good cycling stability (retaining 87% after 100 cycles), and competitive rate performance ( $273 \text{ mA h g}^{-1}$  at  $500 \text{ mA g}^{-1}$ ) compared to those of bare  $\text{SnO}_2$ . This sonochemical method can be also applied to the synthesis of other metal-oxide/graphene composites and this work provides a large-scale preparation route for the practical application of  $\text{SnO}_2$  in lithium ion batteries.

### Introduction

Lithium ion batteries (LIBs) have been intensively used in portable electronics, electric vehicles (EVs), and intelligent power grids due to their superior advantages such as long cycle life, high energy density, environmental friendliness and no memory effect.<sup>1–4</sup> Electrode materials play a critical role on electrochemical performance of LIBs. Among various anode materials, transition-metal oxides have been widely investigated for their abundant resources and high specific capacity. Unfortunately, they all endure dramatic volume change during the lithiation/delithiation process, resulting in pulverization and flaking off of active materials, thus leading to rapid capacity decay.<sup>5,6</sup> Among various transition metal oxides,  $\text{SnO}_2$  is considered as one of the most promising electrode material due to its high theoretical capacity ( $782 \text{ mA h g}^{-1}$ ), low discharge potential ( $<1.5 \text{ V}$ ), environmental benignity and low-cost.<sup>7–9</sup> However, the electrochemical performance of bare  $\text{SnO}_2$  is

unsatisfactory for large volume change ( $\sim 300\%$ ), low electronic conductivity, and poor transport kinetics.<sup>10–13</sup>

To alleviate volume change during lithiation/delithiation process and enhance structural stability of  $\text{SnO}_2$ , an effective strategy is to design nanostructured  $\text{SnO}_2$ .<sup>14–17</sup> However, the agglomeration of nanostructured  $\text{SnO}_2$  during the cycling process usually leads to fast capacity attenuation.<sup>18,19</sup> Recently, nanocomposites have drawn wide attention for their superiorities to integrate multiple properties of different nanoscale building blocks to improve mechanical and electronic properties.<sup>20–24</sup> Particularly, graphene-based nanocomposites with metal, metal oxides or polymers have also demonstrated particular mechanical, electronic, electrochemical and catalytic properties.<sup>25–28</sup> Hence, various  $\text{SnO}_2$ /graphene nanocomposites with enhanced electrochemical performance have been fabricated, in which graphene supplies a mechanical support to prevent volume changes and enhances electrical conductivity of composites.<sup>29–31</sup> In addition, flexible graphene support with high surface area, porosity, electrical conductivity and chemical inertness can prevent nanoparticle agglomeration to achieve a stable electrode structure and provide good electric conductivity for the composite.<sup>32–34</sup>

Various methods have been used to prepare  $\text{SnO}_2$ /graphene nanocomposites and each method has its own merits and demerits. For example, Lee *et al.* prepared  $\text{SnO}_2$ /3D graphene hybrid material by a simple hydrothermal process,<sup>35</sup> Wang and co-workers developed a ternary self-assembly approach to construct layered  $\text{SnO}_2$ -graphene nanocomposites,<sup>36</sup> and

Zhang's group synthesized  $\text{SnO}_2$ @graphene nanocomposites *via* a wet mechanochemical method.<sup>37</sup> Compared to these reported methods, sonochemical methods are more favorable for the construction of nanostructures without involving any surfactants and complex processes, and the morphology and particle size can be regulated by ultrasonic waves.<sup>38–41</sup> In fact, the basic principle of sonochemistry method is the acoustic cavitation phenomenon in a liquid, which arises high temperature and pressure, and high cooling rate instantaneously during the cavitation process.<sup>38,41</sup> Such extreme conditions can trigger the formation of metal oxides on a nanometer scale with homogeneous particle size distribution.<sup>42–45</sup> Herein,  $\text{SnO}_2$ /graphene nanocomposite ( $\text{SnO}_2$ /RGO) was synthesized *via* a simple and effective sonochemical method using  $\text{SnCl}_2$  and graphene oxide (GO) as precursors. When used as a LIBs anode, the as-prepared  $\text{SnO}_2$ /RGO nanocomposite displays large specific capacity (1610  $\text{mA h g}^{-1}$  at 100  $\text{mA g}^{-1}$ ), good cycling performance (87% retention after 100 cycles) and competitive rate capability (273  $\text{mA h g}^{-1}$  at 500  $\text{mA g}^{-1}$ ).

## Experimental

### Synthesis of $\text{SnO}_2$ /RGO nanocomposite

Graphene oxide (GO) was prepared from graphite powders (>95%) according to a modified Hummer's method.<sup>46</sup>  $\text{SnO}_2$ /graphene nanocomposite was synthesized by a sonochemical method using  $\text{SnCl}_2$  and GO as precursors. Firstly, ethanol aqueous solution (1 : 1 mol) and  $\text{SnCl}_2$  (1% mol) were added into the GO aqueous solution under vigorous stirring to obtain uniform mixture. After stirring for 30 min, the mixture was then transferred into a wrapped beaker by ultrasonic irradiation at 50 °C for 3 h under ultrasonic power of 400 W in a bath sonicator. The resulting dark-grey precipitate was collected by centrifugation, washed and then dried at 80 °C under vacuum overnight. Finally, the product was heated at 550 °C for 3 h in argon gas with a heating rate of 5 °C min<sup>-1</sup>. The resulting products with 0 wt% and 30 wt% of GO were marked as bare  $\text{SnO}_2$  and  $\text{SnO}_2$ /RGO nanocomposite, respectively. RGO was obtained from GO by the same heat treatment conditions.

In this work, a sonochemical method was employed to synthesize  $\text{SnO}_2$ /RGO nanocomposite by using  $\text{SnCl}_2$  as reducing agent and graphene oxide (GO) as oxidizing agent. The possible reaction mechanism is proposed according to the following equations:<sup>37</sup>

In the sonochemical reaction,  $\text{SnCl}_2$  is firstly hydrolyzed to  $\text{Sn}(\text{OH})\text{Cl}$  as shown in reaction (1), subsequently  $\text{Sn}(\text{OH})\text{Cl}$  is oxidized to  $\text{SnO}_2$  and GO is reduced to graphene (RGO) under continuous ultrasonic forces. As shown in Fig. 1,  $\text{Sn}(\text{OH})\text{Cl}$  can be dispersed homogeneously on the surface of two-dimensional graphene nanosheets in ethanol solution under constant ultrasonication. The ultrasound treatment triggers the redox

Fig. 1 Illustration of sonochemical method synthesis process of  $\text{SnO}_2$ /RGO.

reaction between  $\text{SnCl}_2$  and GO, and *in situ* synthesis of  $\text{SnO}_2$  nanoparticles onto the graphene surface.

## Measurements

X-ray diffraction (XRD) were performed on a Bruker D8-advance diffractometer with a Ni filter and Cu K $\alpha$  radiation. Scanning electron microscopy (SEM) was observed by using a Hitachi SU8010 microscope. Transmission electron microscopy (TEM) was implemented by a Tecnai G2 20 S-TWIN microscopy at 200 kV. Fourier transform infrared spectroscopy (FT-IR) spectra were recorded on a Nicolet AVATAR-360 spectrometer. Raman spectra were performed on a DXR Raman microscope excited (Thermo Scientific) by 514 nm. Thermogravimetric analysis (TGA) curves were taken on a thermogravimetric analyzer (NETZSCH, TG209F3) from 40 to 800 °C at 20 °C min<sup>-1</sup> in air atmosphere. X-ray photoelectron spectroscopy (XPS) spectra of the samples were recorded on a Thermo MultiLab 2000 X-ray photoelectron spectrometer.

The electrochemical performance was carried out using a 2032-type coin cells (CR2032). A lithium foil was used as the counter electrode and a Celgard-2400 microporous membrane was used as the separator. The working electrode consists of 80 wt% active material, 10 wt% acetylene black and 10 wt% polyvinylidene fluoride (PVDF) binder. A copper foil acted as the current collector. 1.0 M  $\text{LiPF}_6$  solution dissolved in ethylene carbonate (EC) and dimethylcarbonate (DMC) (1 : 1, v/v) was used as the electrolyte. The cells were assembled in an argon-filled glove box. The galvanostatic discharge/charge tests were studied between 0.001 and 2.0 V *versus*  $\text{Li}^+/\text{Li}$  on a multichannel battery testing system (LAND CT2001A). Cyclic voltammetry (CV) experiments and electrochemical impedance spectroscopy (EIS) were performed on an electrochemical working station (CHI770E) using model cells. CV were recorded at scan rate of 0.2 mV s<sup>-1</sup> in the potential range of 0.001–2.0 V. EIS was examined in a frequency range from 0.01 Hz to 100 kHz under AC amplitude of 5 mV.

## Results and discussion

The morphology and microstructure were elucidated by SEM and TEM. Fig. 2a shows distinct lamellar structure of GO sheets, which contains a few layers. Bare  $\text{SnO}_2$  consists of mono-dispersed nanoparticles with an average particle size of about 10 nm, which shows obviously agglomeration (Fig. 2b). In contrast,  $\text{SnO}_2$  nanoparticles are well adhered on the surface of RGO nanosheets in the nanocomposite as shown in Fig. 2c and d. Due to the electrostatic interaction between  $\text{SnO}_2$  and residual oxygen-containing groups in RGO, the sonochemical

Fig. 2 (a) TEM image of GO. (b) SEM image of bare  $\text{SnO}_2$ . (c and d) SEM images of  $\text{SnO}_2/\text{RGO}$ . The inset in (b) shows a TEM image of bare  $\text{SnO}_2$ .

process can effectively inhibit the aggregation of  $\text{SnO}_2$  nanoparticles and realize the uniform distribution of  $\text{SnO}_2$  on the surface of RGO sheets.

XRD patterns of GO, bare  $\text{SnO}_2$  and  $\text{SnO}_2/\text{RGO}$  are given in Fig. 3. GO displays only one broad peak located at  $10.8^\circ$ , indexing to the (001) plane of GO with an interlayer distance of  $8.18\text{ \AA}$ .<sup>47</sup> Bare  $\text{SnO}_2$  and  $\text{SnO}_2/\text{RGO}$  exhibit similar diffraction peaks, which are well indexed to the pure  $\text{SnO}_2$  (JCPDS no. 41-1445), indicating that the reduction of GO does not affect the crystal structure of  $\text{SnO}_2$ . However, the typical stacking peak of graphene nanosheets located at  $26^\circ$  is also absent in the pattern of  $\text{SnO}_2/\text{RGO}$  nanocomposite. This indicates that  $\text{SnO}_2$  particles are formed on the both sides of RGO nanosheets, which prevents graphene sheets from restacking.<sup>48</sup> In addition, compared to sharp diffraction peaks of  $\text{SnO}_2$ ,  $\text{SnO}_2/\text{RGO}$  nanocomposite displays broader XRD peaks, which is attributed to the decrease of particle size (bare  $\text{SnO}_2$ :  $10.8\text{ nm}$ ,  $\text{SnO}_2/\text{RGO}$ :  $7.8\text{ nm}$ , calculated by Scherrer formula:  $D = K\lambda/B \cos \theta$ ), suggesting that the growth of  $\text{SnO}_2$  nanoparticles on the surface of RGO nanosheets can prevent nanoparticles agglomeration. Furthermore, no other peaks can be observed, indicating the complete transformation of  $\text{SnCl}_2$  into  $\text{SnO}_2$  upon sonochemical and heat treatment process.

Fig. 3 XRD patterns of GO, bare  $\text{SnO}_2$  and  $\text{SnO}_2/\text{RGO}$  nanocomposite.

Fig. 4a shows FT-IR spectra of bare  $\text{SnO}_2$ , GO and  $\text{SnO}_2/\text{RGO}$ . FT-IR spectrum of GO is in good agreement with previous works.<sup>49</sup> GO shows the O–H deformation peak at  $1401\text{ cm}^{-1}$ , the O–H stretching vibrations peak at  $3420\text{ cm}^{-1}$  and the C=O stretching vibrations peak at  $1735\text{ cm}^{-1}$ . The peaks at  $1624$ ,  $1220$ , and  $1052\text{ cm}^{-1}$  are due to C=C bending vibrations, C–OH stretching vibrations, and C–O stretching vibrations, respectively. Those peaks weaken or almost disappear for the  $\text{SnO}_2/\text{RGO}$  nanocomposite, implying that GO is completely reduced to RGO nanosheets during the formation of nanocomposite. Additionally, a strong peak at  $624\text{ cm}^{-1}$  is assigned to Sn–O stretching vibrations, confirming the presence of  $\text{SnO}_2$  in the composite.<sup>48,49</sup> The FT-IR results confirm the reduction of GO and the oxidation of  $\text{Sn}^{2+}$  to  $\text{SnO}_2$ , suggesting the formation of  $\text{SnO}_2/\text{RGO}$  nanocomposite.

Fig. 4 (a) FT-IR of GO, bare  $\text{SnO}_2$ , and  $\text{SnO}_2/\text{RGO}$  nanocomposite. (b) Raman spectra of GO, RGO, and  $\text{SnO}_2/\text{RGO}$  nanocomposite. (c) TGA curve of  $\text{SnO}_2/\text{RGO}$  nanocomposite in air atmosphere.

Fig. 4b gives Raman spectra of GO, RGO and  $\text{SnO}_2/\text{RGO}$ . The peaks at 1588 and 1344  $\text{cm}^{-1}$  correspond to the G and D band, respectively. The G band is related to the presence of isolated double bonds in a 2-dimensional hexagonal lattice, while the D band is linked with the defects and disorder in the hexagonal graphitic layers. The relative intensity ratio of D to G bands ( $I_{\text{D}}/I_{\text{G}}$ ) can represent the reduction degree of carbonaceous materials. The defect density is calculated to be 2.0 for  $\text{SnO}_2/\text{RGO}$  nanocomposite, larger than that of GO (0.9) and RGO (1.0). This enhancement of defect density could be ascribed to the exfoliation and reduction of GO with the attachment of  $\text{SnO}_2$  nanoparticles on the surface.<sup>50</sup>

To obtain the content of RGO in the composite, thermogravimetric analysis (TGA) was measured under air as shown in Fig. 4c. In general, the negligible weight loss below 400 °C is attributed to adsorbed water molecules and oxygen-containing groups of graphene in the sample. The significant weight loss between 400 and 600 °C is attributed to the complete combustion of carbon components from RGO. Above 600 °C, the weight of the sample is constant, indicating that the combustion is completed and only  $\text{SnO}_2$  is left. The weight loss of  $\text{SnO}_2/\text{RGO}$  nanocomposite is 18.2% (RGO component), which is different from pre-designed feed ratio of GO (30%). This deviation can be ascribed to the loss of oxygen-containing groups in GO during thermal reduction process.

XPS was further employed to confirm the reduction of GO and formation of  $\text{SnO}_2$  during the sonochemical process. Fig. 5a shows the survey spectra of GO, bare  $\text{SnO}_2$  and  $\text{SnO}_2/\text{RGO}$ . The spectrum of GO only shows two distinguishable peaks of carbon (C 1s, 285 eV) and oxygen (O 1s, 530 eV). In contrast, the spectrum of  $\text{SnO}_2/\text{RGO}$  shows all the peaks of desired carbon, oxygen and  $\text{SnO}_2$ . The Sn 3d peaks of  $\text{SnO}_2/\text{RGO}$  (Fig. 5b) could be resolved into 487.0 and 495.4 eV with an 8.4 eV peak-to-peak separation, corresponding to  $\text{Sn 3d}_{5/2}$  and  $\text{Sn 3d}_{3/2}$ , respectively, which are consistent with the previous reports about  $\text{SnO}_2/\text{C}$  composites.<sup>48,51</sup> Additionally, the peaks of C 1s spectra of  $\text{SnO}_2/\text{RGO}$  and GO could be resolved into four binding energies (Fig. 5c and d), corresponding to four types of carbon atoms (C-C/C=C: 284.7 eV, C-O: 286.7 eV, C=O: 288.7 eV, and O-C=O: 289.6 eV).

Fig. 5 (a) XPS spectra of GO, bare  $\text{SnO}_2$  and  $\text{SnO}_2/\text{RGO}$ . (b) Sn 3d XPS spectra of  $\text{SnO}_2/\text{RGO}$ . C 1s XPS spectra of (c)  $\text{SnO}_2/\text{RGO}$  and (d) of GO.

The C-C/C=C content in  $\text{SnO}_2/\text{RGO}$  (77.8%) is larger than that of GO (36.7%). Meanwhile, C-O amount in  $\text{SnO}_2/\text{RGO}$  declines sharply due to successful removal of oxygen-containing groups in GO, which further confirms the completely reduction of GO.

Fig. 6a shows CV curves of  $\text{SnO}_2/\text{RGO}$  for the first three cycles. It has been established that two-step reactions are involved in the  $\text{SnO}_2$ -based electrodes:

There is an obvious cathodic peak at 0.72 V in the first cycle of the  $\text{SnO}_2/\text{RGO}$ , which is attributed to the reduction of  $\text{SnO}_2$  to metallic Sn and formation of amorphous  $\text{Li}_2\text{O}$  as indicated in reaction (3) as well as the formation of solid electrolyte interphase (SEI).<sup>31,50</sup> The broad cathodic peak at about 0.25 V and anodic peak at about 0.65 V correspond to reversible reaction as indicated in reaction (4). The anodic peak at about 1.32 V represents partial reversibility of the reaction as shown in reaction (3).<sup>31</sup> The CV curves of the second and third cycles are almost overlapped, implying an excellent cycling stability and reversibility of the  $\text{SnO}_2/\text{RGO}$ . Furthermore, charge/discharge profiles of the  $\text{SnO}_2/\text{RGO}$  are displayed in Fig. 6b. There appears two discharge plateaus around 0.8 V and 0.3 V in the first discharge process, originating from the formation of SEI film and alloying of  $\text{Li}_x\text{Sn}$ . A charge plateau at 1.2 V in the first cycle is linked with dealloying of  $\text{Li}_x\text{Sn}$ ,<sup>13</sup> which is consistent with the oxidation-reduction peaks of CV curves. The initial discharge and charge capacities of the  $\text{SnO}_2/\text{RGO}$  electrode are 1610 and 765  $\text{mA h g}^{-1}$ , respectively. This large initial irreversible loss (52%) is common for  $\text{SnO}_2$  materials, which could be assigned to the irreversible transformation reaction as described in eqn (3) and the formation of solid electrolyte interphase (SEI) film.

Fig. 6c compares the cycling performances of  $\text{SnO}_2/\text{RGO}$  with bare  $\text{SnO}_2$  and RGO. Apparently, bare RGO shows good cycling

Fig. 6 (a) CV curves of the  $\text{SnO}_2/\text{RGO}$  at  $0.2 \text{ mV s}^{-1}$ . (b) Charge/discharge voltage profiles of the  $\text{SnO}_2/\text{RGO}$  at a current density of  $100 \text{ mA g}^{-1}$ . (c) Cycling performance and coulombic efficiency of the bare  $\text{SnO}_2$ , RGO and  $\text{SnO}_2/\text{RGO}$  at  $100 \text{ mA g}^{-1}$ . (d) The rate performance of  $\text{SnO}_2/\text{RGO}$ .

stability but low reversible capacity. After 100 cycles, the discharge capacity decreases to  $263 \text{ mA h g}^{-1}$ . Even though bare  $\text{SnO}_2$  delivers a high discharge capacity ( $1024 \text{ mA h g}^{-1}$ ), but the capacity tends to decay quickly to below  $95 \text{ mA h g}^{-1}$  after 100 cycles. In contrast, the cycling performance of  $\text{SnO}_2/\text{RGO}$  electrode is substantially improved. Although there is still some capacity decay within the initial 20 cycles, the capacity of  $\text{SnO}_2/\text{RGO}$  tends to level off in following cycles. It is important to note that  $\text{SnO}_2/\text{RGO}$  delivers initial discharge capacity as high as  $1610 \text{ mA h g}^{-1}$  and a reversible capacity of  $450 \text{ mA h g}^{-1}$  can be retained over 100 cycles ( $C_{100\text{th}}/C_{20\text{th}} = 87\%$ ) with the coulombic efficiency of 100%. These results indicate that  $\text{SnO}_2/\text{RGO}$  shows improved cycling stability and higher reversible capacity than bare  $\text{SnO}_2$ . Moreover, to fully estimate the electrochemical performance of  $\text{SnO}_2/\text{RGO}$  electrode, the rate performance at current densities of 100, 200, 300, 400 and  $500 \text{ mA g}^{-1}$  are also shown in Fig. 6d. As the current density increases from 100 to  $500 \text{ mA g}^{-1}$ , the reversible capacity varies from 650 to 512, 360, 311 and  $273 \text{ mA h g}^{-1}$ , respectively. Additionally, when the current density returns to  $100 \text{ mA g}^{-1}$ , a reversible capacity of  $639 \text{ mA h g}^{-1}$  is recovered, thus demonstrating a competitive rate capability compared to the previously reported  $\text{SnO}_2$ -based composites as shown in Table S1.†<sup>52–55</sup> The above results show that the introducing of graphene nanosheets combines the respective advantages of  $\text{SnO}_2$  and RGO, thus greatly enhances the overall electrochemical capacity and cycling stability of the  $\text{SnO}_2/\text{RGO}$ . In order to investigate the influence of GO content on the electrochemical performance of the composite, we also synthesized a series of  $\text{SnO}_2/\text{RGO}$  nanocomposites with various component ratios *via* regulating the feeding ratios of GO and  $\text{SnCl}_2$  in the sonochemical reaction systems as shown in Fig. S1.† Considering that large amounts of graphene would in turn inevitably reduce the energy density of finished batteries, thus  $\text{SnO}_2/\text{RGO}$  (30 wt%) is considered to exhibit the best comprehensively electrochemical performance.

EIS measurements were performed for the bare  $\text{SnO}_2$ , RGO, and  $\text{SnO}_2/\text{RGO}$  electrode to further elucidate the influence of graphene nanosheets on the electrochemical behavior of the composite (Fig. 7). The inset is the equivalent circuit used for fitting the impedance spectrum.  $R_s$  represents the ohmic resistance from the system and  $C_d$  is the double-layer capacity.<sup>28</sup> In the Nyquist plots, a semicircle in higher frequency region and an

inclined line of approximately  $45^\circ$  slope at lower frequency region were observed for all materials. The semicircle can be ascribed to charge transfer resistance ( $R_{ct}$ ) at the interface between the electrolyte and electrode, while the inclined line corresponds to  $\text{Li}^+$  diffusion process in the bulk of the electrode and represents the Warburg impedance ( $W$ ).<sup>48</sup> The values of  $R_{ct}$  for the bare  $\text{SnO}_2$ , RGO and  $\text{SnO}_2/\text{RGO}$  are calculated to be 1088, 597, and  $464 \Omega$ , respectively. Apparently,  $\text{SnO}_2/\text{RGO}$  shows smaller  $R_{ct}$  than that of bare  $\text{SnO}_2$ , which is ascribed to the enhanced electronic conductivity provided by the graphene substrate. Moreover, the high slope of inclined line for  $\text{SnO}_2/\text{RGO}$  is a characteristic of low  $Z_w$ , suggesting fast  $\text{Li}^+$  diffusion in the composite electrode. The results confirm that the presence of graphene nanosheets indeed facilitates charge transfer and  $\text{Li}^+$  diffusion during the electrochemical lithiation/delithiation process, which accounts for the enhanced electrochemical performance.

## Conclusions

In conclusion, a facile sonochemical method has been developed to synthesize  $\text{SnO}_2/\text{RGO}$  nanocomposite by *in situ* oxidizing  $\text{SnCl}_2$  to  $\text{SnO}_2$  and reducing GO to RGO. The individual dispersed  $\text{SnO}_2$  nanoparticles are fully well-adhered on the both sides of graphene nanosheets. This unique structure results in high specific surface area, stable framework, and remarkable electron and ion transport, thereby resulting in a superior electrochemical performance. When used as LIBs anode,  $\text{SnO}_2/\text{RGO}$  delivers initial discharge specific capacity as high as about  $1610 \text{ mA h g}^{-1}$ , with the initial coulombic efficiency of about 48%. Moreover, the  $\text{SnO}_2/\text{RGO}$  electrode shows good cycling stability, about 87% of the capacity is maintained ( $C_{100\text{th}}/C_{20\text{th}}$ ) after 100 cycles at  $100 \text{ mA g}^{-1}$ . Additionally, the  $\text{SnO}_2/\text{RGO}$  electrode shows a competitive rate performance. A capacity of  $273 \text{ mA h g}^{-1}$  can be retained at a high current density up to  $500 \text{ mA g}^{-1}$ , and  $639 \text{ mA h g}^{-1}$  can still be recovered once the current density is returned to  $100 \text{ mA g}^{-1}$ . This facile sonochemical method can be also applied to the synthesis of other graphene/metal-oxide composites and this work provides a large-scale preparation route for the practical application of  $\text{SnO}_2$  in lithium ion batteries.
