DFT calculation and analysis of the gas sensing mechanism of methoxy propanol on Ag decorated SnO₂ (110) surface

Meihua Li,^{id}*^{ac} Huichao Zhu,^{id}^b Guangfen Wei,^{ac} Aixiang He^{ac} and Yanli Liu^{ac}

Methoxy propanol has been widely used in modern industry and consumer products. Inhalation or skin exposure to methoxy propanol for a long period would bring about safety challenges on human habitat and health. Ag decorated SnO₂ mesoporous material has been synthesized and shown to exhibit high sensitivity and good selectivity to methoxy propanol among other interferential VOC gases. Density Functional Theory study were conducted to yield insight into the surface-adsorbate interactions and therefore the gas sensing improvement mechanism by presenting accurate energetic and electronic properties for the Ag/SnO₂ system. Firstly, an electron transfer model on Ag and SnO₂ grain interface was put forward to illustrate the methoxy propanol gas sensing mechanism. Then, a three-layer adsorption model (TLAM) was proposed to investigate methoxy propanol gas sensing properties on a SnO₂ (110) surface. In the TLAM method, taking SnO₂ (110) surface for the basis, layer 1 illustrates the decoration of metal Ag on SnO₂ (110) surface. Layer 2 represents the adsorption of molecular oxygen on metal Ag decorated SnO₂ (110) surface. Layer 3 indicates the adsorption of methoxy propanol, and for comparison, three other VOC gases (namely, ethanol, isopropanol and *p*-xylene) on Ag decorated SnO₂ (110) surface with oxygen species pre-adsorbed consecutively. All the adsorption processes were calculated by means of Density Functional Theory method; the adsorption energy, net charge transfer, DOS, PDOS and also experimental data were utilized to investigate the methoxy propanol gas sensing mechanism on Ag decorated SnO₂ (110) surface with oxygen species pre-adsorbed.

Introduction

With the extensive industrial applications and natural/anthropogenic emissions of chemical species, volatile organic compounds (VOCs) have become ubiquitous in our environment. Several kinds of VOCs emitted from human life commodities have put forward safety challenges on human habitats and have been reported to have slow yet long term pathogenic effects on human health.¹ Propylene glycol ethers, among which methoxy propanol, have been widely used in modern industry and consumer products. It is reported that the content of methoxy propanol is mostly above 50% in paints, inks, solvents, varnishes, hardeners, auxiliary materials and so on.² Long-term inhalation or skin exposure to methoxy propanol at considerably high concentrations could cause inflammatory changes in healthy subjects' nasal epithelium or impair the mucociliary transport system.³ The MAK value for methoxy

propanol has been set as 100 ppm to protect human bodies from its irritating effects;⁴ in other words, once the concentration of methoxy propanol exceeds 100 ppm, systemic toxicity effects would come into sight.⁵ Thus, a highly sensitive and selective detection of methoxy propanol becomes very essential to human health and safety, especially for the workers who are exposed at workplaces where this chemical compound is largely used or produced.

As a metal oxide semiconductor material with a broad bandgap ($E_g = 3.6$ eV),^{6,7} SnO₂ has always attracted wide interest in the field of gas sensors due to its good conductivity, thermal stability and surface reactivity. On the one hand, the interaction between a target gas and SnO₂ has been widely investigated experimentally;⁸⁻¹² it has been found that the gas sensing properties of SnO₂ mainly depend on its surficial chemical transduction, which involves several stages including the adsorption of the target species and charge transfer between the adsorbate and the sensing material. On the other hand, doping with noble metals is an efficient way to improve the gas sensing properties of pure SnO₂, for which Ag is an excellent candidate.¹³⁻¹⁶ Although it is well known that Ag can improve the gas sensing performance of SnO₂, the enhancement mechanism remains unclear. It has been generally ascribed to a catalytic effect; however, the atomic configuration and chemical

^cKey Laboratory of Sensing Technology and Control in Universities of Shandong, Shandong Technology and Business University, Yantai 264005, China

environment at the material surface, which might have a strong effect on the sensing properties, are hard to characterize, hence posing an essential challenge to the understanding of the gas sensing mechanism of the Ag/SnO₂ system.

Density Functional Theory (DFT) studies yield insight into atomic geometries and the nature of chemical bonding, and therefore can provide a valuable tool for understanding surface-adsorbate interactions by presenting their accurate energetic and electronic properties.^{17–30} However, to the best of our knowledge, DFT calculations and analysis of the methoxy propanol gas sensing performance of a Ag decorated SnO₂ (110) surface have rarely been conducted. In one of our previous research,³¹ a Ag decorated SnO₂ mesoporous material has been synthesized through a two-step synthetic route, and subsequently tested for the detection of VOC gases. This Ag-decorated SnO₂ mesoporous material showed high sensitivity and good selectivity towards methoxy propanol among other interferential VOC gases.

In this work, an electron transfer model of a Ag and SnO₂ grain interface is presented to illustrate the catalytic effect of Ag-doped SnO₂ for methoxy propanol gas sensing. Then, a three-layer adsorption model (TLAM) was proposed to investigate the mechanism of the VOC gas sensing performance of the SnO₂ (110) surface. In our TLAM method, the decoration of Ag metal on the SnO₂ (110) surface was first modelled and optimized in structure. Secondly, molecular oxygen adsorption configurations were proposed and the corresponding DFT calculations on the Ag decorated SnO₂ (110) surface were conducted. Thirdly, the adsorption of methoxy propanol, and for comparison, three other VOC gases (namely, ethanol, isopropanol and *p*-xylene) on the Ag decorated SnO₂ (110) surface with pre-adsorbed oxygen species were modelled and calculated consecutively. At last, according to the results from the calculations, the adsorption energy values, net charge transfer, DOS and PDOS were utilized to investigate the methoxy propanol gas sensing properties of the Ag-decorated SnO₂ material.

Methoxy propanol gas sensing properties and mechanism on the surface of a Ag decorated SnO₂ material

A two-step synthesis route was presented to prepare the Ag decorated SnO₂ mesoporous material. Firstly, carbon nanospheres were obtained by hydrothermal synthesis, and then immersed in an absolute ethyl alcohol solution of SnCl₄·5H₂O. The mixture was centrifuged, washed and calcined to get a pure SnO₂ material. Secondly, AgNO₃ and ascorbic acid were introduced to implement the decoration of Ag nanoparticles on the porous SnO₂ material through a redox reaction. A SEM image of the as-prepared material is shown in Fig. 1(a), where the mesoporous microstructure with a wall thickness of 70 nm, and the decorating Ag nanoparticles with diameters of no more than 100 nm can be easily observed. Fig. 1(b) shows the elemental composition of the prepared material; a weight ratio of 1.62% for the Ag element further confirms the decoration of Ag onto the SnO₂ material. Fig. 2 shows the cross response of our Ag decorated SnO₂ material towards four typical VOC gases, namely, methoxy propanol, ethanol, isopropanol and *p*-xylene, with the response being defined as R_a/R_g (R_a represents the sensor resistance in air, R_g represents the sensor resistance in the presence of the target gas). A relatively high response within a wide gas concentration range from 50 ppm to 300 ppm proves a higher detection selectivity for methoxy propanol compared to the other three gases. It can be seen that the response of the Ag/SnO₂ material to 100 ppm methoxy propanol is ~130, and when the concentration increases to 150 ppm, 200 ppm and 250 ppm, the response accordingly increases to ~580, ~920 and ~1000, respectively. These data fully prove the high sensitivity and good selectivity of the Ag/SnO₂ material to methoxy propanol, and its potential in the detection of methoxy propanol. More detailed experimental description can be found in the literature.³¹

Fig. 1 (a) SEM image, (b) EDS spectrum of our Ag decorated SnO₂ material.

Fig. 2 Selectivity of the Ag decorated SnO₂ material for VOC gases.

It is well known that the gas sensing mechanism of SnO₂ is explained by the *Surface Resistance Controlling Model*. In general, when SnO₂ sensors are exposed to air, atmospheric oxygen molecules adsorbed on the material's surface can grab electrons from the conduction band of SnO₂ and turn into oxygen species such as O₂⁻, O⁻ or O²⁻;³²⁻³⁴ therefore, the material's surficial carrier concentration and electron mobility decrease, which results in a relevant increase in its sensor resistance. When reducing gases (methoxy propanol, ethanol, *etc.*) introduced, they reacted with the ionized oxygen species and released trapped electrons back onto the surface of SnO₂. Consequently, the carrier concentration and electron mobility increased again, while the sensor resistance was correspondingly reduced. The larger the difference in the sensor resistance between the two cases, the higher the sensitivity of the gas sensor to a target gas.

As to Ag decorated SnO₂ materials, the spill-over effect of the Ag metal might play a catalytic role to the contribution of electron quantity according to the well-established "chemical sensitization" mechanism.³⁵⁻³⁸ On the interface of Ag and SnO₂

Fig. 3 Energy band on Ag and SnO₂ grain boundary.

Fig. 4 DOS spectrogram and Band Structure of SnO₂ super cell with 48 atoms.

grains, electrons transfer from SnO₂ to Ag because the Fermi level of the former is higher than that of the latter. Once this transfer process reaches a kinematic equilibrium state, an electron accumulation layer and an electron depletion layer is generated on each side of the grain boundary, as shown in Fig. 3. The barrier height on the side of SnO₂ is

$$qV_D = W_1 - W_2 = 0.2 \text{ eV} \quad (1)$$

and the barrier height on the side of Ag is

$$q\Phi_{ns} = qV_D + E_n = W_1 - W_2 + E_n = W_{1-\chi} = 0.22 \text{ eV} \quad (2)$$

where W_1 is the work function of Ag with a value of 4.72 eV, W_2 is the work function of SnO₂ with a value of 4.52 eV, and χ is the electronic affinity of SnO₂ with a value of 4.5 eV.

This catalytic effect of Ag might further spill electrons on the surface of these materials and promote the ionization of molecular oxygen; so the electrons withdrawn from the Ag/SnO₂ composite materials become amplified and much faster than

Fig. 5 DOS spectrogram and Band Structure of SnO₂ (110) surface.

Fig. 6 Decoration of Ag on SnO₂ (110) surface, (a) Ag is above Sn atom, (b) Ag is above O atom.

those withdrawn from pure SnO₂. Once the material was exposed to methoxy propanol, reactions between methoxy propanol and oxygen species were activated. As the quantity of released electrons after these chemical reactions increased, the sensitivity of Ag/SnO₂ composite materials also increased. The typical reactions of methoxy propanol (chemical formula: CH₃CHOHCH₂OCH₃) and ethanol (chemical formula: C₂H₅OH) with ionized oxygen species are as follows:

It is obvious that as long as there are sufficient adsorbed oxygen species, methoxy propanol will react with them and

release more electrons back to the material surface than in the case of ethanol. This might be the main aspect of the superior sensing ability of methoxy propanol.

Theoretical methods and computing platform

Based on the above-mentioned *Surface Resistance Controlling Theory* applied to our SnO₂ gas sensing material, a three-layer adsorption model (TLAM) was proposed to investigate the methoxy propanol gas sensing performance of the SnO₂ (110) surface. In our TLAM method, the SnO₂ (110) surface is considered the base of the composite; layer 1 refers to the decoration of Ag metal on SnO₂, and layer 2 represents the adsorption of molecular oxygen on the Ag metal decorated SnO₂

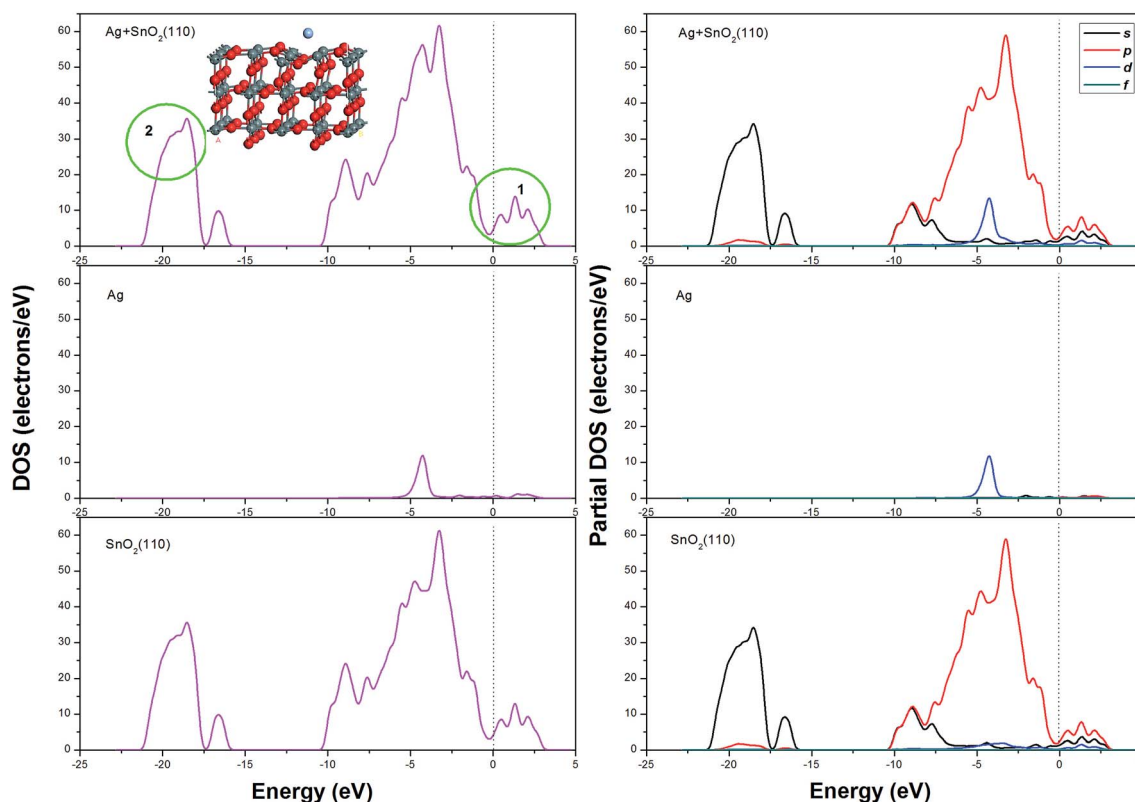

Fig. 7 DOS and PDOS spectrogram of Ag decorated SnO₂ (110) surface.

(110) surface. Layer 3 indicates the adsorbed methoxy propanol, and for comparison, three other VOC gases (namely, ethanol, isopropanol and *p*-xylene) on the Ag decorated SnO₂ (110) surface where the oxygen species were pre-adsorbed.

In this paper, the DFT method was employed to carry out the calculations. All DFT calculations were implemented through the DMol³ package in the Materials Studio platform.^{39,40} The exchange and correlation energy calculations were performed by applying the Generalized Gradient Approximation through the Perdew–Burke–Ernzerhof method (GGA-PBE),⁴¹ which adopts double numerical basis sets polarization functions (DNP). The applied convergence criteria of optimal geometry were as follows: 1×10^{-5} Ha (energy), 0.002 Ha·Å⁻¹ (force) and 0.005 Å (displacement). A $3 \times 1 \times 1$ Monkhorst–Pack *k*-point mesh was utilized for the Brillouin zone sampling and a $3 \times 1 \times 1$ Monkhorst–Pack grid was used to calculate the total energy and density of states (DOS). The Milliken population analysis (MPA)⁴² method was used to calculate the charge transfer during the gas adsorption process.

Results and discussion

Layer 1 in TLAM method: modelling and optimization of SnO₂ (110) surface with Ag decoration

Due to the minimum surface energy, SnO₂ (110) is the most thermodynamically stable one among all crystal surfaces of

SnO₂. In this section, the SnO₂ atomic model with tetragonal structure (*Pmmn*(42)) was firstly built, and then a crystal model with 48 atoms in the super cell was established with lattice constants $a = b = 4.73727$ Å, $c = 3.18638$ Å. The DOS (Density of States) spectrogram and band structure of SnO₂ super cell are shown in Fig. 4. It could be seen that the bandgap of the SnO₂ material is 3.602 eV, which is in line with the experimental data,^{43,44} and the valence bandwidth of SnO₂ is 8.8 eV, coinciding with the experimental evidence.⁴⁵ As the conduction band bottom and the valence band top are both at the zero point of the Brillouin zone (G point), it could be inferred that the as-built SnO₂ model belongs to a direct transition semiconductor.

The SnO₂ (110) surface was cleaved from the as-optimized SnO₂ bulk and a vacuum of 12 Å was added to simulate the periodic boundary conditions. The calculated DOS spectrum and band structure of SnO₂ (110) surface are shown in Fig. 5. Compared with the bulk material, the band gap of SnO₂ (110) was reduced to 2.061 eV, while the valence bandwidth was increased to 10.5 eV. Furthermore, there are four places (labelled as 1–4) where obvious changes could be observed: in place 1, the peak shifted from 7.5 eV to 3 eV; in place 2–4, the DOS curve changed sharply and differentiated into several small peaks.

For the decoration of Ag on the SnO₂ (110) surface, two kinds of configurations were considered; in one case, Ag atom was above Sn atom and in the other case Ag was above O atom, as shown in Fig. 6(a) and (b), respectively. In each configuration, the structure on the left of the arrow is the case before decoration and the right one is the case after decoration. The total energy of each optimized configurations has the same value of -3538.727 Ha, and the net transfer charge of Ag atom is $-0.136e$ and $-0.085e$, respectively. The DOS and PDOS spectrum of Ag decorated SnO₂ (110) surface are shown in Fig. 7; it is very interesting that the band gap has disappeared and the DOS curve in the conduction has differentiated into three small peaks (labelled as 1), which might imply an enhanced electric conductivity for SnO₂ (110) surface to some extent. In addition, in the DOS fragment labelled as 2, the curve became smooth, which might imply that the energy distribution of electrons became gradual. A more detailed PDOS spectrum could be seen showing that this phenomenon was mainly attributed by *s* and *p* electrons of SnO₂ (110). Comparing the DOS spectrum before and after Ag decoration, it is reasonable to deduce that the catalysis of Ag atom, especially the *d* electrons in Ag, plays an

important role in the electrical conductivity changes of SnO_2 (110) surface.

Layer 2 in TLAM method: pre-adsorption of molecular oxygen on Ag decorated SnO_2 (110) surface

In order to understand the adsorption property of molecular oxygen on Ag decorated SnO_2 (110) surface, six kinds of possible adsorption configurations (labelled as Ag-1 to Ag-6 in sequence) was built as shown as Fig. 8. In Ag-1, Ag-2 and Ag-3 configurations, molecular oxygen (O_2) was placed respectively perpendicularly to the OA axis, parallelly to the OA axis and parallelly to the OB axis, and all the three configurations take the optimized Ag decorated SnO_2 (110) surface as shown in Fig. 6(a) as the adsorptive substrate. In Ag-4, Ag-5 and Ag-6 configurations, molecular O_2 was placed respectively perpendicularly to the OA

axis, parallelly to the OA axis and parallelly to the OB axis, and all the three configurations take the optimized Ag decorated SnO_2 (110) surface as shown in Fig. 6(b) as the adsorptive substrate.

All calculations of six adsorption configurations have been carried out successively and the results are summarized in Table 1. There into, adsorption energy was adopted to judge the adsorption strength of molecular oxygen, which is defined as follows:⁴⁶

$$E_{\text{ads}} = E_{\text{adsorbate+surface}} - E_{\text{surface}} - E_{\text{adsorbate}} \quad (5)$$

E_{ads} is the adsorption energy, $E_{\text{adsorbate+surface}}$ represents the total energy of the whole adsorption system, E_{surface} represents the initial energy of the adsorption surface and $E_{\text{adsorbate}}$

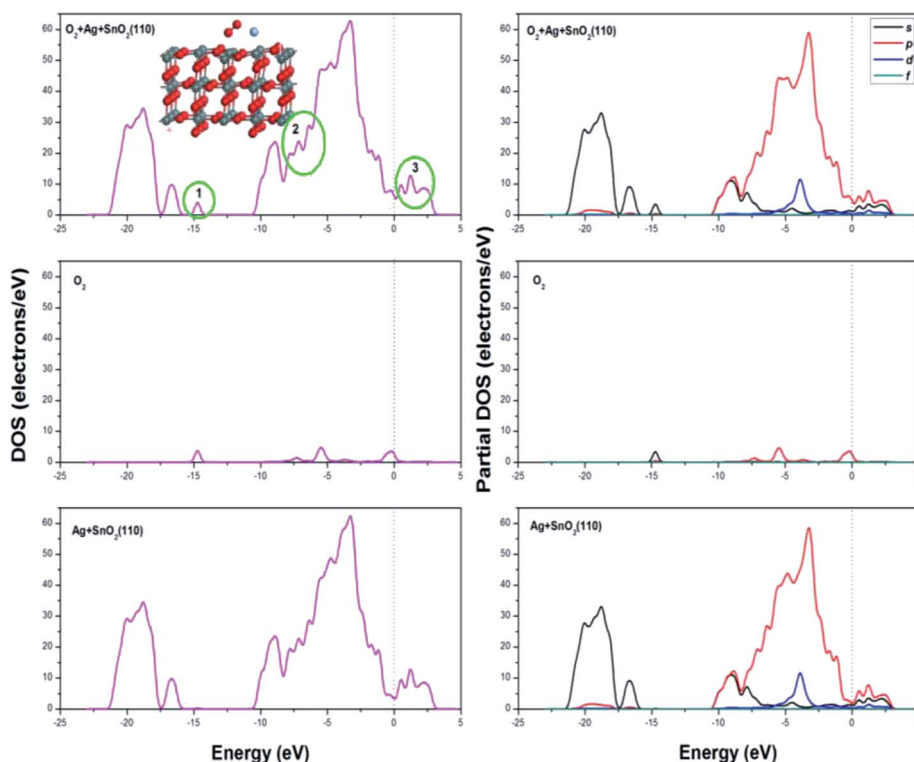

Fig. 10 DOS and PDOS spectrogram after O_2 adsorption on Ag decorated SnO_2 (110) surface.

Fig. 11 Configured molecular structure of methoxy propanol, ethanol, isopropanol and *p*-xylene.

represents the energy of the adsorbate. In general, E_{ads} with a negative value indicates that the adsorption is exothermic and therefore the system after adsorption is energetically stable.^{47,48}

It could be seen from Table 1 that, firstly, the adsorption energies of six configurations are all negative, which means that molecular oxygen could be adsorbed spontaneously on the SnO₂ (110) surface. The absolute value of adsorption energy in Ag-1 configuration is the greatest, which means the strongest adsorption strength, and in other words, this kind of adsorption was most likely to take place. Secondly, after adsorption, the O–O band length in oxygen species increased than the original O–O band length (1.226 Å) before adsorption, and among them, the increment of O–O band length in Ag-1 configuration is the greatest. This case proves that the adsorption process would lead to a dissociation tendency of the two O atoms in oxygen species. Thirdly, oxygen species had negative net transfer charges in all adsorption configurations; Ag had negative charge in Ag-2 and Ag-3 configurations, while the polarity of

transfer charge in Ag-1, Ag-4, Ag-5 and Ag-6 configurations were positive.

Taking Ag-1 configuration for example, a three-dimensional (3D) plot of deformation charge density is shown in Fig. 9, where the blue regions represent electron trapping and yellow regions correspond to electron releasing; specifically, the transferred charge of O₂ molecule is $-0.468e$, while that of Ag atom is $0.032e$. The DOS and PDOS spectra after O₂ adsorption for Ag-1 configuration are shown in Fig. 10; it is obvious that a small DOS peak in the range of -15 to -13 eV (as labelled 1) attributed by O₂ appeared, in places labelled as 2 and 3; the DOS value both increased, which implied the increase of electron energy and chemical activity in turn.

In short, in Ag-1 configuration, the adsorption of molecular oxygen on the SnO₂ (110) surface would be the strongest and molecular oxygen would capture the maximum electrons from the material surface. Additionally, it is obvious that oxygen species moved closer to the SnO₂ (110) surface in Ag-1 configuration, while in the other five configurations, oxygen species moved farther from the surface or showed almost no change, which implies more adsorption easiness in Ag-1 configuration. So, in the subsequent research, the oxygen species adsorbed surface in Ag-1 configuration would be taken as the adsorption substrate for the upcoming target gases.

Layer 3 in TLAM method: adsorption of methoxy propanol on Ag metal decorated SnO₂ (110) surface with oxygen species pre-adsorbed

According to the traditional sensing theory, the chemical reaction between the target gas and pre-adsorbed oxygen species would cause the conductivity change through an electron exchange mechanism. In order to study the high sensitivity and good selectivity of the Ag metal decorated SnO₂ material to methoxy propanol, three more kinds of VOC gases (also widespread in our life) were configured for comparison, namely, ethanol, isopropanol and *p*-xylene. Molecular structures of the abovementioned VOC gases are shown in Fig. 11.

For each VOC gas, two typical adsorption configurations on Ag metal decorated SnO₂ (110) surface with oxygen species pre-adsorbed were simulated, namely, vertical configuration (gas molecule was placed vertically) and parallel configuration (gas molecule was placed parallelly). The two adsorption configurations of methoxy propanol on SnO₂ (110) surface are shown in Fig. 12 and the case of the other three gases are similar.

The adsorption energy of four kinds of VOC gases on Ag metal decorated SnO₂ (110) surface with oxygen species pre-

Fig. 12 Vertical and parallel adsorption configurations on oxygen species pre-adsorbed and Ag decorated SnO₂ (110) surface of methoxy propanol.

Table 2 Adsorption energy of different gases on oxygen species pre-adsorbed and Ag metal decorated SnO₂ (110) surface

Adsorption energy (eV)	Target VOC gases			
	Methoxy propanol	Ethanol	Isopropanol	<i>p</i> -Xylene
Vertical	−2.231	−1.170	−1.932	−1.960
Parallel	−3.184	−1.823	−0.707	−1.850
Average value	−2.708	−1.497	−1.320	−1.905

adsorbed were calculated and the results are summarized in Table 2. It could be seen that the absolute value of adsorption energy for methoxy propanol is the largest in the vertical configuration, parallel configuration or the average value, which implies that the adsorption strength of methoxy propanol on SnO₂ (110) surface is the strongest.

Transfer charge of different gases on Ag metal decorated SnO₂ (110) surface with oxygen species pre-adsorbed are summarized in Table 3. Compared with the data in Table 1, the negative charge of oxygen species pre-adsorbed in all cases increased after gas adsorption, which states that pre-adsorbed oxygen species obtained more charges. On the other hand, all the four gases lost electrons in every adsorption configuration and the charge transferred from methoxy propanol is the maximum.

The DOS and PDOS spectrogram for the adsorption of methoxy propanol are shown in Fig. 13; it could be seen that three more peaks could be found in the energy range of -13 to -11 eV (labelled as 1), which was attributed by the adsorbate of methoxy propanol; the DOS value increased in the place labelled as 2. The changes in DOS and PDOS would further account for the increase in the electron energy and hence a better electrical conductivity.

In brief, when methoxy propanol was adsorbed on Ag metal decorated SnO₂ (110) surface with oxygen species pre-adsorbed, the adsorption energy and transfer charge are both the maximum, which implies the strongest adsorption, chemical reaction and therefore the influence on the conductivity of adsorption surface during the adsorption of methoxy propanol gas.

Table 3 Transfer charge of different gases on oxygen species pre-adsorbed and Ag decorated SnO₂ (110) surface

Transfer charge (e)	Methoxy propanol		Ethanol		Isopropanol		<i>p</i> -Xylene	
	Vertical	Parallel	Vertical	Parallel	Vertical	Parallel	Vertical	Parallel

Conclusions

In summary, based on *Surface Resistance Controlling Theory* of SnO₂ gas sensing material, firstly, an electron transfer model on Ag and SnO₂ grain interface was put forward to illustrate the methoxy propanol gas sensing mechanism. Then, a three-layer adsorption model (TLAM) was proposed to investigate the VOC gas sensing mechanism on Ag decorated SnO₂ (110) surface. The calculation results of layer 1 showed that Ag atom indeed gained negative charges and therefore accumulated more electrons on the surface of Ag metal decorated SnO₂ materials than the case of pure SnO₂, which was in good line with the catalytic effect, as mentioned in this paper. In contrast, Ag atom could get more charge from the SnO₂ (110) surface when decorated above Sn atom than above O atom. The results of layer 2 showed that the adsorption of molecular oxygen on Ag metal decorated SnO₂ (110) surface was the strongest; molecular oxygen captured the maximum electrons from the material surface when molecular O₂ was above the Ag atom perpendicular to the OA axis. In layer 3 of TLAM, for comparison, three more gases (ethanol, isopropanol and *p*-xylene) were configured to study the high sensitivity and good selectivity of Ag metal decorated SnO₂ material to methoxy propanol. The results show that the adsorption energy and transfer charge of methoxy propanol are both the maximum among the target gases, which implies the strongest adsorption, chemical reaction and the influence on the conductivity of adsorption surface, and therefore provides more theoretical evidences for high sensitivity and good selectivity of Ag metal decorated SnO₂ materials to methoxy propanol.
