Molybdenum (Mo) is the most commonly used back-contact material for copper zinc tin selenide (CZTSe)-based thin-film solar cells. For most fabrication methods, an interfacial molybdenum diselenide (MoSe₂) layer with an uncontrolled thickness is formed, ranging from a few tens of nm up to ≈1 μm. In order to improve the control of the back-contact interface in CZTSe solar cells, the formation of a MoSe₂ layer with a homogeneous and defined thickness is necessary. In this study, we use plasma treatments on the as-grown Mo surface prior to the CZTSe absorber formation, which consists of the deposition of stacked metallic layers and the annealing in selenium (Se) atmosphere. The plasma treatments include the application of a pure argon (Ar) plasma and a mixed argon–nitrogen (Ar–N₂) plasma. We observe a clear impact of the Ar plasma treatment on the MoSe₂ thickness and interfacial morphology. With the Ar–N₂ plasma treatment, a nitrated Mo surface can be obtained. Furthermore, we combine the Ar plasma treatment with the application of titanium nitride (TiN) as back-contact barrier and discuss the obtained results in terms of MoSe₂ formation and solar cell performance, thus showing possible directions of back-contact engineering for CZTSe solar cells.

Introduction

CZTSe-based thin-film solar cells have been widely investigated in recent years as the substitution for copper indium gallium selenide (CIGS)-based thin-film solar cells, replacing the rare and expensive elements indium (In) and gallium (Ga) with zinc (Zn) and tin (Sn). Due to the higher earth abundance of its constituents, CZTSe promises significantly lower raw material costs. Mo has been proven to be an appropriate back-contact material in CIGS technologies.^{1–6} Due to the similar device structure to CIGS solar cells, Mo is also widely used as a back-contact material for CZTSe solar cells.^{7,8} Due to the high temperature annealing process, uncontrolled formation of an interfacial MoSe₂ layer with a thickness ranging from a few tens

of nm up to ≈1 μm is commonly observed in most fabrication methods.^{9–11}

With Mo as the back-contact material, MoSe₂ can form not only by a direct reaction of Mo and excess Se during absorber deposition, but also by decomposition of the CZTSe absorber at the CZTSe/Mo interface due to the difference in formation enthalpies.¹² MoSe₂ is considered to have the advantages of improving adhesion and lowering the existing potential barrier at the back-contact interface.^{2,13} However, a too thick MoSe₂ interfacial layer can cause additional series resistance and mechanical instability in the device structure. Consequently, the suppression or the control of MoSe₂ formation appears to be a useful approach for improving the overall quality of the back contact and its interface with the absorber.

Methods for limiting the MoSe₂ formation can be mainly divided into two groups: controlling the temperature during CZTSe formation by a multiple-step thermal process,¹⁴ and suppression of Se diffusion by back-contact barriers.^{15–18} In this study, we combine the second direction with plasma treatments, striving to control the MoSe₂ formation without changing our standard absorber fabrication process. This allows for reproducing our standard fabrication process for high-quality CZTSe absorbers,¹⁹ while the plasma treatments on the Mo surfaces are adopted as independent steps prior to the formation of the CZTSe absorbers.

In detail, a plasma treatment with pure Ar is performed on the as-grown Mo surface in order to improve the homogeneity of the back-contact interface that forms during selenization. Furthermore, we perform a mixed Ar–N₂ plasma treatment on the as-grown Mo surface to attempt the formation of Mo_xN_y as a back-contact barrier to suppress MoSe₂ formation. Such a nitrated Mo surface was discussed in literature to possibly have beneficial effects on interface stability and quality in thin-film CIGS solar cells.^{2,20} Finally, as comparison, we combine the Ar plasma treatment with the application of TiN back-contact barrier, which was demonstrated as a possible Se barrier in literature.^{15,16} We discuss our results in terms of MoSe₂ thickness, thickness homogeneity and resulting solar cell performance.

Experimental

Sample preparation

In this study, three types of back-contact structures were prepared: standard Mo, Mo/TiN and Mo/TiN/Mo. A standard Mo layer was sputtered onto soda-lime-glass (SLG) by an Ar plasma with a power density of 6.1 W cm⁻² at a pressure of 2.7 × 10⁻³ mbar, consisting of two sub-layers with a thickness of ≈ 275 nm for each. For Mo/TiN and Mo/TiN/Mo back contacts, a TiN layer (≈ 10 nm) was sputtered onto the standard Mo layer by an Ar plasma with a power density of 1.9 W cm⁻² at a pressure of 2.7 × 10⁻³ mbar. For the Mo top layer in the Mo/TiN/Mo case, a 50 nm Mo layer was sputtered onto the as-grown Mo/TiN layer under the same conditions as the standard Mo film.

For the desired modification and improvement of as-grown Mo surfaces, two types of plasma treatments were performed in this study: a pure Ar plasma treatment and a mixed Ar–N₂ plasma treatment. Pure Ar plasma treatments were performed with a power of 100 W at a pressure of 5 × 10⁻³ mbar for 180 seconds. The substrates for Ar plasma treatments in this study were Mo, Mo/TiN and Mo/TiN/Mo (Fig. 1(a), (d) and (e)). They were kept at room temperature during the plasma process. The Ar–N₂ plasma treatments were performed by using two different

sets of process parameters: (1) under standard conditions but with added N₂ and longer duration of 20 min (atomic percentage for Ar–N₂: 75–25%), which we refer to as standard mixed process in the following, and (2) under enhanced N₂ admixture, plasma power, and process time (atomic percentage for Ar–N₂: 50–50%, 150 W, 60 min), which we refer to as the N₂-enhanced mixed process. The Mo substrates for both mixed Ar–N₂ plasma treatments were heated up to 400 °C during the plasma process (Fig. 1(b) and (c)).

For all types of back contacts with and without plasma treatments, a standard fabrication process for absorber, window layer, and front contact has been established in our lab.^{14,19} In detail, precursors with a Zn/Cu–Sn/Zn structure were deposited onto the back contacts by DC-sputtering at room temperature. The samples were then placed in a semi-closed graphite box, together with selenium (Se) pellets and tin (Sn) wire, and annealed in a conventional tube furnace at 530 °C (heating ramp: 10 °C min⁻¹, dwelling time: 20 min). Subsequently, a cadmium sulfide (CdS) layer with a thickness of ≈ 50 nm was deposited onto the as-grown CZTSe absorbers (≈ 1.2 μm) *via* a chemical bath deposition (CBD) process. Finally, i-ZnO (≈ 75 nm) and Al:ZnO (≈ 550 nm) layers were deposited by RF-sputtering as transparent front contacts. This standard fabrication process is schematically illustrated in Fig. 2. Before analysis, every sample was mechanically scribed to 9 cells with an area of ≈ 0.25 cm² respectively. The composition of all as-grown absorbers was measured by EDX and found to be [Cu]/([Zn] + [Sn]) ≈ 0.79 ± 0.05, and [Zn]/[Sn] ≈ 1.35 ± 0.06.

Characterization

To characterize the cross-section morphology of fabricated solar cells and obtain elemental composition of the as-grown absorbers, a FEI Helios Nanolab 600i Scanning Electron Microscope (SEM) combined with an Ametek ApolloX Energy-Dispersive X-ray (EDX) detector was used in this study. Current–voltage (*I*–*V*) characteristics were measured with a Keithley 2400 SMU under standard AM 1.5 illumination from a PET SS100AAA solar simulator. The cells were directly contacted in four-wire configuration at the Al:ZnO and Mo layers. For understanding the impact of the mixed Ar–N₂ plasma treatment on the Mo surface, XPS measurements were performed in an Omicron surface science instrument using non-monochromatized Mg K_α radiation from a DAR450 X-ray source and an Argus CU electron analyser. For the XPS studies, samples were transferred from Oldenburg to Karlsruhe.

To avoid surface contamination from air exposure, the samples were extracted from the processing chamber, sealed under inert nitrogen atmosphere, and introduced into the surface science instrument *via* glove boxes, respectively.

Results and discussion

Plasma treatments on Mo back contacts

Fig. 3(a) shows that, without plasma treatment on the Mo substrate, a MoSe₂ layer is formed at the CZTSe/Mo back-contact interface, with a significant thickness variation ranging from ≈ 150 nm to ≈ 950 nm. In contrast, Fig. 3(b) shows that the MoSe₂ thickness is constant at ≈ 1 μ m for the Mo substrate, which underwent the Ar plasma treatment, while Fig. 3(c) shows that the MoSe₂ thickness is constant at ≈ 900 nm for the Mo substrate with standard mixed Ar–N₂ plasma treatment. The formation of a thicker MoSe₂ interfacial layer with significantly smaller local deviations for the Ar plasma-treated sample can be explained by a removal of contaminants present on the Mo surface, which could have a passivation-like behavior by blocking the Se diffusion at the Mo interface and/or directly hampering the reaction to MoSe₂. For the as-grown Mo substrates, the surface could be partially contaminated with O₂, H₂O, and organic components (*e.g.*, residuals from the oil vapor of the vacuum pumps), which is unavoidable during storage and sample transfer through ambient conditions. They distribute randomly and possibly disturb the reaction of Se at the Mo surface during the annealing process, thus leading to a large variation in MoSe₂ thickness at different positions. By the use of Ar plasma treatments, organic contaminants and weakly bonded molecules can be removed, leading to a more homogeneous and reproducible reaction during CZTSe absorber formation.

In comparison, the mixed Ar–N₂ plasma treatment leads to a slightly thinner MoSe₂ interfacial layer than the pure Ar

treatment does and shows a similarly small variation in thickness. The improved thickness uniformity can be ascribed to the same cleaning effect of the plasma treatment as that in the pure Ar case. For the sample with Ar–N₂ plasma treatment, a slight reduction in the MoSe₂ layer thickness can likely be explained by a nitrogen-related surface passivation induced by the N₂ plasma.

To confirm that the above discussed observations are related to the plasma treatment and are not significantly influenced by the presence of precursor layers, bare Mo substrates (*i.e.*, no CZT precursor layer) were also selenized, and the SEM cross-sections are shown in Fig. 4. In order to avoid excess selenization of the Mo-only samples (*i.e.*, entire Mo layer would be selenized and no elemental Mo is left), Se amounts for these samples were reduced by half. We find that a thicker MoSe₂ (≈ 750 nm) layer is formed for the sample which underwent the Ar plasma treatment compared to the sample without plasma treatment (≈ 550 nm). This confirms that the reduction in MoSe₂ thickness observed in Fig. 3 does not have significant influence from the presence of the added CZT precursor layer, and that it is predominantly a result of the above discussed cleaning effect. Another explanation could be a microscopic roughening of the Mo surface (below the resolution limit of our observations) by material erosion due to the plasma treatment, which enhances the surface area and consequently could also lead to a higher reactivity of the surface. For the sample with Ar–N₂ plasma treatment, a very thin MoSe₂ (≈ 60 nm) layer is formed. The effect of the above-discussed possible N-related surface passivation is clearly more obvious in this case without the added precursor layer.

To study the impact of mixed Ar–N₂ plasma treatments on the structure of the Mo substrates and to confirm a possible incorporation of N into the Mo surface, a Mo substrate without plasma treatment is compared to two Ar–N₂ plasma-treated samples with different Ar/N ratios in the plasma gas, which were described in the Experimental section above as “standard

Fig. 3 SEM cross-section of CZTSe solar cells prepared on the Mo substrates (a) without plasma, (b) with Ar plasma and (c) with Ar–N₂ plasma treatments.

Fig. 4 SEM cross-section of selenized bare Mo substrates (a) without plasma, (b) with Ar plasma and (c) with Ar–N₂ plasma treatments.

mixed” and “N-enhanced” plasma treatments. The “standard mixed” sample is identical to the sample discussed above. The N-enhanced sample was added in order to further confirm the N-related modification of the sample surface.

Fig. 5(a) shows the XPS survey spectra of these three samples. For all samples, Mo signals are seen (as expected), together with oxygen (O 1s at 530 eV) and carbon (C 1s at 285 eV). Small Cu, Zn, and Sn signals can also be seen as a result of minor cross

contamination in the fabrication process. The Zn 2p signal is most prominent and thus labeled in Fig. 5(a), but the XPS intensities of all metal contaminant signals are significantly reduced after the plasma treatments.

For both plasma-treated samples, clear N Auger-signals (N KVV \sim 880 eV) are found, being more pronounced for the enhanced plasma treatment procedure. Furthermore, Fig. 5(b) shows a pronounced N 1s signal at 397.5 eV, which matches reported values for molybdenum nitrides.²¹ Fig. 5(b) also shows the Mo 3p_{1/2} and 3p_{3/2} peaks, which shift to higher binding energy after plasma treatment. Without the plasma treatment, a shoulder of the Mo peaks (at 398 eV for Mo 3p_{3/2} and 415 eV for Mo 3p_{1/2}) is indicative of the presence of Mo oxide. Finally, Fig. 5(b) shows a small peak at \sim 403 eV for both plasma-treated samples, which we ascribe to either embedded N₂ and/or N-O bonds.²¹

Fig. 5(c) shows the Mo 3d signals, together with tabulated peak positions for the Mo 3d_{5/2} peak.²¹ The here observed position of the “no plasma” sample fits well with metallic Mo (and also shows a characteristic metallic asymmetry), while a shoulder best seen for the Mo 3d_{3/2} peak (at 235 eV) indicates the presence of Mo oxide. The Mo 3d peaks also shift towards higher binding energy for the plasma-treated samples (as expected), matching the tabulated values for Mo_xN_y. To summarize the XPS results, we find a removal of Mo oxides, the formation of a Mo_xN_y phase at the surface, and a small contribution of molecular N₂ or N-O bonds after the Ar-N₂ plasma treatments.

To analyze the impact of the different treatments on resulting device performance, solar cells were fabricated from untreated, Ar treated, and “standard mixed” plasma treated Mo substrates. The obtained efficiencies all ended up in the range of the usual reproducibility of our process and varied between 9.5% and 11.5% device efficiency, with no obvious trends. The results are shown and discussed in the ESI,[†] indicating a possible improvement of the sample uniformity as a result of plasma treatments and thus supporting the discussion in the previous section.

Fig. 5 (a) XPS survey spectra, (b) Mo 3p and N 1s spectrum, and (c) Mo 3d spectrum of Mo substrates. Black spectra were recorded for a sample without Ar-N₂ plasma treatment, red and blue spectra were collected after an Ar-N₂ plasma treatment with an Ar/N ratio of 75/25 and 50/50, respectively.

Plasma treatments with TiN back-contact barrier

The application of a TiN barrier layer on Mo back contacts was shown in literature in context of other CZTSSe fabrication methods to allow an effective reduction of MoSe₂ formation.^{15,16} To investigate the impact of the Ar plasma treatment on the samples containing such a Se diffusion barrier layer and to obtain further insights into the impact of the overall MoSe₂ thickness on the final solar cell performance, samples with a TiN back-contact barrier were also analyzed. In Fig. 6(a) and (b), SEM cross sections show a strongly reduced MoSe₂ formation (MoSe₂ thickness < 100 nm) for Mo/TiN back contacts, without and with Ar plasma treatment. For another sample containing a thin Mo layer on top of the Mo/TiN back contact (*i.e.*, Mo/TiN/Mo back-contact arrangement), only the Mo atoms located above the TiN undergo selenization and form MoSe₂ (thickness constant at \approx 230 nm) (Fig. 6(c)). These results indicate that TiN works as an effective Se diffusion barrier also

Fig. 6 SEM cross-section of CZTSe solar cells with TiN back-contact barriers: (a) Mo/TiN back contact without plasma treatment, (b) Mo/TiN back contact with Ar plasma treatment and (c) Mo/TiN/Mo back contact with Ar plasma treatment.

in our fabrication method, and that its effect is not reduced by the applied plasma treatment.

Fig. 7 shows a comparison of the CZTSe solar cell performance with TiN back-contact barriers. In agreement with the previously reported work by Schnabel *et al.*¹⁶ on a solution-based fabrication process, the Mo/TiN/Mo back-contact structure shows superior behavior compared to the two cells with Mo/TiN back-contact configuration. The results suggest that the direct contact of TiN with the absorber layer has a negative impact on the back-interface properties, which may result from the existence of a potential electronic barrier induced by TiN between the CZTSe absorber and the Mo back contact. For the Mo/TiN/Mo case, in which no direct contact of TiN with the CZTSe absorber exists, the negative impact of TiN is largely

Fig. 7 Box plots of solar cell parameters (a) energy conversion efficiency η , (b) open circuit voltage V_{oc} , (c) short circuit current density J_{sc} and (d) fill factor FF for the samples with TiN back contact barriers. For every type of back contacts, 6 cells are included.

eliminated, and the resulting CZTSe/MoSe₂ interface may lead to improved electronic properties.^{2,13} The solar cells based on this configuration perform more closely (*i.e.*, mainly 8–9% efficiency) to the devices without an extra back-contact barrier discussed above. However, the results do not indicate any improvement of the device properties for reducing the MoSe₂ layer thickness from $\approx 1 \mu\text{m}$ range down to less than 250 nm.

Conclusions

To develop a reliable fabrication process for CZTSe-based thin-film solar cells with efficiencies >10%, stable back-contact interfaces with a reproducible and uniform behavior are important. This becomes even more critical for upscaling in an industrial context. An Ar plasma treatment of the Mo back contact before the deposition of the CZTSe absorber can significantly improve the morphological homogeneity and thickness uniformity at the back interface. However, it also facilitates the formation of a slightly thicker MoSe₂ interfacial layer between the CZTSe absorber and the Mo back contact. A modified plasma treatment with a mixed Ar–N₂ plasma was tested for further modification of the Mo back contact. By an appropriate adjustment of the parameters for the plasma process, a nitridation of the Mo surface (*i.e.*, the formation of Mo_xN_y compounds) is possible. This procedure provides a combination of the cleaning effect under Ar plasma with the formation of a very thin Mo_xN_y layer that may act as a passivation layer at the back interface and lead to a reduction of MoSe₂ formation during the selenization.

For CZTSe based thin film solar cells, MoSe₂ appears to play a beneficial role, in terms of adhesion and band alignment between the Mo back contact and the CZTSe absorber. Unless it is too thick or too inhomogeneous in thickness to cause mechanical instability, the thickness of MoSe₂ does not seem to play a crucial role for the solar cell performance. In other words, as Mo still appears to be the best choice for back contacts of CZTSe solar cells, the focus of back-contact engineering in future research should be directed away from the general thickness concern and rather towards the understanding and improvement of more decisive properties of the formed MoSe₂ layer and its interface to the absorber. This may include the as-grown crystalline direction and texture, as well as the optimal energy level alignment for a heterojunction with a low hole barrier and, possibly, an electron reflector at the back contact.
