Structural analysis and antioxidant activity of an arabinoxylan from *Malvastrum coromandelianum* L. (Garcke)

 Shanti Devi, Ajeet K. Lakhera and Vineet Kumar *

Malvastrum coromandelianum L. (Garcke) is extensively used in traditional medicinal systems to treat various ailments. In the present study, an alkali-soluble polysaccharide (MAP) was isolated from the leaves of *M. coromandelianum* in 1.15% (w/w) yield. MAP was composed of L-rhamnose, L-arabinose, D-xylose, D-glucose and D-galactose in a 1.00 : 6.04 : 19.88 : 1.07 : 3.03 molar ratio along with D-glucuronic acid (1.95). Methylation/linkage analysis revealed a backbone of $\rightarrow 4\text{-}\beta\text{-D-Xylp}(1\rightarrow$ (30.09 mol%) with a side chain of $\rightarrow 3\text{-}\alpha\text{-L-Araf}(1\rightarrow$ (15.21 mol%) residues. The structure of MAP was elucidated by a combination of degradative and derivatization techniques, including hydrolysis, alditol acetate derivatization, methylation, GC-MS, partial hydrolysis, ESI-MS and NMR (1D, 2D) spectral analysis. Based on correlation analysis, MAP was found to be an arabinoxylan comprising a backbone of $\rightarrow 4\text{-}\beta\text{-D-linked Xylp}(1\rightarrow$ with branching at O-2 by a $\rightarrow 3\text{-}\alpha\text{-L-Araf}(1\rightarrow$ and $\rightarrow 3\text{-}\beta\text{-D-Xylp}(1\rightarrow$ chain. MAP also exhibited ferric ion reducing activity, with a reducing power of 0.914 ± 0.01 ($R^2 = 0.972$) at 1 mg mL^{-1} concentration, which showed dose-dependent behavior. MAP can be utilized as a potential antioxidant.

1. Introduction

Reactive oxygen species (ROS), such as singlet oxygen ($^1\text{O}_2$), superoxide anions (O_2^-), hydroxyl, peroxy and peroxy-nitrite, are generated during normal cellular respiration in the body.^{1,2} Under normal circumstances, these species regulate cell growth and control viruses and bacteria.³ However, excessive ROS in the body can attack tissues and disrupt redox homeostasis, which result in oxidative stress⁴ and eventually lead to T-cell damage, decreased immune function and aging, diabetes, immuno-suppression, neuro-degeneration, increasing cardiovascular and cerebrovascular disease risk, *etc.* ROS also act as strong carcinogens and damage DNA *via* altering the genes such as oncogenes and tumor suppressor, apoptosis-regulating, and DNA-repair genes; this causes numerous chronic ailments, *e.g.*, cancer and arteriosclerosis.^{5,6} Antioxidants play noteworthy roles in the prevention of free radical damage to the body by quenching ROS. In this context, polysaccharides are gaining massive popularity as potent natural antioxidants from plants. Polysaccharides can inhibit lipid peroxidation, enhance the body's ability to scavenge free radicals, inhibit cardiovascular and cerebrovascular diseases, *etc.*⁷ Algal polysaccharides are found to prevent oxidative damage in living organisms.⁸ *Astragalus*⁹ and *Rhizoma Dioscorea nipponica* polysaccharide¹⁰ block the NF- κ B pathway to inhibit

ROS production. *Lycium barbarum* polysaccharides enhance the activities of superoxide dismutase (SOD) and glutathione peroxidase (GSH-Px) in chickens.¹¹ *Ganoderma lucidum* polysaccharides exhibit *in vitro* antioxidant activities.¹² A polysaccharide from *Cordyceps sinensis* slows ROS generation by inhibiting PDGF-BB-induced inflammation.¹³ An extracellular polysaccharide from *Morchella* can significantly improve the activity of enzymes, *viz.*, GSH-Px and SOD in the blood, spleen, heart, liver, and kidneys of mice and decrease the malondialdehyde content in these organs.¹⁴

Therefore, polysaccharides from plants are a promising source of antioxidants, which can effectively prevent damage due to oxidative stress and hence prevent diseases. In our laboratory, the polysaccharides from plant species used in traditional medicine are being characterized, and their activity profiles are being studied to provide leads for future drug development based on their structure-activity relationships.^{15–19} In our continuous endeavor towards this goal, it was observed that a polysaccharide from *Malvastrum coromandelianum* (Garcke) Linn showed significant ferric ion reducing ability using the potassium ferri-cyanide assay. Interestingly, *M. coromandelianum* is an alien weed species found throughout India;^{20,21} it is known to possess diverse pharmacological and biological activities. The species is reported to have emollient, resolvent, bechic and anti-dysenteric properties, and it is widely used in traditional systems of medicine as an anti-inflammatory and analgesic agent and also to treat ulcers,²² stomachache,²³ jaundice, *etc.* Its flowers are used to treat cough along with chest and

lung diseases.²⁴ Different parts of the species are employed in diverse herbal formulations to treat gout,²⁵ rheumatic arthralgia,²⁶ laying hen salpingitis,²⁷ otitis,²⁸ and tumors;²⁹ it is also used in herbicidal compositions³⁰ and medicinal wine.³¹

Pharmacological screening of the aqueous extract exhibited significant antidiabetic and antihyperlipidemic activities.^{32,33} The extract also inhibited inflammation induced by carrageenan and pain due to formalin stimulation.³⁴ A crude water extract from the aerial parts exhibited antibacterial activity against methicillin-resistant strains of *Staphylococcus aureus*.^{35,36} Further, in view of the fact that natural plant polysaccharides are currently gaining significant popularity as potent natural antioxidants, concomitant with the vast pharmacological activity of the species, it was hypothesized that the polysaccharide constituting the major fraction of water extract of *M. coromandelianum* is responsible for its activity. However, to date, there have been no studies regarding the purification, characterization or antioxidant activities of polysaccharides from *M. coromandelianum*.

In the present study, a polysaccharide was isolated from leaves of *M. coromandelianum* using 1 M NaOH solution, and its ferric reducing power activity was examined using the potassium ferricyanide assay. Interestingly, the polysaccharide showed positive results and was found to significantly reduce ferric ions in a dose-dependent manner. Thus, it was thought to be worthwhile to explore the structure of the alkali soluble polysaccharide (MAP) from the species. The structural characterization was carried out *via* chemical degradation and derivatisation methods, *viz.* hydrolysis, alditol acetates, and methylation, concomitant with GC-MS and ESI-MS analysis. The results were further corroborated by 1D and 2D NMR spectroscopy (¹H, ¹³C, HSQC and HMBC). Structural analysis of the polysaccharide may lead to enhanced utilization of this species in diverse biological and pharmaceutical applications in addition to other industrial applications based on its structure–activity relationship. The encouraging results of our investigation offer a strong basis for the development of novel polysaccharide-based antioxidants from this species.

2. Experimental

2.1. Materials

The leaves of *M. coromandelianum* were collected from the Forest Research Institute campus, Dehradun in July 2014. The species was authenticated by Dr H. B. Naithani, Systematic Botanist, Botany Division, and voucher specimen no. 170580 was deposited at the herbarium of Systematic Botany Discipline, Botany Division, Forest Research Institute, Dehradun.

All the chemicals and reagents used were of analytical grade. The standard solutions were freshly prepared before experimentation. Sephadex G-200 was purchased from Pharmacia, Stockholm, Sweden. Dialysis membrane with a molecular weight cutoff (MWCO) of 12 to 14 kDa was procured from Himedia Laboratories Pvt. Ltd., Mumbai, India. UV-vis spectra

were recorded on a Thermo Scientific Spectrascan UV 2700 spectrophotometer.

2.2. Isolation, purification and homogeneity analysis of the polysaccharide

The leaves of *M. coromandelianum* were washed thoroughly under running water and dried in shade at room temperature. The polysaccharide was extracted by following the method of Kumar and Kumar.¹⁶ Briefly, air dried leaves (100 g) were shredded and extracted with distilled water at 30 °C with continuous stirring for 3 h (3 times) followed by filtration. The obtained residue was stirred at 80 °C for 3 h (3 times) to isolate the hot water-soluble polysaccharide. Further, the residue left after hot water extraction was stirred with 1 M NaOH solution at ambient temperature for 1 h and filtered. The filtrate was neutralized using 0.5 M HCl and centrifuged at 2000 rpm for 15 minutes to remove all undissolved impurities. The supernatant was concentrated to a small volume and poured into 3 volumes of ethanol with constant stirring. The polysaccharide precipitated as a fluffy mass and was separated by centrifugation. The precipitates were again dissolved in a minimum quantity of water and re-precipitated with ethanol. This step was repeated two times. The obtained polysaccharide was washed sequentially with diethyl ether, acetone, and ethanol to eliminate impurities. The supernatant was decanted off every time. The precipitates were dried and dissolved in a minimum amount of distilled water (50 mL) and the undissolved mass was removed by ultracentrifugation at 12 000 rpm.³⁷ The supernatant was freeze dried to obtain the crude alkali-soluble polysaccharide.

A dilute solution (5 mg mL⁻¹) of alkali-soluble polysaccharide was passed through a freshly regenerated cation exchange resin column [Dowex-50 W-X8] followed by an anion exchange resin column [Seralite SRA-400], and the eluents were analyzed by the Molisch carbohydrate test.³⁸ The combined eluents were concentrated to a small volume and dialyzed against distilled water using a dialysis membrane (MWCO: 12 to 14 kDa) for 72 h. The dialyzed solution was concentrated and re-precipitated with four volumes of ethanol. The precipitates were separated, dried, dissolved in distilled water and lyophilized to obtain the crude polysaccharide as an off-white amorphous mass (1.15 g).

2.3. Gel permeation chromatography of MAP

The homogeneity analysis of the crude polysaccharide was performed using GPC. A Pharmacia column (1.6 × 40 cm) was packed with Sephadex G-200 as a gel permeation medium using double distilled water as the mobile phase, and 200 mg (MAP) polysaccharide was loaded. Fractions of 2.5 mL each at an elution rate of 0.30 mL min⁻¹ were collected using a Gilson fraction collector (Model-202). The absorbance of the fractions was studied using the anthrone–sulphuric acid method³⁹ at 620 nm, and a graph was plotted of absorbance *vs.* the fractions collected after elution. The fractions comprising the major peak were pooled, dialyzed and lyophilized to obtain the pure native alkali-soluble polysaccharide, which was designated as MAP.

2.4. Complete hydrolysis and paper chromatography

MAP (5 mg) was completely hydrolyzed by refluxing with 2 N sulphuric acid (5 mL) for 25 h followed by neutralization using barium carbonate slurry; then, it was filtered and concentrated to a syrupy liquid. The resulting liquid was subjected to paper chromatography along with standard monosaccharides using 1 chr and 3 chr Whatman chromatography paper. The papers were run for 45 to 120 h using the following solvent systems; (a) *n*-butanol : formic acid : water; 12 : 1 : 7 (upper layer); (b) *n*-butanol : pyridine : water; 6 : 4 : 3; and (c) ethyl acetate : acetic acid : *n*-butanol : water; 4 : 3 : 2 : 2. The paper chromatograms were dried at room temperature, followed by detection of the monosaccharides (neutral and acidic) using aniline phthalate spray and ammoniacal silver nitrate complex independently by employing standard protocols.⁴⁰

2.5. Carboxyl reduction of polysaccharide

MAP was reduced using the method by Taylor, Shively and Conard.⁴¹ The polysaccharide (50 mg) solution in distilled water (100 mL) was adjusted to pH 4.75 using 1 M HCl. To the resulting solution, solid 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (167 mg, EDC·HCl) was added. The mixture was stirred for 45 min at pH 4.75, followed by dropwise addition of 3 M NaBH₄ solution at 25 °C during a one hour period. During the addition of sodium borohydride, the pH was maintained at 7.0 using 4 M HCl solution. At this stage, the reaction mixture was further stirred for 1 h, and the pH of the solution was decreased to 4 by addition of dil. HCl (1 M) to destroy excess sodium borohydride. The resulting solution was dialyzed (12 to 14 kDa) exhaustively against distilled water for 72 h, concentrated to a small volume and precipitated by addition of ethanol. The precipitates were filtered, dissolved in a minimum quantity of water and lyophilized to obtain the reduced polysaccharide (MAP-R; 31 mg). The complete reduction of the polysaccharide was analyzed and confirmed by the negative carbazole–sulphuric acid color test for uronic acid.

2.6. Monosaccharide analysis

MAP and the reduced polysaccharide (MAP-R, 10 mg each) were hydrolysed using 2 N H₂SO₄ for 6 h with pinitol (1 mg) as an internal standard. Alditol acetate as a standard monosaccharide and the sample were prepared by following the method by Jansson *et al.*⁴² and subjected to GLC analysis⁴³ using an Agilent 7890B gas chromatograph equipped with a flame ionization detector (FID). The initial temperature of the column was 190 °C with a hold time of 1 min; the temperature was increased at a rate of 3 °C per minute until attainment of the final temperature of 260 °C, with holding for 10 min. Helium was used as a carrier gas with a flow rate of 1.2 mL min⁻¹. The monosaccharide composition (for neutral as well as acidic sugar residues) was calculated by comparing the GLC chromatograms of native and reduced polysaccharides.

The uronic acid was further quantified spectrophotometrically by the 3,5-DMP method.⁴⁴ All the experiments were performed in triplicate.

2.7. Linkage analysis

Linkage analysis of MAP was performed by methylation of the reduced and native polysaccharides with the modified Hakomori method and derivatization to PMAA, followed by comparing the GC-MS results.⁴⁵ Briefly, the polysaccharide (50 mg) was dissolved in DMSO (10 mL; dried over molecular sieves) in a stream of nitrogen. Alkoxide ions were formed by portionwise addition of sodium hydride at 60 °C, and the reaction mixture was left for 1 h with continuous stirring. At this stage, the nitrogen flow was stopped and the reaction mixture was cooled over an ice bath followed by addition of methyl iodide. The permethylated polysaccharide was extracted with chloroform (3 × 10 mL). The combined fractions were washed with distilled water, dried over anhydrous sodium sulphate and concentrated under vacuum.

The permethylated derivatives were hydrolysed with 90% (v/v) formic acid (5 h) followed by hydrolysis with 2 M TFA for 6 h. The hydrolysates were reduced to alditols with sodium borohydride and converted to partially methylated alditol acetates (PMAA) using pyridine: acetic anhydride in a 1 : 1 ratio. The PMAAs were analyzed by GC-MS (Agilent 7890B gas chromatograph with a 5977A mass spectrometer with electron ionization (EI) and a quadrupole analyzer) using an RTX 2330 column and helium as a carrier gas. The program used to run the PMAA derivatives was as follows: the initial temperature of the column was 170 °C, and the temperature was increased at a rate of 6 °C per minute up to 240 °C with final holding for 10 min. 10 µL of sample was injected with a split ratio of 10 : 1. The linkages were identified by the relative retention times and fragmentation patterns of the mass spectra for individual PMAA peaks.

2.7. Partial hydrolysis and ESI-MS analysis

MAP (5 mg) was partially hydrolysed using 0.5 M and 1 M hydrochloric acid (5 mL) for 1 h separately. The partially hydrolysed solution was dried under vacuum on a rotary evaporator. Traces of acid were removed by passing a stream of nitrogen. ESI-MS analysis was performed on a Waters Micro-mass Q-TOF micro instrument equipped with the Waters Alliance 2795 separations module in unit resolution (MRM) acquisition mode. The injection volume of analyte was 20 µL and the flow rate was 0.4 mL min⁻¹. MS was operated in positive and negative ionization mode, and the spectra were acquired with a *m/z* range of 0 to 2000. Other parameters used for the mass spectrometer were desolvation gas: 550 L h⁻¹, cone gas: 30 L h⁻¹, desolvation temperature: 300 °C, source temperature: 110 °C. The capillary and cone voltages were set at 3000 V and 30 V, respectively, and a collision energy of 4 eV was used. N₂ (6 to 7 bar) and argon (5 to 6 bar) were used as drying gases.

2.8. NMR spectral analysis

MAP (35 mg) was deuterium-exchanged with 99.9% D₂O (3 × 650 µL) three times using freeze–thaw cycles prior to NMR analysis. The deuterium-exchanged polysaccharide was dissolved in D₂O (650 µL) and the spectra were recorded on a JEOL JNM-ECS400 spectrometer. The NMR measurements included

various experiments, *viz.* ^1H , ^{13}C , DEPT-135, COSY, HSQC and HMBC. The experiments were performed at 292 K. The raw data were processed with Mestrec Nova version 9.0.0.

2.9. Reducing power

The reducing power of MAP was determined by the potassium ferricyanide assay according to the standard protocol.¹ Briefly, 1 mL phosphate buffer (0.2 M, pH 6.6) was added to 0.5 mL potassium ferricyanide (1%, w/v). To the above solution, 1 mL of sample solution (ascorbic acid and MAP) with varying concentration (0.2 to 1.8 mg mL⁻¹, w/v in distilled water) was added. The resulting mixtures were incubated at 50 °C in a water bath for 20 minutes and cooled to ambient temperature. This was followed by addition of 1 mL trichloroacetic acid (10%, w/v) and 0.2 mL freshly prepared ferric chloride solution (0.1%, w/v). The final solution was vortexed, and the absorbance was measured at 700 nm. The reducing power was calculated using the formula:

$$\text{Reducing power} = [\text{As}_{700} - \text{Ac}_{700}]$$

where As_{700} is the absorbance of the sample and Ac_{700} is the absorbance of a control in which FeCl_3 solution was replaced by water.

3. Results and discussion

3.1. Isolation of polysaccharide

The alkali-soluble polysaccharide (MAP) was isolated in 1.15% (w/w) yield. The ash content of MAP was 0.75% (w/w) on a dry weight basis. The aqueous solution (1%, w/v) of MAP has a pH value of 6.4.

3.2. GPC of MAP

A graph of the fractions collected from GPC against absorbance was plotted using the anthrone-sulphuric acid method³⁹ at 620 nm, as shown in Fig. 1.

The fractions of the major eluted peaks (23–34) were collected and pooled, dialyzed against distilled water (48 h) and lyophilized to obtain the homogeneous polysaccharide (146 mg).

3.3. Monosaccharide analysis

Qualitative evaluation of MAP with paper chromatography indicated the presence of five neutral monosaccharides and one acidic sugar residue. The sugar residues identified in MAP were rhamnose (Rha), arabinose (Ara), xylose (Xyl), glucose (Glc), galactose (Gal), and glucuronic acid (GlcA). The monosaccharide composition of MAP was quantitatively investigated by GLC. Based on comparison with monosaccharide standards, MAP was found to be composed of xylose (64.52 mol%) and arabinose (18.87 mol%). The other sugar residues were found to be rhamnose, glucose, and galactose in 3.27, 3.25 and 10.09 mole percentages, respectively. After complete reduction with EDC, HCl and NaBH_4 , the carboxyl-reduced polysaccharide MAP-R was obtained. MAP-R was found to be composed of Rha, Ara, Xyl, Glc and Gal in 3.04, 18.36, 60.42, 8.97, 9.21 mole percentages, respectively. The mol% of glucuronic acid was 5.76 based on the percentage increase of glucose in the reduced polysaccharide (MAP-R) vis-à-vis native MAP. The molar ratio of monosaccharides Rha, Ara, Xyl, Glc, Gal and GlcA in the alkali-soluble polysaccharide was 1.00 : 6.04 : 19.88 : 1.07 : 3.03 : 1.95. The arabinose/xylose ratio of MAP was found to be 0.3.

The glucuronic acid content was analyzed using a spectrophotometric method based on the 3,5-dimethyl phenol assay. It was found to be 6.78% (w/w) \pm 0.51 (avg \pm st dev) in MAP.⁴⁴

3.4. Linkage analysis

The linkage pattern of MAP was revealed by complete methylation of native (MAP) and reduced (MAP-R) polysaccharides followed by hydrolysis, derivatisation to PMAA and GC-MS analysis, as explained in Section 2.6. The PMAAs were characterized by relative retention time and mass fragmentation pattern. The results of the

Fig. 1 Elution pattern of MAP in GPC.

Table 1 Linkage analysis of MAP

| PMAA derivative | MAP (mol%) | MAPR (mol%) | Linkage identified | Observed mass fragments (<i>m/z</i>) |
|--|------------|-------------|--------------------|--|
| 1,5-Ac ₂ -2,3,4-Me ₃ -rhamnitol | 3.23 | 3.13 | t-Rhap | 43, 59, 87, 99, 89, 101, 117, 131, 161, 175 |
| 1,4-Ac ₂ -2,3,5-Me ₃ -arabinitol | 3.35 | 3.19 | t-Araf | 43, 45, 59, 87, 101, 117, 129, 145, 161 |
| 1,3,4-Ac ₃ -2,5-Me ₂ -arabinitol | 16.19 | 15.21 | 1,3-Araf | 43, 59, 71, 87, 99, 101, 117, 129, 173, 205, 233 |
| 1,3,5-Ac ₃ -2,4-Me ₂ -xylitol | 12.83 | 12.25 | 1,3-Xylp | 43, 59, 71, 87, 101, 117, 233 |
| 1,4,5-Ac ₃ -2,3-Me ₂ -xylitol | 32.26 | 30.09 | 1,4-Xylp | 43, 59, 71, 87, 99, 101, 117, 129, 161, 189 |
| 1,2,4,5-Ac ₄ -3-Me-xylitol | 19.35 | 17.96 | 1,2,4-Xylp | 43, 74, 87, 101, 129, 145, 161, 189, |

| 1,4,5-Ac ₃ -2,3,6-Me ₃ -galactitol | 9.68 | 8.99 | 1,4-Galp | 43, 45, 58, 71, 87, 99, 101, 117, 129, 131, 157, 161, 173, 233 |
| 1,4,5,6-Ac ₄ -2,3-Me ₂ -glucitol | 3.11 | 2.93 | 1,4,6-Glcp | 43, 57, 71, 85, 99, 117, 127, 142, 161, 173, 201, 261 |

methylation analysis of MAP are presented in Table 1. MAP was found to contain 32.26 mol% 2,3-*O*-Me₂-1,4,5-*O*-Ac₃-pentitol and 19.35 mol% 3-*O*-Me-1,2,4,5-*O*-Ac₄-pentitol. According to the monosaccharide analysis, xylose is the most abundant sugar residue present in MAP, which indicates that 2,3-*O*-Me₂-1,4,5-*O*-Ac₃-pentitol and 3-*O*-Me-1,2,4,5-*O*-Ac₄-pentitol are 1,4-linked Xylp and 1,2,4-linked Xylp, respectively; this was confirmed on the basis of the fragmentation pattern and relative retention times. According to the literature, both these linkages are assumed to be present in the backbone of xylan.^{46–48} Similarly, the other major linkages characterized in MAP were 16.19 mol% 1,3-linked Araf, 12.83 mol% 1,3-linked Xylp and 9.68 mol% 1,4-linked Galp with 3.11 mol% 1,3,4-linked Glcp; these probably form branches in MAP. The non-reducing terminal end linkages were found to be t-linked Rhap (3.23 mol%) and t-linked Araf (3.35 mol%) in MAP. Methylation analysis of MAP-R (reduced MAP) showed t-linked Glcp at 6.25 mol%, suggesting that glucuronic acid is present as t-linked GlcpA in the polysaccharide. The excess percentage of xylose followed by arabinose when combined with the linkage results reveals the arabinoxylan nature of the polysaccharide. The methylation results are in agreement with the monosaccharide composition analysis.

3.5. Partial hydrolysis and ESI-MS analysis

MAP was partially hydrolysed using 0.5 M and 1 M HCl to obtain a mixture of oligomers. Because the individual linkages between various monosaccharides were already identified by GC-MS investigation of the PMAA derivatives, ESI-MS (*n* = 1) of the partially degraded polysaccharide was performed to support the PMAA analysis and to establish the arrangement of monomer buildups in the oligomers to better understand the structure of the polysaccharide. The hydrolysed mixture was studied in positive as well as negative ion mode to obtain maximum information about the oligomeric pattern. Oligomers containing pentose (Pent), hexose (Hex), uronic acid (UA) and rhamnose (Rha) with DP7 to DP2 were identified in the mass spectrum. ESI-MS analysis revealed a pentose sugar with an anhydro mass unit of 132.0 to be the most abundant sugar residue in MAP.

The hydrolysate prepared using 0.5 M HCl furnished oligomers up to DP4 in positive ion mode (Fig. 2a). The ions of partial hydrolysates were obtained as sodium adducts of oligomers.

Two tetramers of [Pent₃ + Hex + Na]⁺ and [Pent₄ + Na]⁺ at *m/z* 599.07 and 569.11, respectively, were identified. Three trimers of *m/z* 497.19, 437.24 and 467.22 were attributed to sodium adducts of oligomers [Pent + Hex₂ + Na]⁺, [Pent₃ + Na]⁺ and [Pent₂ + Hex + Na]⁺, respectively. The dimers with *m/z* 365.33, 335.33, and 305.35 were recognized as [Hex₂ + Na]⁺, [Pent + Hex + Na]⁺ and [Pent₂ + Na]⁺, respectively.

The hydrolysate formed using 1 M HCl exhibited spectra with good intensity and an increase in the number of peaks (Fig. 2b). The oligomers up to DP7 were identified in positive ion mode as sodium adducts. The oligomers with higher DP (7 to 5) include two heptamers, [Pent₆ + UA + Na-18]⁺ (*m/z* 990.91) and [Pent₇ + Na-18]⁺ (*m/z* 946.98); three hexamers, [Pent₃ + Hex + UA + Rham + Na-18]⁺ (*m/z* 903.01), [Pent₅ + UA + Na-18]⁺ (*m/z* 859.04) and [Pent₆ + Na-18]⁺ (*m/z* 815.09); and three pentamers, [Pent₂ + Hex + UA + Rham + Na-18]⁺ (*m/z* 771.14), [Pent₄ + UA + Na-18]⁺ (*m/z* 727.19) and [Pent₅ + Na-18]⁺ (*m/z* 683.23). The identified oligomers with lower DP include five tetramers, five trimers and three dimers. The observed tetramers were [Pent₄ + Na]⁺ (*m/z* 569.12); [Pent₃ + Hex + Na]⁺ (*m/z* 599.07); [Pent + Hex + UA + Rham + Na-18]⁺ (*m/z* 639.26); [Pent₃ + UA + Na-18]⁺ (*m/z* 595.29); and [Pent₄ + Na-18]⁺ (*m/z* 551.34). The ion fragments of trimers at *m/z* 507.36, 463.23, 419.27, 437.25, and 467.23 were attributed to [Hex + UA + Rham + Na-18]⁺, [Pent₂ + UA + Na-18]⁺, [Pent₃ + Na-18]⁺, [Pent₃ + Na]⁺, and [Pent₂ + Hex + Na]⁺, respectively. The recognized dimers were characterized as [Pent₂ + Na-18]⁺, [Pent₂ + Na]⁺, and [Pent + Hex + Na]⁺ with *m/z* 287.36, 305.35 and 335.34, respectively.

ESI-MS in negative mode produced chlorine and hydrogen ion adducts of oligomers. Oligomers up to DP5 were found in the partial hydrolysate mixture obtained using 0.5 M HCl (Fig. 2c). The oligosaccharides at *m/z* 735.08, 603.20, 471.31, 339.39, 449.3, 317.39 and 335.22 were identified as [Pent₄ + UA + Cl-4H][−] (pentamer); [Pent₃ + UA + Cl-4H][−] (tetramer); [Pent₂ + UA + Cl-4H][−] (trimer); [Pent + UA + Cl-4H][−] (dimer); [Pent₃ + Cl][−] (trimer); [Pent₃ + Cl][−] (dimer); and [Pent + Hex + Cl][−] (dimer).

The hydrolysate obtained with 1 M HCl (Fig. 2d) produced intense peaks up to DP6 which include one hexamer [Pent₅ + UA + Cl-4H][−] (*m/z* 866.93); four pentamers, [Pent₄ + Hex + Cl][−] (*m/z* 743.05), [Pent₄ + UA + Cl-4H][−] (*m/z* 735.08), [Pent₅ + Cl][−] (*m/z* 713.06), and [Pent₅-H][−] (*m/z* 677.13); four

[Pent₂ + Cl][−] (*m/z* 317.39), and [Pent₂-H][−] (*m/z* 281.43). One monomer, [Pent-H][−], was observed at *m/z* 149.43.

The abundance of pentose-containing oligomers in the ESI-MS spectra supported the monosaccharide and methylation results, which showed xylose (a pentose sugar) to be the most abundant residue in MAP. The complete oligomeric patterns identified are presented in Table 2.

3.6. NMR analysis and structure of MAP

NMR spectra of MAP were recorded on a JEOL JNM-ECS400 spectrometer. The completely deuterium-exchanged MAP (35 mg dissolved in 650 μL of D₂O) was subjected to 1D (¹H, ¹³C, DEPT-135) and 2D (HSQC, HMBC, TOCSY, COSY) experiments to acquire significant information for the elucidation of the structure of MAP. The anomeric protons appeared between 4.20 and 5.20 ppm in the ¹H NMR spectrum at 5.01, 4.90, 4.59, 4.83, 4.44, 4.29, 4.23, 5.11, 4.39 and 5.05 ppm (Fig. 3a). In the ¹H NMR spectrum, one signal was found at 1.01 ppm which was highly shielded; this was assigned to the methyl protons of rhamnose residues. The ¹³C NMR spectrum (Fig. 3b) showed ten anomeric carbon signals at 107.48, 107.24, 104.03, 101.62, 101.47, 101.68, 101.67, 97.44, 96.39, and 91.91 ppm; these are labeled as A, B, C, D, E, F, G, H, I and J, respectively. The corresponding anomeric proton signals in the ¹H NMR spectrum were marked with the contribution of HSQC. The signal at 16.49 ppm was assigned to the methyl carbon of rhamnose, and the signal at 174.75 ppm was assigned to C-6 of GlcpA. All ¹H and ¹³C NMR assignments were marked with the assistance of COSY, HSQC, HMBC and TOCSY [Fig. 3c–e] spectra. The chemical shifts of all the

residues of MAP were assigned completely and are shown in Table 3.

Residue A showed an anomeric carbon chemical shift at 107.24 ppm, and its anomeric proton shift was observed at 5.01 ppm. Other proton chemical shifts were assigned from the COSY and TOCSY spectra. The other carbon signals of residue A were observed at 76.10, 80.74, 80.67 and 60.65, corresponding to C-2, C-3, C-4 and C-5, respectively. The intensity of the anomeric carbon chemical shift is weaker and was assigned to α-linked Ara₁f(1→; this is supported by the methylation results, which show a lower percentage of α-linked Ara₁f(1→ compared to →3)-α-linked Ara₁f(1→. The proton and carbon chemical shifts were in agreement with literature values.^{46,48–50}

Residue B showed a carbon chemical shift at 107.48 ppm with a proton shift at 4.90 ppm. The C-3 chemical shift is also deshielded, with a chemical shift value of 83.75 ppm. Methylation analysis showed that the percentage of →3)-α-linked Ara₁f(1→ is much higher than that of α-linked Ara₁f(1→. The anomeric signal for residue B is more intense than that for residue A in the HSQC spectrum. All these factors suggest that this residue is →3)-α-linked Ara₁f(1→. The carbon signals of residue B were observed at 76.45, 80.93, and 58.31, corresponding to C-2, C-4 and C-5 from the HSQC spectrum. These assignments were consistent with previous data.^{48,49}

Residue C showed anomeric carbon and proton chemical shifts at 104.03 and 4.59 ppm, respectively. Its anomeric proton chemical shift indicates that it is β-linked. According to methylation fragmentation analysis and comparison of the NMR data, residue C was assigned as →4)-β-linked Gal₁p(1→, which was found to be consistent with the literature.⁵¹ The other

carbon chemical shifts were 70.92, 72.09, 68.78, 72.26 and 66.18, which correspond to C-2, C-3, C-4, C-5 and C-6, respectively.

The anomeric carbon chemical shift of residue D was found at 101.62 ppm, with the anomeric proton chemical shift at 4.83 ppm. The chemical shifts of other protons were assigned through COSY, and the corresponding carbon shift values were recognized with HSQC. The chemical shift values of the other carbons were found at 68.78, 70.70, 73.38, 71.81 and 16.49 ppm and were assigned to C-2, C-3, C-4, C-5 and C-6, respectively. The NMR data was in agreement with literature data.⁴⁹ The spectral assignments and methylation results indicate that residue D is α -linked Rhap(1 \rightarrow).

Residues E, F and G showed anomeric carbon/proton shift values at 101.47/4.44, 101.68/4.29, and 101.67/4.23 ppm,

respectively. \rightarrow 4)- β -linked Xylp(1 \rightarrow , \rightarrow 2,4)- β -linked Xylp(1 \rightarrow and \rightarrow 3)- β -linked Xylp(1 \rightarrow are the most abundant linkages found in the methylation study, and they were found to be 32.26, 19.35 and 12.83 mol%, respectively. The anomeric carbon and proton intensities of residues E, F and G were found to be the most abundant peaks in the spectra. The carbon chemical shift C-3 (81.02 ppm) of residue E was found to be deshielded, and C-4 (75.99 ppm) of residue F was also deshielded. Similarly, C-2 (74.49 ppm) and C-4 (81.02 ppm) of residue G showed deshielding. The chemical shifts of C-2, C-4, and C-5 of residue E were observed at 75.38, 81.02 and 63.63 ppm, respectively. The chemical shifts of C-2, C-3 and C-5 of residue F were observed at 72.38, 74.49, and 62.48 ppm, respectively. The chemical shifts of C-3 and C-5 of residue G were observed at 77.21 and 62.49 ppm, respectively. The spectral assignments and methylation results

Fig. 3 (A) ^1H NMR spectrum of MAP, (B) ^{13}C NMR spectrum of MAP, (C) HSQC spectrum of the anomeric region, (D) HSQC spectrum of the rhamnose region, (E) HSQC spectrum of the ring region, (F) HMBC spectrum with inter and intra-residue connectivities.

revealed residues E, F, and G to be $\rightarrow 3$)- β -linked Xylp(1 \rightarrow , $\rightarrow 4$)- β -linked Xylp(1 \rightarrow and $\rightarrow 2,4$)- β -linked Xylp(1 \rightarrow . The other proton and carbon chemical shifts were assigned completely from the HSQC, COSY and TOCSY spectra, and the values were found to be in agreement with literature data.^{48,50,52,53}

The anomeric carbon signal of residue H was found at 97.44 ppm, and the anomeric proton shift was 5.11 ppm. The C-6 of residue H was found at 174.75 ppm, which is highly deshielded due to the carboxylic group of uronic acid. Other carbon signals were found at 70.92, 73.34, 80.74 and 71.81 ppm and were assigned to C-2, C-3, C-4 and C-5, respectively. These values were assigned to β -linked GlcpA(1 \rightarrow and compared with the literature.^{54,55} Sometimes, GlcpA is also found in C-6 methyl ester form; however, in the present case, uronic acid was not methyl-esterified because no signal was found near 53 ppm for the -OMe carbon.^{48,56} Also, no ester carbonyl peak was found in the FT-IR spectra, confirming that the GlcpA present in MAP is not methyl esterified.

Residue I showed anomeric C1/H1 chemical shifts at 96.39/4.39 ppm with significant intensity. The other proton and carbon shift values were assigned with the aid of the COSY and HSQC spectra. The carbon chemical shift values at 72.76, 73.38, 76.10, and 59.45 ppm were assigned to C-2, C-3, C-4 and C-5, respectively. In conformity with the literature,^{57,58} the anomeric chemical shift value was found to be consistent with β -linked Xylp(1 \rightarrow with a free reducing end, which is well reported in xylans from different plant sources. No evidence was found regarding β -linked Xylp(1 \rightarrow residue in the methylation analysis; however, based on the NMR analysis, residue I was assigned to β -linked Xylp(1 \rightarrow with a free reducing end.

Residue J showed anomeric C1/H1 chemical shifts at 91.91/5.05 ppm with weak intensity. The other carbon signals of residue J were observed at 70.92, 72.09, 75.99, 65.62 and

58.31 ppm for C-2, C-3, C-4, C-5 and C-6, respectively. All the ^1H and ^{13}C chemical shift assignments of residue J were achieved using the COSY and HSQC spectra. Compared with previous reports⁵⁹ on methylation data and NMR peak intensity, residue J was assigned to $\rightarrow 4,6$)- β -linked Glcp(1 \rightarrow .

The sequence of glycosyl residues in MAP was determined with the assistance of long-range HMBC coupling, as shown in Fig. 3f. The cross peaks of both anomeric carbons and the protons of the glycosyl residues were examined for both intra- and inter-residual connectivity. Cross-peaks were found between H-1 (5.01 ppm) of residue A and C-1 (107.48 ppm) of residue B, representing $\rightarrow 3$)- α -linked Ara(1 \rightarrow residues linked to O-1 of α -linked Ara(1 \rightarrow . Cross-peaks were found between H-1 (4.23 ppm) of residue E and C-1 (101.67 ppm) of residue G, which indicates that the $\rightarrow 3$)- β -linked Xylp(1 \rightarrow residues are linked to O-2 of $\rightarrow 2,4$)- β -linked Xylp(1 \rightarrow . There were cross connections of H-1 (4.23 ppm) of residue G with C-4 and C-5 of residue F, showing that $\rightarrow 2,4$)- β -linked Xylp(1 \rightarrow is connected with $\rightarrow 4$)- β -linked Xylp(1 \rightarrow . The methylation results show that $\rightarrow 4$)- β -linked Xylp(1 \rightarrow is the most abundant linkage in MAP; this was further supported by the HMBC spectra because the cross peak intensity for $\rightarrow 4$)- β -linked Xylp(1 \rightarrow residues in HMBC is the maximum. Also, HMBC showed the greatest number of cross connecting linkages for $\rightarrow 4$)- β -linked Xylp(1 \rightarrow . The inter-connections between $\rightarrow 4$)- β -linked Xylp(1 \rightarrow residues were found to be H-4 (3.06 ppm) with C-1 (101.68 ppm) and H-5 (3.93 ppm) with C-1 (101.68 ppm), indicating connections between $\rightarrow 4$)- β -linked Xylp(1 \rightarrow . The cross connection of H-4 (3.06 ppm) of residue I with C-3 (73.38 ppm) of residue B indicates that β -linked Xylp(1 \rightarrow is connected to O-3 of $\rightarrow 3$)- α -linked Ara(1 \rightarrow . Intra-residual

connectivities were found for residue F $\rightarrow 4$)- β -linked Xylp(1 \rightarrow at H-1 (3.06 ppm)/C-2 (72.38 ppm); H-3 (3.36 ppm)/C-4 (75.99 ppm); C-2 (72.38 ppm); H-2 (3.61 ppm)/C-5 (62.48 ppm); C-1 (101.68 ppm); and C-3 (74.49 ppm). Other intra-residual connectivities observed for residue H were α -linked GlcpA (1 \rightarrow at H-5/C-6; for residue I, β -linked Xylp(1 \rightarrow at H-2/C-1 and H-5/C-2; and for residue J, $\rightarrow 4,6$) α -linked Glcp (1 \rightarrow at H-5/C-1. All the HMBC connectivities are summarized in Table 4.

Summarizing the linkage results and the NMR and partial acid hydrolytic analysis, a tentative structure (Fig. 5) is proposed for alkali-soluble polysaccharide MAP isolated from the leaves of *M. coromandelianum*. MAP was found to comprise a backbone of $\rightarrow 4$)- β -linked Xylp(1 \rightarrow with branching at O-2 mostly by $\rightarrow 3$)- α -linked Araff(1 \rightarrow and $\rightarrow 3$)- β -linked Xylp(1 \rightarrow with a few residues of $\rightarrow 4$)- β -linked Galp (1 \rightarrow . The structure was found to be similar to that of arabinoxylans. It is presumed that $\rightarrow 3$)- α -linked Araff(1 \rightarrow and α -linked Araff(1 \rightarrow are present in the L-configuration of MAP and $\rightarrow 3$)- β -linked Xylp(1 \rightarrow , $\rightarrow 4$)- β -linked Xylp(1 \rightarrow and $\rightarrow 2,4$)- β -linked Xylp(1 \rightarrow are present in its D-configuration because similar linkages have been reported in the literature for plant-based arabinoxylan-type polysaccharides.^{60,61}

3.7. Reducing power of MAP

MAP was analyzed for its ferric ion reducing ability using the potassium ferricyanide assay.¹ Solutions of MAP and standard ascorbic acid were prepared in five concentrations, viz. 0.2, 0.6, 1.0, 1.4, and 1.8 mg mL⁻¹. Both MAP and the standard showed dose-dependent behavior and increased reducing ability with increasing concentration of the sample. MAP and the standard

showed ferric ion reducing powers of 0.914 ± 0.01 ($R^2 = 0.972$, $p < 0.05$) and 2.178 ± 0.004 ($R^2 = 0.730$), respectively, at 1 mg mL⁻¹ concentration, as shown in Fig. 4.

The antioxidant activities of carbohydrates, including monosaccharides, oligosaccharides and polysaccharides, have been discussed and validated by different researchers. Nishizawa *et al.*⁶² determined the abilities of galactinol and raffinose to scavenge hydroxyl radicals *in vitro*. It was observed that the second-order rate constants for the reactions between galactinol or raffinose and hydroxyl radicals were higher than those reported for typical antioxidants, such as ascorbate and reduced glutathione or citrulline. The studies concluded that galactinol and raffinose scavenge hydroxyl radicals as a novel function to protect plant cells from oxidative damage caused by methyl viologen treatment, salinity, chilling or drought. In another study, while comparing the antioxidant activities of monosaccharides and disaccharides, Morell *et al.*⁶³ observed that the free radical scavenging activity of disaccharides, viz. maltose and sucrose, was greater than that of deoxyribose. It was proposed that the difference between the free radical scavenging activities and stabilities of disaccharides and monosaccharides is due to the variation in the number of hydroxyl residues, which are essential for HO[•] (hydroxyl radical) quenching. Wehmeier and Mooradian⁶⁴ reported that the antioxidant potency of deoxyribose was comparable to that of ascorbate using the 2,2-azobis(2-amidinopropane) dihydrochloride (AAPH) assay. Further, it was suggested that because glucose and ascorbate are highly similar in their molecular structures and share identical transporters, glucose and other related molecules can act as antioxidants under certain conditions. Van den *et al.*⁶⁵ reported that sucrose and sucrosyl oligosaccharides (SOS), including fructans and raffinose family oligosaccharides (RFOs), fulfill various functional roles in plant metabolism. SOS may either directly detoxify ROS in chloroplasts and vacuoles or indirectly stimulate the classic antioxidant defense system. The *in vitro* antioxidant studies of polysaccharides also indicate that they are effective antioxidants.⁶⁶ However, the underlying mechanism is still being investigated because the relationships between antioxidant activity and physicochemical properties or structural features are very complex and therefore have not been comprehensively elucidated and confirmed.^{67–69} The main physicochemical properties which determine the antioxidant activity of polysaccharides are dependent upon the monosaccharides constituting the main backbone and side chains as well as their linkages, functional groups, molecular weights, water solubility, degrees of branching, triple helical structures, *etc.*^{68,70–75} It was also observed that the free radical scavenging activity increased when the monosaccharides were arrayed in polymeric form.⁷⁶ A number of researchers reported that the structural properties of polysaccharides may affect the complex interactions of monosaccharides in polysaccharides to improve their hydrogen atom-donating capability, which in turn plays an important role in their antioxidant activity.^{71,77,78} In continuum, other researchers reported that the antioxidant activity of polysaccharides increases with increasing uronic acid content, which is due to the capability of uronic acids to chelate metal ions and in turn

Fig. 4 Reducing power of MAP ($R^2 = 0.972$, $p < 0.05$).

Fig. 5 The proposed structure of MAP, R = t-Xylp with a free reducing end. Note: stereochemistry was not considered when drawing the structure.

scavenge DPPH radicals.^{75,79,80} In addition, recent research reports have indicated that pure polysaccharides have remarkable antioxidant activity.^{81,82}

In brief, the antioxidant activity of polysaccharides is dependent on their hydrogen atom donating ability and the capability of uronic acids to chelate metal ions. Thus, in the present study, the antioxidant activity of MAP is due to the uronic acids in the arabinoxylan backbone.

4. Conclusion

In the present study, an alkali-soluble polysaccharide (MAP) was isolated from the leaves of *M. coromandelianum* using 1 M

NaOH in 1.15% (w/w) yield and was found to reduce Fe^{+3} ions in a dose-dependent manner. Further, structural analysis showed that the polysaccharide is mainly composed of xylose (60.42 mol%) and arabinose (18.36 mol%), indicating that MAP is an arabinoxylan with an A/X ratio of 0.3. Based on GLC analysis, the molar ratios of monosaccharides L-rhamnose, L-arabinose, D-xylose, D-glucose and D-galactose are 1.00, 6.04, 19.88, 1.07 and 3.03, respectively, and that of D-glucuronic acid is 1.95. The glycosidic linkage analysis showed that MAP consists of $\rightarrow 4$ - β -Xylp(1 \rightarrow (30.09 mol%) as a backbone with monosubstitution at O-2 of $\rightarrow 2,4$ - β -Xylp(1 \rightarrow (17.96 mole%) with other sugar residues. $\rightarrow 3$ - β -Xylp(1 \rightarrow (12.25 mol%) and $\rightarrow 3$ - α -Araf(1 \rightarrow (15.21 mol%) are the main side chain residues.

The terminal residues in MAP are α -Araf(1 \rightarrow (3.19 mol%), α -GlcP(1 \rightarrow (6.25 mol%) and α -Rhmp(1 \rightarrow (3.13 mol%), respectively. The oligomeric pattern consisting of xylose residues was abundantly clarified from ESI-MS analysis of partial hydrolysates (0.5 M and 1 M HCl) of MAP clearly indicated that xylose units are linked as oligomers (heptamer, hexamer, etc.). Based on the monosaccharide composition, methylation and partial hydrolysis studies concomitant with NMR analysis, MAP was found to be an arabinoxylan. Further, the reducing power of MAP was determined using the potassium ferricyanide assay, which showed dose-dependent behavior. These results may be useful to understand the biological and medicinal activities of the polysaccharide based on further structure–activity relationship studies, thereby offering an opportunity for better utilisation of a species widely used in traditional systems of medicine.

Conflicts of interest

The authors have no conflicts of interest to declare.

Acknowledgements

The authors are grateful to the Director, Forest Research Institute (FRI), Dehradun for providing laboratory facilities. Thanks are also due to Dr H. B. Naithani, Systematic Botanist, Forest Research Institute for authentication of the plant material.
