1 Introduction

Nitrogen oxides (NOx), emitted from combustion of fossil fuels in industrial stationary sources, have caused a series of environmental problems such as acid rain, haze, and ozone depletion. Selective catalytic reduction of NOx by ammonia (NH3-SCR) is one of the most promising NOx abatement technologies. The widely used catalyst in NH3-SCR is V2O5/WO3/TiO2, whose optimum working temperature is higher than 350 °C. In practical application, the SCR reactor is usually located downstream of dust and SO2 removing modules to avoid catalyst deactivation from dust, SO2 and other poisons. As a result, the temperature of flue gas is usually lower than 300 °C, and the flue gas has to be reheated to meet the V–W–Ti working temperature, which will increase the cost of deNOx. Therefore, a better choice is to develop catalysts with high deNOx efficiency, high resistance to water vapor/SO2, and a low working temperature window.

Ce–Mn composites have been reported widely for their excellent low temperature deNOx efficiency and high N2 selectivity. The catalytic ability of Ce–Mn composites is related to the pore structure, specific area, and redox behavior. For example, MnOx–CeO2 nanosphere catalyst showed superior performance compared to its counterpart MnOx–CeO2 without any defined structural morphology. MnOx–CeO2 hollow nanotube synthesized through the interfacial oxidation–reduction reaction showed 96% NOx conversion at 100 °C, and the authors attributed to the uniform distribution of active species and the hollow porous architectures which provided huge specific surface area and sufficient acidic sites. However, the activity of MnOx–CeO2 composites is still low in the presence of SO2 and H2O. Lots of efforts have been done to improve SO2 and H2O resistance of MnOx–CeO2 composites. For example, adding a third dopant (Sn, Cr, W, Eu etc.) into MnOx–CeO2 composites can further improve the deNOx efficiency and SO2 resistance. Cobalt or nickel doped MnOx–CeO2 catalysts showed high SCR activity and good tolerance of SO2, and the authors suggested different SCR reaction pathways and mechanisms of SO2 tolerance between Co/Ni doped and un-doped MnOx–CeO2. Mesoporous catalysts have been proved a good choice to improve SO2 resistance. Zha prepared a MnCeW catalyst on mesoporous TiO2 spheres, and the catalyst showed excellent SCR activity in a wide temperature range. Fe2O3 promoted halloysite-supported CeO2–WO3 catalysts showed improved NOx reduction in the presence of SO2, and the authors confirmed that the increase of Brønsted acid site derived from Fe2O3 promotion is the main cause.
Based on previous studies, the catalytic performance of NH3-SCR activity, including NOx conversion efficiency, N2 selectivity and H2O + SO2 resistance are mainly determined by following factors: pore structure and surface area, the distribution of manganese and cerium states, and the active oxygen species including adsorbed oxygen, oxygen vacancy and lattice oxygen, as well as surface acidity. Inspired by the above studies, we have fabricated MnOx-CeO2 with different pore structures by various methods, and the relationship of NH3-SCR activity and structure was discussed. To further improve the H2O + SO2 resistance of the catalysts, nickel/cobalt was introduced to the MnOx-CeO2 catalysts, and the catalytic performance was evaluated.

2 Experimental section

2.1 Catalysts preparation

All chemical reagents used in this work including Mn(ac)2·4H2O (99.0%), Ce(ac)3·1.5H2O (99.0%), Co(ac)2·4H2O (99.0%), Ni(ac)2·4H2O (99.0%), C2H2O4·2H2O (99.5%), Mn(NO3)2·50% wt, Ce(NO3)3·6H2O, Co(NO3)2·6H2O, Ni(NO3)2·6H2O and NaOH were purchased from Xilong Cop. (China) and used without further purification. To prepare MnOx-CeO2 composites with different pore structures, an oxalate route, a nano-casting strategy and a simple precipitation method were applied.

In an oxalate route, calculated metal salts (the molar ratio of Mn and Ce was 6 : 4) were dissolved in deionized water at room temperature, labeled as solution A. Then, C2H2O4·2H2O (the molar ratio of C2H2O4·2H2O to total metals is 1.2) was dissolved in ethanol, labeled as solution B. The mixtures of A and B were stirred for 24 h. The precipitates were washed, dried, and finally calcined at 550 °C for 4 h. The sample was labeled as 6Mn4Ce-O. Nickel or cobalt doped MnOx-CeO2 composite was prepared as the same procedure. The samples were denoted as 1Ni6Mn3CeO and 1Co6Mn3Ce-O, respectively.

In a nano-casting route, KIT-6 silica was employed as a hard template, and the MnOx-CeO2 catalyst was synthesized as a hard template and the MnOx-CeO2 catalyst was synthesized as a hard template and the MnOx-CeO2 catalyst was synthesized as a hard template by a simple "two-solvent" approach. KIT-6 silica was prepared as previously reported studies. In a typical procedure, 1.0 g KIT-6 was suspended in 80 ml n-hexane and stirred at room temperature for 2 h. Then a mixed solution of Mn(NO3)2 and Ce(NO3)3 was added slowly with vigorous stirring. A n-hexane solution containing MnOx-CeO2 sample was synthesized by a co-precipitation method using NH3·H2O as precipitant, and the sample was labeled as 6Mn4Ce-C.

2.2 Catalytic activity tests

Before SCR activity test, the catalysts were crushed and sieved to 40–60 mesh. A fixed-bed quartz flow reactor was used to perform SCR activity test. The typical reactant gas contained 200 ppm NOx, 200 ppm NH3, 5%O2, 100 ppm SO2 (when used), 5 vol% H2O (when used) and balance of N2. In a typical experiment, 100 mg catalyst was used, corresponding to gas volume hourly space velocity (GHSV) of 72 000 h⁻¹. The temperature range was set to 100–300 °C. An FTIR spectrometer (Bruker Vertex 70 spectrometer, USA) equipped with a heated, multiple path gas cell (10 m) was used to collect the FTIR spectra. The NOx conversion and N2 selectivity were calculated as follows:

\[
\text{NOx conversion(%) = } \frac{[\text{NO}]_{in} - [\text{NO}]_{out}}{[\text{NO}]_{in}} \times 100\%.
\]

\[
\text{N2 selectivity(%) = } \frac{[\text{NO}]_{in} + [\text{NH}_3]_{in} - [\text{NO}]_{out} - 2[N_2O]_{out}}{[\text{NO}]_{in} + [\text{NH}_3]_{in}} \times 100\%.
\]

2.3 Characterization

XRD patterns were recorded on a PANalytical X’Pert PRO X-ray diffractometer using Ni filtered Cu Kz (λ = 0.15418 nm) radiation at 40 kV and 30 mA, in 2θ from 5° to 90° with a scanning step of 0.034°. The specific surface area and pore size distributions of all catalysts were obtained according to the Brunauer–Emmett–Teller (BET) and Barrett–Joyner–Halenda (BJH) methods, respectively, using N2 adsorption–desorption method on an automatic surface analyzer (SSA-7300, BJ-Builder, China) at 77 K. Each sample was pre-degassed at 150 °C for 3 h. Surface species of as-prepared catalysts were determined by X-ray photoelectron spectroscopy (XPS) using a XLESCALAB 250 Xi electron spectrometer (Thermo Scientific, USA) with monochromatic Al Kz radiation (1486.6 eV).

H2 temperature-programmed reduction (H2-TPR) was conducted on a Micromeritics Chemisorb 2720 analyzer (Micromeritics, USA) at a heating rate of 10 °C min⁻¹ with 5% H2/Ar gas. The H2 consumption was recorded continuously to investigate reduction abilities. NH3 temperature-programmed desorption (NH3-TPD) was performed on a Micromeritics Autochem II 2920 analyzer (Micromeritics, USA). The catalysts were firstly heated to 300 °C for 1 h in helium, and then cooled down to 50 °C. After saturated in pure NH3 for 30 min, the samples were purged in pure helium for 1 h to remove the physically adsorbed NH3. The TPD curve was finally recorded in helium from 50 °C to 600 °C at a heating rate of 10 °C min⁻¹. SO2 temperature-programmed desorption (SO2-TPD) was performed on a TP5080B apparatus (Tianjin XQ, China). 50 mg of 40–60 mesh catalysts was firstly heated to 300 °C for 1 h in 30 ml min⁻¹ helium, and then cooled to 200 °C. The catalyst was saturated in 2000 ppm SO2 for 1 h, and then purged with 30 ml min⁻¹ helium for 1 h to remove residual SO2 at 200 °C. At last, the catalyst was heated from 200 °C to 850 °C in helium at 10 °C min⁻¹.

A Bruker Vertex 70 spectrometer (Bruker, USA) equipped with diffuse reflectance accessory (PIKE, and MCT/A detector cooled by liquid nitrogen) was used for recording the in situ DRIFT spectra of the samples. Twenty mg KBr powder was placed under proper amount of samples, and a specially made steel stick was used to smash the sample to a flat surface. The
sample was pretreated at 300 °C for 2 h in N₂ (50 ml min⁻¹). The reaction system was cooled to 200 °C in N₂, and the spectra were collected as background. The spectra were recorded by accumulating 32 scans at a resolution of 4 cm⁻¹.

3 Results and discussion

3.1 NH₃-SCR performance

All composites prepared by different methods were tested for NH₃-SCR in a temperature range of 100–350 °C, as shown in Fig. 1A. The NOx conversion of all catalysts first increased and then decreased. The NOx conversion rates at the whole temperature range of the three catalysts followed the sequence of 6Mn4Ce-O > 6Mn4Ce-C > 6Mn4Ce-N. The NOx conversion of 6Mn4Ce-O reached its maximum of 99% at ~170 °C; and its NO conversion rate remained >80% at the temperature range of 120–275 °C. The NOx conversion of 6Mn4Ce-C was slightly lower than that of 6Mn4Ce-O. The catalyst prepared from nanocasting route showed the worst catalytic performance.

Resistance to H₂O and SO₂ is an important factor that needs to be considered in the evaluation of NH₃-SCR catalysts, as there is more or less SO₂ and H₂O in gas that needs to be managed. The H₂O + SO₂ resistance of three samples is shown in Fig. 1B. After H₂O + SO₂ was introduced into the flue gas, the NOx conversion rate of 6Mn4Ce-O, 6Mn4Ce-N and 6Mn4Ce-C decreased to ~70%, ~62.5% and ~59%, respectively. This indicated that different structure of catalysts had a profound effect on resistance of H₂O and SO₂.

Addition of transition metal oxides (CrOₓ, NiOₓ, CoOₓ, SnO₂, etc.) into MnOₓ or CeO₂ were shown to improve the SCR activity in presence of SO₂ and H₂O by increasing the surface acidity concentration of Lewis or Brønsted acid sites. Based on above results, the H₂O and SO₂ resistance of sample prepared from oxalate route was better than other two samples. Therefore, we prepared Co/Ni doped MnOₓ–CeO₂ composites by oxalate route to further improve their resistance to H₂O and SO₂. As shown in Fig. 1C, addition of nickel or cobalt can both increase the NOx conversion rate at temperature range of 100–280 °C. For example, the NOx conversion of 1Ni6Mn3Ce-O and 1Co6Mn3Ce-O were 99% at 200 °C, slightly higher than that of 6Mn4Ce-O (96% at 200 °C). Besides, the N₂ selectivity of 6Mn4Ce-O was lower than those of 1Ni6Mn3Ce-O and 1Co6Mn3Ce-O (Fig. 1C). The above results showed that addition of nickel or cobalt slightly improves the SCR activity and N₂ selectivity. The H₂O and SO₂ resistance of transition metal oxide doped composites were shown in Fig. 1D. With co-existence of H₂O and SO₂, NOx conversion decreased sharply to 70%, 80% and 20% over 6Mn4Ce-O, 1Ni6Mn3Ce-O and 1Co6Mn3Ce-O.

Fig. 1  (A) NOx conversion as a function of temperature over MnOₓ–CeO₂ prepared by different methods; (B) H₂O + SO₂ resistance over prepared by different methods at 200 °C; (C) NOx conversion as a function of temperature over nickel/cobalt doped MnOₓ–CeO₂; (D) H₂O + SO₂ resistance over nickel/cobalt doped samples by oxalate method at 200 °C; (reaction conditions: [NOx] = [NH₃] = 200 ppm, [O₂] = 5 vol%, [SO₂] = 100 ppm, [H₂O] = 5 vol% (when used), N₂ as balance gas, flow rate = 100 ml min⁻¹, GHSV = 60 000 h⁻¹).
and 1Co6Mn3Ce-O, respectively. When H₂O and SO₂ were cutoff, the deNOx activity of 6Mn4Ce-O, 1Ni6Mn3Ce-O and 1Co6Mn3Ce-O resumed. In previous studies, MnOₓ–CeO₂ composite exhibited low SO₂ tolerance because of sulfate species formation. Therefore, many efforts have been done to improve the SO₂ resistance of MnOₓ–CeO₂ catalysts. For example, novel MnOₓ–CeO₂ nano-sphere catalyst showed improved SO₂ tolerance than MnOₓ–CeO₂ catalyst without defined structural morphology.⁴ CeO₂–MnOₓ showed relatively good resistance to SO₂ because of its core–shell structure.⁵ In our study, both preparation methods and addition of a third dopant were help to improve the resistance to SO₂ and H₂O. This phenomenon illustrated structure, as well as different interaction among third dopants and Mn–Ce composites may play important roles in NH₃-SCR, which will further be discussed in following parts.

3.2 Structural properties

3.2.1 XRD and BET analysis. The XRD patterns of all samples were shown in Fig. 2. The diffraction peaks of 6Mn4Ce-O mainly represented CeO₂ (JCPDF#34-0394) and Mn₂O₃ (JCPDF#41-1442). While the diffraction peaks of 6Mn4Ce-N and 6Mn4Ce-C exhibited broad reflections of CeO₂, no obvious peaks related to MnOₓ.

The diffraction peaks of 1Ni6Mn3Ce-O and 1Co6Mn3Ce-O exhibited broad reflections of CeO₂, no obvious peaks related to MnOₓ, NiO or cobalt oxides. Similar results⁶ were reported in the case of Ni(0.4)–MnOₓ spinel. It is commonly accepted than amorphous structure is easy to embed and intercalate protons rapidly,⁷ therefore promoting adsorption/desorption and redox reaction on the surface of catalysts.⁸ In our study, although the deNOx efficiency and N₂ selectivity of catalysts were similar, the SO₂ + H₂O resistance varied a lot. It can be concluded that amorphous structure caused by addition of a third dopant may be responsible for the good performance of catalysts.

The N₂-adsorption–desorption isotherms and corresponding Barrett–Joyner–Halenda (BJH) pore size distribution curves for catalysts were shown in Fig. 3 (inset). The isotherms of all catalysts showed a characteristic type IV pattern, with a hysteresis loop of type H₁ in the IUPAC classification, indicating the existence of meso-pores and micro-pores. At low P/P₀, the isotherm curve of 6Mn4Ce-O had a relatively lower slope than those of other catalysts, indicating its higher degree of crystallinity, consistent with XRD results. As shown in Fig. 3 (A, inset) and Table 1, the specific surface area of 6Mn4Ce-N (152.116 m² g⁻¹) was higher than 6Mn4Ce-O (116.678 m² g⁻¹) and 6Mn4Ce-C (77.269 m² g⁻¹); while the pore diameter followed the sequence of 6Mn4Ce-N < 6Mn4Ce-O < 6Mn4Ce-C. This result showed that the specific surface area is not positively correlated with the NOx conversion, similar to the report from Qi.⁹ Mesoporous materials present lots of edges and corners for adsorption of reactants; and the pores facilitate mass transfer at the gas–solid phase boundary.¹⁰ Large surface area contributed more active sites, which would facilitate the adsorption of reactants. However, the SO₂ and H₂O in flue gas may also occupy the active sites of catalysts, leading to a drop of SCR conversion. The smaller pores in catalysts from oxalate routes may possibly inhibit the reaction of NOₓ, NH₃ with SO₂ and H₂O. Although 6Mn4Ce-O has a higher degree of crystallinity, which may not facilitate the synergistic effect between elements, the smaller pores in it can balance its structure.

Fig. 2 XRD patterns of as-prepared samples, (A) samples from different methods, and (B) nickel or cobalt doped samples from oxalate route.
eV) before analysis. O1s spectra were fitted into two peaks. The peak centered at $\sim$529.2–529.7 eV was related to surface lattice oxygen (denoted as O_{latt}), and the peak at higher binding energy ($\sim$532.4 eV) was ascribed to surface chemisorbed oxygen (including adsorbed oxygen, hydroxyl and carbonate, denoted as O_{ads}). Compared with 6Mn4Ce-O and 6Mn4Ce-N, the O_{latt} peak of 6Mn4Ce-C shifted to lower binding energy (529.7 eV to 529.2 eV). This phenomenon indicated that different synthesis method can regulate element valence. The relative ratios of O_{ads}/O_{latt} were 1.96, 1.26 and 1.09 for 6Mn4Ce-O, 6Mn4Ce-N and 6Mn4Ce-C, respectively. O_{ads} are considered as the active sites for SCR, because they can provide acid sites to adsorb NH_{3} as O_{ads} or NH_{3}(ads).[29] From this point of view, more O_{ads} species lead to improved activity and good H_{2}O and SO_{2} durability. The H_{2}O and SO_{2} durability sequence of 1Ni5Mn3Ce-O, 6Mn4Ce-O, and 1Co6Mn3Ce-O was consistent with O_{ads}/O_{latt} ratio (1Ni5Mn3Ce-O > 6Mn4Ce-O > 1Co6Mn3Ce-O). Again, this indicated oxalate route and introduction of nickel leading to moderate ratio of Mn^{3+}/Mn^{4+} was help to improve SO_{2} + H_{2}O resistance. In our study, the surface Mn^{3+} species was related to SO_{2} + H_{2}O resistance. As shown in Table 2, the sequence of Mn^{3+} species was 6Mn4Ce-O > 6Mn4Ce-N > 6Mn4Ce-C, consistent with catalytic sequence in Fig. 1B. For samples from oxalate route, the sequence of Mn^{3+} species was 1Ni6Mn4Ce-O > 6Mn4Ce-O > 1Co6Mn4Ce-O, indicating a third dopant can regulate the surface manganese species. Based on the above various characterization studies, it was observed that different preparation method or a third dopant can regulate interaction among Mn, Ce, Ni/Co oxides, which would bring about an appropriate content of active Mn^{3+} and oxygen species on the surface of catalyst.

### 3.2.3 Temperature programming

Redox properties are crucial for the NH_{3}-SCR activities, and H_{2}-TPR spectra were employed to investigate redox properties of the catalysts. The H_{2} consumption as a function of reaction temperature was shown in Fig. 5. For 6Mn4Ce-O, three reduction peaks were observed. The peak centered at 286 °C could be assigned to reduction of Mn^{3+} $\rightarrow$ Mn^{3+}, and the peak centered at 243 °C could be ascribed to Mn^{3+} $\rightarrow$ Mn^{2+}. The broad peak at 381 °C was related to the reduction of surface oxygen of CeO_{2} (Ce^{4+} $\rightarrow$ Ce^{3+}).[31] There was no significant peaks related to Mn^{3+} $\rightarrow$ Mn^{2+} for samples prepared from nano-casting route and co-precipitation route, consistent with XPS and XRD results, indicating their less portion of Mn^{3+}. While for 1Ni6Mn3Ce-O and 1Co6Mn3Ce-O, all peaks shifted to lower temperature range, indicating the incorporation of Ni/Co, Mn and Ce enhances the reducibility of catalyst.

NH_{3}-TPD was employed to investigate NH_{3} adsorption, therefore to examine the acidic sites on different catalysts, as presented in Fig. 6. There were two main peaks on all spectra. The peak at the mid-temperature range (100–400 °C) is related to the desorption of NH_{3} coordinated to Lewis acid sites, and the peak at high-temperature range (400–550 °C) is considered to the desorption of NH_{3} coordinated to Brønsted acid sites.[15,24] Compared with catalysts prepared from nano-casting and precipitation method, the peak related to Lewis acid sites of

6Mn4Ce-O moved toward lower temperature range, indicating the existence of weak Lewis adsorption sites. As described above, samples from oxalate route may have more acidic sites during the decomposition of precursors. The ratios of NH$_3$ adsorption on Brønsted acid site to Lewis acid sites of different catalysts are shown in Table 2. Oxalate route was easier to produce more Brønsted acid sites than other two methods. And addition of nickel can greatly increase the ratio of Brønsted acid/Lewis acid sites. Based on the above various characterization studies, it was observed that different preparation method or a third dopant could regulate interaction among Mn, Ce, Ni/Co oxides, which would bring about an appropriate content of active Mn$^{3+}$ and oxygen species on the surface of catalyst.

As samples from the oxalate route had different resistance to SO$_2$ and H$_2$O, SO$_2$-TPD tests were performed on these three samples, and the results were shown in Fig. 7. There were two main desorption peaks in the temperature range of 300–600 °C, and 650–800 °C, labeled as 1 and 2, respectively. The small and broad peak in area 1 was reported to be assigned to desorption of SO$_2$ adsorbed on the surface of catalysts. In this paper, the area labeled 1 of 1Ni5Mn4Ce was slightly smaller than the other two catalysts, which indicated less SO$_2$ adsorption on it. The main peak at 650–580 °C was associated to desorption of SO$_2$ released from the decomposition of metal sulfates. The area 2 of 1Ni5Mn4Ce was much smaller compared with others, which indicated nickel adding can inhibit formation of metal sulfates. Similar conclusion could be achieved from the TG-DTA test of samples after SO$_2$ + H$_2$O resistance experiments, as shown in ESI.$^\dagger$

3.3 *In situ* DRIFTS

To better understand gas adsorption on different catalysts from oxalate route, *in situ* DRIFTs was conducted, and the results were shown in Fig. 8. Fig. 8A showed *in situ* DRIFTS spectra of NH$_3$ + O$_2$ adsorbed on three samples. The bands at 1235, 1565, 1610 cm$^{-1}$ were ascribed to NH$_3$ coordinated on Lewis acid sites.$^{36}$ The band at 1457 cm$^{-1}$ was due to the symmetric bending vibration of NH$_4^+$ chemosorbed on the Brønsted acid sites.$^{38}$ Meanwhile, a band at 3230 cm$^{-1}$ was due to the N–H stretching vibrations of the NH$_4^+$. Comparing with 1Co6Mn3Ce-O, 6Mn4Ce-O and 1Ni6Mn3Ce-O revealed more

![Fig. 4 O1s, Mn2p and Ce3d spectra of (A) samples from different methods, and (B) nickel or cobalt doped samples from oxalate route.](image-url)
Brønsted acid sites, consistent with NH$_3$-TPD results. Wu obtained the same result that addition of nickel could significantly improve the Brønsted acid sites on FeVO$_4$/TiO$_2$.\footnote{Fig. 8B displayed the in situ DRIFTs spectra of NO$_x$ + O$_2$ adsorption on catalysts at 200 °C. The peaks centered at 1606 cm$^{-1}$ can be ascribed to bridging monodentate nitrates, and peaks centered at 1267, 1209, 1568 and 1540 cm$^{-1}$ were assigned to bidentate nitrates.\footnote{It was noteworthy that bidentate nitrates species on 1Ni6Mn3Ce-O were more than those on other catalysts, indicating nickel addition increased NO uptake. However, cobalt doping leaded to the decrease of bands related to bidentate nitrates, indicating its suppression to NO adsorption.}

As 1Ni6Mn3Ce-O showed the best H$_2$O and SO$_2$ resistance, the in situ DRIFTs were further displayed to understand the mechanism, and the results were shown in Fig. 9. The 1Ni6Mn3Ce-O was firstly exposed to NH$_3$ for 60 min, and then SO$_2$ and H$_2$O was introduced to the reaction gas. The bands corresponding to NH$_3$[a] was quickly diminished, and new bands related to SO$_2$ adsorption appeared, as shown in Fig. 9A. While 1Ni6Mn3Ce-O was firstly exposed to NO + O$_2$ for 60 min, and then SO$_2$ was introduced to the reaction gas, no new bands appeared, which indicated that NO was more easily adsorbed on the surface of catalysts. The 1Ni6Mn3Ce-O was exposed to NH$_3$ + NO + O$_2$ at 200 °C for 60 min, and there were peaks related to

\end{figure}
NH₃ and NOx adsorption, indicating the co-adsorption of NH₃ and NOx. After 100 ppm SO₂ and H₂O were added for another 60 min, no new bands appeared and the intensity of the original bands remained unchanged. This indicated that SO₂ and H₂O in the flue gas had no impact on NH₃-SCR of 1Ni₆Mn₃Ce-O, which was in agreement with the results in Fig. 1. The NH₃-SCR reaction on 1Ni₆Mn₃Ce-O may follow L–H mechanism, NH₃(a) and NO(a) reacted to form N₂ and H₂O. When SO₂ and H₂O were introduced into the flue gas, NO(a) was more prone to react with NH₃(a) than SO₂. All of these contribute to excellent H₂O and SO₂ resistance.

4 Discussion and conclusions

It was commonly accepted that there was an intense correlation between catalytic performance and structural properties, such as morphologies, crystal plans, crystal phases and porous structures. A porous structure provided much surface area and makes the adsorption and diffusion of reactant molecules easy to conduct on the surface of catalysts. In this report, catalysts with different pore structures were created by oxalate route, nanocasting strategy and co-precipitation method. Based on above analysis, catalyst from oxalate route showed best NOx conversion, including NOx conversion and SO₂ and H₂O resistance. Catalyst from oxalate route presented proper ratio of Mn³⁺, surface oxygen species, surface acidic sites, moderate pore size and specific surface area.

Because the catalytic process over single oxide catalysts was limited, the addition of another component into the system would be favorable. In this study, cobalt or nickel was added to Mn–Ce composites, which enhanced the interaction between different elements. However, the deNOx performances of
catalysts were varied based on the added elements. The introduction of nickel leads to the co-existence of Lewis acid sites and Bronsted acid sites. Addition of cobalt leads to much more Lewis acid sites. It has been proved in previous analysis that Bronsted acid sites are better for the resistance of H2O and SO2.

Several methods have been developed to reduce the poisonous effect of H2O and SO2 to SCR, such as selecting most active support, metal modification, rational design of structure and morphology, and pre-sulfation.44,45 The mechanism of these methods was to make a balance among redox properties, effective acid sites, and the formation/decomposition of ammonium sulfate, therefore enhancing the denOx properties and suppressing the blocking effect of H2O and SO2. In this study, introducing nickel into Mn–Ce composite gave rise to more Bronsted acid sites, which was responsible for good H2O and SO2 resistance.

Different preparation methods including oxalate route, nanocasting strategy and traditional co-precipitation were applied to obtain MnOx–CeO2 mixed oxides. The mesoporous Mn–Ce base catalysts prepared from oxalate route showed high denOx efficiency and good SO2 and H2O resistance in the low temperature range. A third dopant such as nickel or cobalt was introduced to the composite to increase SO2 and H2O durability. The nickel–manganese–cerium ternary oxides showed the best SO2 and H2O durability. The reason can be ascribed to its smaller pores and amorphous structure and proper amount of surface Mn3+/oxygen species, which could decrease the chemical adsorption of SO2.
