Black titania nanotubes/spongy graphene nanocomposites for high-performance supercapacitors

Dalia M. El-Gendy, a,b Nabil A. Abdel Ghany c,b and Nageh K. Allam d,b,*

A simple method is demonstrated to prepare functionalized spongy graphene/hydrogenated titanium dioxide (FG-HTiO2) nanocomposites as interconnected, porous 3-dimensional (3D) network crinkly sheets. Such a 3D network structure provides better contact at the electrode/electrolyte interface and facilitates the charge transfer kinetics. The fabricated FG-HTiO2 was characterized by X-ray diffraction (XRD), FTIR, scanning electron microscopy (FESEM), Raman spectroscopy, thermogravimetric analysis (TGA), UV-Vis absorption spectroscopy, and transmission electron microscopy (TEM). The synthesized materials have been evaluated as supercapacitor materials in 0.5 M H2SO4 using cyclic voltammetry (CV) at different potential scan rates, and galvanostatic charge/discharge tests at different current densities. The FG-HTiO2 electrodes showed a maximum specific capacitance of 401 F g\textsuperscript{−1} at a scan rate of 1 mV s\textsuperscript{−1} and exhibited excellent cycling retention of 102% after 1000 cycles at 100 mV s\textsuperscript{−1}. The energy density was 78.66 Wh kg\textsuperscript{−1} with a power density of 466.9 W kg\textsuperscript{−1} at 0.8 A g\textsuperscript{−1}. The improved supercapacitor performance could be attributed to the spongy graphene structure, adenine functionalization, and hydrogenated titanium dioxide.

Introduction

Electrochemical supercapacitors have attracted great attention lately due to their high power density, reversibility, and long cycle life.\textsuperscript{1} Based on their charge storage mechanism, supercapacitors can be classified into two types: electric double-layer capacitors (EDLCs) and pseudocapacitors. While EDLCs store energy physically by charge accumulation at the electrode/electrolyte interface,\textsuperscript{2} pseudocapacitors (battery-type) store energy chemically by fast and reversible faradaic reactions at the electrode surface.\textsuperscript{3} The pseudocapacitive materials, such as metal oxides and conducting polymers,\textsuperscript{4,5} can achieve relatively higher capacitance than EDLCs. However, they are limited by the low cyclability due to the structural degradation of the electrodes during the faradaic reactions.\textsuperscript{6} To this end, carbonaceous materials loaded with metal oxides or polymers are widely investigated as alternatives,\textsuperscript{7–9} including carbon nanotubes (CNTs), activated carbons (AC), graphite, graphene oxide, and graphene. These materials have been actively used due to their advantages, including ease of fabrication and workability under a wide temperature range. Different modifications have applied to those materials to increase their surface area and tailor their pore size distribution (PSD), resulting in an improvement of their energy and power densities.\textsuperscript{8,9}

Specially, graphene-based materials are given much consideration as an effective electrode material owing to their unique properties, such as high specific surface area, excellent chemical stability, electrical and mechanical properties, and the large scale production of graphene.\textsuperscript{10–12} To this end, the Hummers’ method is widely used to produce graphene oxides (GO).\textsuperscript{13} However, the poor electrical conductivity of GO reduces the efficiency of charge transfer and reduces long cycle life.\textsuperscript{14} These problems can be overcome by removing partially the O-containing groups via chemical reduction or by thermal annealing.\textsuperscript{15,16} Also, by using reducing agents such as (hydrazine, dimethyl hydrazine, and NaBH4) to prepare the graphene. This method is harmful to the environment and the resulted graphene has a strong tendency to restack due to the π–π interactions.\textsuperscript{17,18} Therefore, an easy, eco-friendly process to reduce GO is urgently required. Carbon based materials have the high specific surface area, high electrical conductivity, and highly stable. But, carbon based material suffer from low energy density. Compared to, transition metal oxides have high specific capacitance and energy densities. For examples ruthenium, oxide-based materials used to supercapacitors application have high specific capacitance but are more expensive than the other metal oxides such as MnO2, Co3O4, TiO2, and SnO2. Therefore, it is rational to combine low-cost metal oxides with carbon materials to obtain high energy density and high power density through the preparation of a composite.\textsuperscript{19,20}
Herein, a simple method is confirmed to prepare functionali-
zation spongy graphene/hydrogenated titanium dioxide
composites to prevent graphene sheets from restacking
together, resulting in interconnected, porous 3D network
crinkly sheets. Such 3D network structure provides better
contact at the electrode/electrolyte interface and facilitates
the charge transfer kinetics. Functionalized spongy graphene/
hydrogenated titanium dioxide has been produced by func-
tionalization of the graphene oxide with adenine. Afterward
hydrothermal, functionalized spongy graphene oxide (FGO)
with HTiO2 was obtained, which helps to prevent the stacking
between graphene interlayers. The FG-HTiO2 electrodes showed
high performance upon their use in electrochemical capacitor
assembly.

Experimental methods

Materials

Graphite powder (<20 µm) and Nafion 117 solution (5%) were
purchased from Sigma Aldrich. Sulphuric acid (H2SO4, 99%)
from Sham Lab. Hydrogen peroxide (H2O2, 30% v/v) from LOBA
Chemie, absolute ethanol and HCl (33%) were purchased from
El-Nasr Pharmaceutical Company, Egypt. Finally, potassium
permanganate (KMnO4, 99%), from Arabic Laboratory Equip-
ment Co., Ti foils (99.5% purity, 0.1 mm thickness) were
purchased from Sigma Aldrich and, before anodization, cleaned
by sonication in acetone, ethanol, and followed by washing with
deionized (DI) water and drying in air. The electrolytes were
HClO4 purchased from Sigma Aldrich, and all the solutions
were prepared from reagent-grade chemicals and deionized
water. Adenine (Merck) was used directly without further purifi-
cation. Distillated water was used for washing the products.

Synthesis of spongy graphene oxide (SGO)

GO was prepared from natural graphite using a modified
Hummers’ method.21 In a typical experiment, graphite (1.5 g),
NaNO3 (1.5 g) and H2SO4 (70 ml) were mixed and stirred in an
ice bath. Subsequently, 9 g of KMnO4 were added slowly. The
reaction mixture was warmed to 40 °C and stirred for 1 h. Water
(100 ml) was then added and the temperature was increased to
90 °C for 30 min. Finally, 300 ml of water were added slowly,
followed by the slow addition of 10 ml of 30% H2O2. The reac-
tion mixture was filtered and washed with 0.1 M HCl and water.
The GO precipitate was dispersed in a water/methanol (1 : 5)
mixture and puriﬁed with three repeated centrifugation steps at
10 000 rpm for 30 min. The puriﬁed sample was dispersed in
deionized water and centrifuged at 2500 rpm and ﬁnally washed
with deionized water and sonicated for 1 hour to obtain highly
exfoliated graphene oxide. The GO precipitate was dispersed in
water/methanol mixture and puriﬁed with repeated centrifuga-
tion steps at 10 000 rpm for 30 min. Note that washing with
0.1 M HCl and water resulted in highly exfoliated GO sheets. To
prepare SGO, GO solution (4 mg l−1) was frozen at −18 °C for 2
days. After the GO solution was completely frozen, the tube was
peregrinated to a freeze-dryer and dried at a temperature of
−53 °C and a pressure of 10 Pa for 3 days.22

Preparation of adenine-functionalized graphene oxide

GO (0.1 g) was dispersed in distilled water (10 ml), then (0.3 g)
adene and equimolar amount of NaOH in distilled water (10
ml) were added. The mixture was stirred for 24 h. The resulted
precipitate was centrifuged, washed well with water/ethanol
mixture and ﬁnally dried at 60 °C.23

Preparation of TiO2 and hydrogenated TiO2 (H-TiO2)
nanotubes powder

Pieces Ti foil (1 cm × 1 cm) was anodized in 0.1 M HClO4
aqueous electrolyte in a two-electrode cell with the titanium foil
as the working electrode and a platinum foil as the counter
electrode at 25 °C and a constant potential of 20 V. Finally, the
foil was converted into TiO2 nanotube powder. Later, the as-
grown TiO2 nanotube powder (white precipitate) was washed
several times with DI water, collected by centrifugation, and
lastly oven-dried at 60 °C about 15 h.24 Eventually, a white
powder was obtained and to produce well-deﬁned crystalline
structures, sample A was annealed at 550 °C under air, while
sample B was annealed at 550 °C under hydrogen to compare
structures of powders for 2 h with a heating rate of 30 °C min−1
using Advantec KM-100 electric muffle furnaces.

Preparation of functionalized graphene-hydrogenated
titanium (FG-HTiO2)

The functionalized graphene-hydrogenated TiO2 was prepared
by the hydrothermal reduction method. Briefly a speciﬁc
amount of functionalized graphene oxide powder with hydro-
genated TiO2 equivalent to 10, 20, 25 and 30 wt% from FGO
mass were added to a 100 ml conical flask containing 40 ml of
deionized water and sonicated for 30 min to obtain a homoge-
nous dispersion; the samples were named as FG-HT1, FG-HT2,
FG-HT3 and FG-HT4, respectively. The solutions were trans-
fferred to a Teflon-lined autoclaves and heated at 170 °C for 8 h,
and then left to cool at room temperature to get grey product.
These products were washed several times with deionized water
and collected through centrifugation. Finally, the solid prod-
cucts were dried in an oven at 60 °C. The steps are summarized in
Scheme 1.

Preparation of electrodes and electrochemical measurements

Glassy carbon (GC) electrode (5.0 mm diameter) was polished
with alumina nanopowder and rinsed with deionized water.
Fresh dispersion of the sample was prepared for each experi-
ment by dispersing 5.0 mg of the FG powder in 0.5 ml Nafion
117 solution (1%) by ultra-sonication for 30 min. Then 10 µl
suspension of the material was cast onto the surface of the
electrode with a micropipette, ﬁnally, the working electrode was
dried at 60 °C for 10 min and left to cool down. All the elec-
trochemical measurements were done in a three-electrode
system: where the working electrode was made from a glassy
carbon disk, the standard calomel electrode (SCE) and platinum
wire were used as reference and counter electrodes, respectively.
The electrochemical measurements were carried out in 0.5 M
H2SO4 using Auto lab-302N electrochemical workstation
The cyclic voltammetry (CV) measurements were done in the potential range \(-0.2\) to \(1\) V at various scan rates \((1\, \text{to} \, 100 \, \text{mV s}^{-1})\). Galvanostatic charge/discharge measurements were run from \(-0.2\) to \(1\) V at current densities of \(0.8, 1, 2, 3, \text{A g}^{-1}\).

**Characterization techniques**

The crystal structure of the prepared materials was examined by X-ray diffraction (XRD, XPERT-PRO-Analytical) with Cu Kα radiation \((\lambda = 1.54 \, \text{Å})\). The surface morphology was investigated by field-emission scanning electron microscope (FESEM-Zeiss SEM Ultra-60). The morphology of the samples was investigated using high-resolution transmission electron microscope (HRTEM, JOEL JEM-2100) operating at an accelerating voltage of \(120\, \text{kV}\). The infrared (IR) spectra were recorded using a JASCO spectrometer (FT/IR-6300 type A) in the range \(400\, \text{to} \, 4000 \, \text{cm}^{-1}\). UV/Vis spectrophotometric measurements were made using a Shimadzu 2040 spectrophotometer. Raman measurements were performed using a micro-Raman microscope with an excitation laser beam wavelength of \(325\, \text{nm}\). The weight loss of the samples was collected by TGA thermal analyzer (TA TGA-Q500) from room temperature to \(800\, \text{°C}\) at a heating rate \(10 \, \text{°C min}^{-1}\) in nitrogen atmosphere, the time-dependent anodization currents were recorded using a computer controlled Keithley 2000 multimeter and Advantec KM-100 electric muffle furnaces.

**Results and discussion**

Fig. 1 shows FESEM images of the fabricated materials. Fig. 1a depicts the surface of the fabricated spongy graphene oxide (SGO), indicating a great increase in the thickness of the layers, which is possibly due to the formation of oxygen groups in the basal plane of graphene. Upon the addition of adenine, Fig. 1b, the graphene becomes more exfoliated with further increase in volume, resulting in flake-like structure with wrinkled edges and crumbled graphene morphology. Fig. 1c shows typical SEM images of the side and close-up top view of the nanotubes powder prepared in HClO₄ electrolyte by rapid breakdown anodization. The tubes are well-arranged and produce very promptly in dense bundles of approximately \(20\, \text{to} \, 25\, \text{μm}\) in length with average nanotube diameter of \(24\, \text{nm}\). Fig. 1d shows an FESEM image of the hydrogenated titanium dioxide nanotubes (H-TiO₂ NTs) grown on FG. The intercalation of H-TiO₂ nanotubes between graphene layers plays an effective role to accumulate a large amount of ion salts on the surface of the electrode. Moreover, this unique morphology is useful to prevent the aggregation of the graphene sheets. The EDS
spectrum of the graphene-hydrogenated TiO$_2$ hybrid nanocomposite is shown in Fig. 1e, indicating the presence of carbon (C), titanium (Ti), and oxygen (O) elements. The Ti and O elements originated from the TiO$_2$ nanoparticles, and the C was contributed by the graphene nanosheets. The corresponding TEM images, Fig. 1f showing the graphene-hydrogenated TiO$_2$ hybrid nanostructure is a smooth and transparent surface with a nanotubular structure of TiO$_2$ nanotubes.

Fig. 2a shows the XRD pattern of pristine and H : TiO$_2$ samples, revealing major peaks at 2$\theta$ of 25.3, 37.8, 48.0, 53.9, and 55.1, with d of 3.51, 2.37, 1.89, 1.69, and 1.66 Å corresponding to diffraction from (101), (044), (200), (105) and (211) planes of the tetragonal anatase TiO$_2$ phase, respectively. Note that the hydrogenation process does not change the crystalline phase of TiO$_2$. However, the intensity and the peaks of hydrogenated TiO$_2$ is higher than that of pristine TiO$_2$ and the crystallite size of H : TiO$_2$ (31.8 nm) is larger than that of pristine TiO$_2$ (23.6 nm), indicating the creation of oxygen vacancies upon hydrogen annealing leading to the formation of Ti$^{3+}$. Fig. 2b compares the XRD patterns of pristine graphite, SGO, FG, HTiO$_2$ and FG-HTiO$_2$. An intense peak centred at 2$\theta$ = 26.5° was observed for graphite. The broad peak observed in the XRD pattern of SGO centred at 2$\theta$ = 12° proves the formation of abundant oxygen-containing groups by the oxidation process. After functionalization and hydrothermal treatment, the SGO is reduced and converted into FG, as indicated by the new characteristic peak at 2$\theta$ = 24.8°. Notably, in case of HTiO$_2$ nanocomposite, the main peak appeared at 2$\theta$ = 25.1° indexed to the

---

Fig. 1 FESEM images of (a) spongy GO, (b) FGO, (c) HTiO$_2$, (d) FG-HTiO$_2$, (e) EDS image and, (f) the TEM image of FG-HTiO$_2$ of the functionalize graphene-hydrogenated TiO$_2$ hybrid nanostructure.
anatase phase of TiO$_2$ and the main characteristic peak of FG at 25.0° leads to an overlap with the (101) peak of anatase TiO$_2$ at 25.1°.

Fig. 3a compares the FTIR spectra of air and hydrogen-annealed titania samples, showing similar absorption features in the range 500–4000 cm$^{-1}$. Note the appearance of OH absorption bands near 3400 cm$^{-1}$, owing to a bridging OH group (Fig. 3b). The peaks at $\sim$3700 cm$^{-1}$ can be ascribed to the presence of the O–H stretching and wagging modes. The strength of the terminal O–H mode is reduced when white TiO$_2$ is changed to black TiO$_2$ upon hydrogen annealing. Note that incorporated hydrogen into the TiO$_2$ probably does not passivate a significant number of O dangling bonds as this would otherwise increase the absorption. The peak at 1725 cm$^{-1}$ almost disappears and the peak emerged at 1637 cm$^{-1}$ is characteristic of the C–O stretching in the amide group, which cannot be found in the spectrum of GO. Stretching of the amide C–N appears as a strong peak at 1188 cm$^{-1}$. The peaks at 1560 and 1618 cm$^{-1}$
are characteristic of graphene vibration, and the peak attributed to the OH and NH stretching groups at 3475 cm\(^{-1}\) confirm the covalent functionalization of the neat graphite by adenine, assuring the successful functionalization process. The peak at 3415 cm\(^{-1}\) is attributed to N–H stretching.\(^{27}\) These results demonstrate that adenine molecules were covalently bonded to GO by the amide linkage. The peak observed at 651 cm\(^{-1}\) corresponds to the Ti–O–Ti vibration of the TiO\(_2\) phase.\(^{28}\) For the graphene–TiO\(_2\) hybrid nanostructure, the intensities of the bands corresponding to the oxygen functional groups were reduced compared to GO, signifying the reduction of oxygen in the as-prepared graphene–TiO\(_2\) hybrid nanostructures. The strong band observed at 588 cm\(^{-1}\) indicated the Ti–O–C vibration.\(^{28}\) Note that the peak intensity of the C–O and C–O–C (epoxide) groups, respectively, decreased in FGO, FG, and FG-HTIO\(_2\) after the hydrothermal reduction with HTIO\(_2\) that resulted in FG-HTIO\(_2\).

Raman spectroscopy is an effective process to examine the structural features of carbon-based materials. Fig. 4a shows the Raman spectra for air and hydrogen-annealed TiO\(_2\) electrodes. The peak intensity of hydrogenated TiO\(_2\) was lower than that of the air-annealed counterpart. The Raman peaks at 144 cm\(^{-1}\) and 636 cm\(^{-1}\) were shifted to a higher frequency, indicating the formation of oxygen vacancies due to the hydrogen annealing, in agreement with Liu et al. who proposed the formation of Ti\(^{3+}\).\(^{29}\) The intensity ratio of the D and G bands (I\(_D\)/I\(_G\)) is a convenient parameter for the determination of the sp\(^2\) domain size of carbon structures containing sp\(^3\) and sp\(^2\) domains. GO exhibited the G band at 1576 cm\(^{-1}\) and the D band at 1354 cm\(^{-1}\). While the intensity of the D band for FG-HTIO\(_2\) was increased compared to that of SGO, the G band is still prominent and the I\(_D\)/I\(_G\) ratio is 0.99 with the I\(_D\)/I\(_G\) ratio of FG-HTIO\(_2\) being 1.01. The higher I\(_D\)/I\(_G\) ratio of FG-HTIO\(_2\) (1.01) than that of SGO (0.99) indicates the reduction in the size of the in-plane sp\(^2\) domains. The notable bands located at 147 (E\(_g\)), 402 (B\(_{1g}\)), 513 (A\(_{1g}\)), and 635 (E\(_g\)) as well as the small peaks at 159 cm\(^{-1}\) are attributed to the intercalated TiO\(_2\) nanotubes with graphene.\(^{30,31}\)

To evaluate the thermal stability of GO, FGO, FG and FG-HTIO\(_2\), TGA analysis was performed by heating under N\(_2\) atmosphere to 800 °C at a rate of 10 °C min\(^{-1}\), Fig. 5. At temperatures below 100 °C, the mass loss can be related to the removal of adsorbed H\(_2\)O. For GO, it is thermally unstable and the mass loss occurs in three steps: the first step is detected below 110 °C that can be associated with vapor content and loss of interstitial H\(_2\)O\(^32\) with a total mass loss of ~8%, the second stage is detected in the range 130–250 °C as a sharp drop peak that accounts for a mass loss of ~65%, owing to the decay of hydroxyl groups, presented water on GO, and carboxyl group to produce gases such as H\(_2\)O and CO\(_2\). Note that CO\(_2\) is generally created because of the decomposition of carboxyl group due to
the thermal treatment at temperatures less than 500 °C. The third step is extended from 350 °C up to 800 °C, resulting in a notable mass loss of ~80%, which can be attributed to the decomposition of carboxyl groups formed on the surface of graphene oxide to yield CO gas. FGO showed higher thermal stability than SGO. The first humilition step of FGO appeared nearly in the similar range to that of SGO (145–173 °C), while the second step of the degradation appeared at a greatly higher temperature of 365–415 °C. Upon functionalization of SGO with adenine, the labile oxygen groups underwent chemical reaction to form a strong covalent bond with the amino groups of adenine, which noticeably decreased the volume of labile groups in FGO. This results in a very low weight loss at about 145–173 °C in FGO, which is in agreement with the decrease in the FTIR peak intensity at 1725 cm⁻¹. This is typical due to the stretching vibrations υ(C=O) of COOH group equivalent to carbonyl and carboxyl groups that have disappeared, with the peak emerged at 1637 cm⁻¹ is characteristic of the C=O stretching in the amide group, see Fig. 3b. The weight loss of the hydrothermally reduced FG shows a slight weight loss of about 10% up to 670 °C, indicating that the oxygen-based groups in GO formed heat-stable structures through covalent bonding with adenine. In the case of the FG-HTiO2 nanocomposite, the weight loss of the sample was greatly limited, which may indicate that FG imposed a control on the mobilization of titanium oxide nanotubes, leading to homogeneous heating and preventing heat concentration. This also supports a strong contact between FG and H-TiO2.

To study supercapacitive performance of the fabricated samples, cyclic voltammetry (CV) measurements were performed in 0.5 M H2SO4 where the specific capacitance of the electrodes was calculated using eqn (1).

\[ C_s = \frac{\int I dv}{m \Delta V} \]  

where \( C_s \) is the specific capacitance, \( m \) is the weight of the electrode (g), \( I \) is the response current density (A g⁻¹), \( \Delta V \) is the potential difference, and \( v \) is the potential scan rate (mV s⁻¹).

Fig. 6a shows a comparison of the cyclic voltammograms of SGO, FG-HT1, FG-HT2, FG-HT3 and FG-HT4 electrodes in the potential range of −0.2 to 1 V at a scan rate of 5 mV s⁻¹. It was observed that with increasing TiO2 content, the specific capacitance firstly increases to a maximum value and then declines, with an optimum loading of TiO2 of 20 wt%. Fig. 6b shows that the specific capacitance decreases with increasing the scan rate from 1 to 25 mV s⁻¹, which can be related to the insufficient time available for ion diffusion and adsorption inside the smallest pores within a large particle at high scan rates. The sudden drop in the capacitance of the FG-HT4 can be related to the presence of high concentration of HTO2 that tend to agglomerate and block the pores of graphene, thus masking the effect of graphene nanosheets (GNS). In this case, the ions in the electrolyte might not have enough time to move into the complex micropores of the electrodes (diffusion limited) at high scan speeds. Note that the specific capacitance of the functionalized graphene-HTO2 hybrid electrode was much higher than that of the SGO and FG electrodes, which is also higher than previous reports. This higher capacitance value can be ascribed to the faradaic and non-faradaic reactions arising from graphene and hydrogenated TiO2. Also, the donor densities of TiO2 nanotubes are significantly improved by well-ordered introduction of oxygen vacancy (Ti⁴⁺ sites) states through thermal treatment in hydrogen gas. Furthermore, we anticipate that hydroxyl groups will be introduced on TiO2 surface during hydrogenation, which could modify the electrochemical activity of TiO2 and therefore increase its pseudocapacitance, Fig. 6c and d. The specific capacitance of the FG-HT2 electrode reached as high as 401 F g⁻¹ at a scan rate of 1 mV s⁻¹ and drops to 110.4 F g⁻¹ at a scan rate of 100 mV s⁻¹, which again implies that the ions in the electrolyte might not have enough time to enter into the complex micropores of the electrodes (diffusion limited) at high scan speeds, Fig. 6e. Note that the obtained specific capacitance of 401 F g⁻¹ at a scan rate of 1 mV s⁻¹ is much higher than that previously reported for graphene-TiO2 electrodes (165 F g⁻¹ at 1 M Na2SO4 at 5 mV s⁻¹).

Galvanostatic charge/discharge measurements are necessary to determine the electrochemical performance of all material to be used as supercapacitors. The specific capacitance was calculated at different current densities using eqn (2)

\[ C_i = \frac{I \Delta t}{m \Delta V} \]  

where \( I \) is the discharge current (A), \( \Delta t \) is the discharge time (s), and \( \Delta V \) is the potential window (V).

Fig. 7a shows a comparison of the galvanostatic charge/discharge graphs for FG and FG-HTO2 at 2 A g⁻¹ current density. The FG-HTO2 nanocomposite achieved better specific capacitance (375 F g⁻¹ at 1 A g⁻¹) than FG at the same current density. Fig. 7b shows the galvanostatic charge/discharge graphs of the fabricated FG-HTO2 at different current densities (0.8–3 A g⁻¹). All the charge–discharge curves are quasi-triangular, indicating fast and capable charge transfer and high electrical conductivity. This can be attributed to the presence of active nitrogen atoms from adenine and the high electronegativity of nitrogen as well as the hydrogenated titanium dioxide that may create dipoles on the surface of graphene, which may draw charged species into the surface. The influence of N, O atoms and HTO2 on the capacitance can also be ascribed to the inductive effect of the σ-bonded structure from N, O heteroatoms and hydrogenated titania, which help in the polarization of some bonds and distribution of electrons on the surface, resulting in reversible faradaic redox reactions. Fig. 7c presents relationship between the specific capacitance and current density, where a decrease in specific capacitance is observed as the current density increases. The calculated specific capacitances obtained from charge and discharge curves of FG-HTO2 are 393.3, 375, 261.6, and 202.5 F g⁻¹ at 0.8, 1, 2 and 3 A g⁻¹, respectively. Note that the obtained specific capacitance at 0.8 A g⁻¹ (393.3 F g⁻¹) is very close to that calculated from the cyclic voltammograms (401 F g⁻¹), which is much higher than that previously reported for graphene/TiO2 hybrid electrodes. Moreover, the FG-HTO2 electrode exhibits excellent rate capability of 51.5% at a current density of 3 A g⁻¹. The energy and power densities are very important performance
metrics of supercapacitors, which can be calculated from the galvanostatic charge/discharge graphs using eqn (3) and (4):

\[ E = \frac{1}{2} C_s (\Delta V)^2 = \frac{I \Delta V t}{2m} \]  

\[ P = \frac{E}{t} = \frac{I \Delta V}{m} \]

where \( E \) and \( P \) refer to the average energy density (W h kg\(^{-1}\)) and average power density (W kg\(^{-1}\)), respectively, and \( C_s \) is the specific capacitance calculated from the charge/discharge curves, \( I \) is the discharge current (A), \( t \) is the discharge time (h), \( \Delta V \) is the potential window (V), and \( m \) is the mass of the FG-HTiO\(_2\) electrode (kg).

Fig. 6 (a) Comparative cyclic voltammograms of FG-H1, FG-H2, FG-H3 and FG-H4 nanocomposite at a scan rate of 5 mV s\(^{-1}\), (b) average specific capacitances of FG-HT1, FG-HT2, FG-HT3 and FG-HT4 nanocomposites at various scan rates of 1, 5, 10 and 25 mV s\(^{-1}\). (c) comparative cyclic voltammograms of FG-HT2, FG and SGO electrodes at a scan rate of 5 mV s\(^{-1}\); (d) cyclic voltammograms of FG-H2 electrodes at different scan rates, and (e) the corresponding specific capacitance of FG-H2 electrodes at different scan rates in 0.5 M H\(_2\)SO\(_4\).
Ragone’s plot for the FG-HTiO₂ electrode at different current densities is shown in Fig. 7d. The energy density can reach up to 78.66 W h kg⁻¹ with a power density of 466.9 W kg⁻¹ at 0.8 A g⁻¹. It is worthy to mention that the achieved energy density for FG-HTiO₂ electrode (78.66 W h kg⁻¹) at 0.8 A g⁻¹ is much higher than those reported for graphene-based electrodes fabricated by different methods.²³,⁴⁷–⁵⁰ Fig. 7e shows the cycle life test of the FG-HTiO₂ performed at a scan rate of 100 mV s⁻¹ for 1000 cycles. The specific capacitance sharply increased from the initial cycle until 1000 cycle to reach 100.2% of the initial cycle, indicating the excellent cycling stability of the FG-HTiO₂ electrodes. Table 1 compares the obtained results to those

![Graph showing Ragone's plot for FG-HTiO₂ electrode at different current densities.](image-url)

**Fig. 7** (a) Comparative galvanostatic charge/discharge plots of FG and FG-H2 nanocomposite at a current density of 2 A g⁻¹, (b) galvanostatic charge/discharge of FG-H2 at different current densities of 0.8, 1, 2 and 3 A g⁻¹, (c) the corresponding specific capacitance of FG-H2 electrode, (d) Ragone plot at different current densities of 0.8, 1, 2, and 3 A g⁻¹, and (e) the first and 1000th CV cycles at a scan rate of 100 mV s⁻¹ of FG-H2 electrodes in 0.5 M H₂SO₄.
reported in literature, showing the superiority of our fabricated hybrid electrodes.

Conclusions

A simple method is demonstrated to prepare functionalized spongy graphene/hydrogenated titanium dioxide (FG-HTiO₂) nanocomposite electrodes. The electron microscopy (FESEM and TEM) study showed the formation hydrogenated titanium nanotubes H-TiO₂ NTs that are grown onto FG sheets. This was supported by the XRD analysis. Also, the FTIR spectra showed a peak at 3475 cm⁻¹ that is attributed to the OH and NH stretching groups, confirming the covalent functionalization of the neat graphene by adenine, and a peak at 588 cm⁻¹ indicating the Ti–O–C vibration. The higher \( I_{D}/I_{G} \) ratio in the Raman spectra of FG-HTiO₂ (1.01) than that of GO (0.99) indicates the reduction in the size of the in-plane sp² domains. Also, the notable bands located at 147 (Eg), 402 (B1g), 513 (A1g) and (635 Eg) as well as the small peaks at 159 cm⁻¹ are attributed to intercalated TiO₂ nanotubes, thus confirming the formation of the FG-HTiO₂ structure. The TGA analysis of the FG-HTiO₂ showed a slight weight loss at 670 °C. Upon their use as supercapacitor electrodes, the FG-HTiO₂ electrodes showed a maximum specific capacitance of 401 F g⁻¹ at scan rate of 1 mV s⁻¹ and exhibited excellent cycling retention of 100.2% after 1000 cycles at 100 mV s⁻¹. The energy density was 75 Wh kg⁻¹ with a power density of 592.4 W kg⁻¹ at 1 A g⁻¹. These results demonstrate that the fabricated FG-HTiO₂ hybrid electrodes are promising electrode materials for high-performance supercapacitors. The specific capacitance improved due to the synergistic effects of the spongy graphene structure, hydrogenated titania and the presence of adenine.
