Exhaustive exploration of the conformational landscape of mono- and disubstituted five-membered rings by DFT and MP2 calculations†

Carlos A. Stortz *^a and Ariel M. Sarotti *^b

The conformational landscape of 22 different non-, mono-, and disubstituted compounds with a five-membered ring was thoroughly explored by *ab initio* (MP2) and DFT (B3LYP and M06-2X) methods with the 6-311+G** basis set. Our results showed that the conformational preference of these compounds was governed mainly by the specific characteristics of the substituents, with a minor influence of the level of theory employed. After a detailed analysis of the computational data, we found an interesting preference of the electronegative substituents to take pseudo-axial positions, whereas alkyl groups preferred adopting the pseudo-equatorial locations. Such preferences were pronounced with MP2 and M06-2X and underestimated by B3LYP. Despite each level of theory affording different landscapes in many cases, as a general trend, we noticed that M06-2X afforded much higher correlation with the MP2 results than B3LYP.

Introduction

Conformational analysis is of central relevance to understand the chemistry and spectroscopy of organic molecules,¹ and understanding the factors controlling the conformational landscape of flexible systems has attracted the interest of generations of chemists. In a certain way, it can be considered that the history of conformational analysis is the history of organic chemistry itself. In the case of cyclic compounds, it has long been known that the molecules pucker to release the strain arising from the (hypothetical) planar structure. This was first recognized by Sachse in 1890 by postulating the chair and boat forms of cyclohexane.² This brilliant idea, eagerly confronted at that time, had to wait half a century to be finally consolidated, initially with the work of Beckett, Pitzer, and Spitzer in 1947,³ and then with the seminal publication of Barton in 1950.⁴ Ever since, extensive experimental and computational works have been carried out to understand the conformational behavior of substituted cyclohexanes or the related six-membered rings.⁵ Despite the number of different conformations being high (involving chairs, boats, skews, half-chairs, and envelopes), the conformational preference of simple systems is usually

relegated to the analysis of the relative stability of the two possible chair-like conformations.

However, the situation becomes much more challenging when dealing with cyclopentanes or heterocyclic analogues due to their inherent conformational flexibility. These rings are known to exist as a combination of different puckered conformations, where each atom can assume many relative positions.^{6–8} There are two extreme representative conformations, namely, envelope (E) and twist (T). In the E shape, the torsional strain is reduced dramatically by avoiding the strain that would result from the eclipsing of the hydrogens positioned in a perfect planar conformation. In this arrangement, one atom sticks out from the plane containing the other four ring atoms though this position is not fixed but rotates around the ring through the up and down motions of the methylene groups or heteroatoms. As a result of this pseudorotation, an infinite number of intermediate conformations can be found with similar energies. In the twist conformation, three adjacent atoms lie on the main plane, and the other two contiguous atoms are twisted, lying above and below the main plane. The total torsional strain of *T* is about 40% of the total torsional strain of the unpuckered structure.¹

The puckering of cyclopentanes has been confirmed experimentally by several methods, including entropy measurements⁹ and electron scattering.¹⁰ It is accepted that the E and T conformations show very low pseudorotational barriers (about the value of *RT* at room temperature or even lower), providing fast interconversion between conformers. Naturally, this idealized conformational landscape can be changed in substituted rings, depending both on the nature of the substituent and the substitution pattern.¹¹ In addition, the presence of heteroatoms

at the five-membered ring also affects the conformational preference of the system.^{12,13} As a result, the conformational landscape of five-membered rings cannot be easily predicted as in the case of their six-membered analogues. For this reason, this field has received some attention with respect to both theoretical¹⁴ and spectroscopic methods.¹⁵ Given the biological importance of furanoses and pyrrolidines, most of the studies have been carried out on these compounds.^{13,16} The number of computational studies dealing with cyclopentane motifs are much more scarce.¹⁷ To the best of our knowledge, no quantum-based study has been carried out to systematically explore the conformational landscape of mono- and disubstituted five-membered rings. The stability of a given conformation is the result of a fine balance between different types of interactions, which can be estimated differently depending on the level of theory employed during the calculations. Among the plethora of current DFT functionals, B3LYP is undoubtedly one of the most popular and widely employed ones. However, there are many reports suggesting that it is not optimal to describe the conformational behavior of carbohydrates, indicating that the emerging M06-2X provides a better performance.¹⁸ For this reason, herein, we reported the potential energy surfaces (PESs) of a wide variety of five-membered rings computed with these two functionals. A comparison of the results with those obtained with the more computationally demanding MP2 *ab initio* method was also provided.

Results

To achieve our goals, we selected a complete set of 22 compounds (Fig. 1) with different types of five-membered rings and substituents.

The use of puckering parameters provided a substantial help to understand the pseudorotational pathways. In a pioneering work, Altona and co-workers developed a quantitative description of puckering and conformation in terms of the maximum angle of torsion (θ_m) and the “phase angle” of pseudorotation (Δ) computed from the five torsion angles in the five-membered

ring; their study mainly focused on the D ring of steroids and analogues.¹⁹ Later, in 1972, Altona and Sundaralingam refined this concept for nucleosides.²⁰ Two years later, Cremer and Pople generalized the puckering calculation to any type of cyclic compound.²¹

In the particular case of five-membered rings, both models (AS and CP) describe the puckering in terms of amplitude (q) and phase coordinate (Φ). The only difference between the two models is that the phase coordinates shift by a constant angle (90°). In this work, we used the CP definition, in which perfect envelope conformations were defined by Φ values as multiples of 36° (including 0°), whereas the corresponding twist conformations shifted by 18° . Other Φ values gave rise to intermediate geometries between E/T closer to one or the other depending on the specific phase shifting (Fig. 2).

Energies and stationary points

In this study, we evaluated the performance of two well-known DFT methods, namely, B3LYP and M06-2X along with that of MP2. All the stationary points were found using the 6-311+G** basis set except for larger compounds at the MP2 level. In these cases, the geometry optimizations were carried out using the 6-31+G** basis set, and the energies were recomputed at the higher level. We set tight convergence criteria and a pruned (99,590) integration grid, which were crucial for the correct exploration of the potential energy surface (PES). After the exhaustive exploration of PES for all the systems under study, we noticed three different patterns regarding the conformational landscape: a two-conformer (one minimum, one TS), a four-conformer (two minima, two TSSs), and a six-conformer pattern (three minima, three TSSs). It is important to point out that some molecules under study were symmetrical, making different conformations equivalent (this is indicated in Fig. 3–10 by the symmetry dotted line or lines).

Fig. 1 Set of the 22 compounds studied.

Fig. 2 The Cremer–Pople (CP) rotational wheel.

Cyclopentane (1). We started our study by evaluating the performance of the three methods to explore cyclopentane. Despite it being the simplest system under study, it gave one of the most troublesome results as they were highly dependent on the method followed. This was not surprising considering the small energy differences involved. In the case of MP2, three minima of identical energies were found with E, T, and E/T shapes with the lowest frequencies close to zero (-0.5 to -2.5 cm^{-1}). In the case of B3LYP, the T shape represented the global minima, but it was very close in energy with E and E/T (0.003 kcal mol^{-1}). The E/T shape disappeared (converged to T) when using a superfine grid (96, 32, 64). As a consequence of the extremely flat PES, a switch between the local minima and saddle point occurred when changing the convergence criteria and integration prune. For instance, using Gaussian 09 default settings, the E shape was located as a minimum, whereas the T and E/T were saddle points with negative frequencies (-22.4 and -21.1 cm^{-1} , respectively); however, using tight convergence criteria and ultrafine integration, these last two became minima and the E conformation changed to TS (-12.9 cm^{-1}), whereas for the superfine integration, only the last appeared as TS (-8.3 cm^{-1}). In any case, the chemical significance of imaginary frequencies with such low magnitudes could be argued. With M06-2X, the usage of any type of grid did not qualitatively change the results: the three shapes stayed even after superfine usage, maintaining negligible energy differences (up to 2 cal mol^{-1}) between the conformers. The low energy differences, despite being beyond the precision offered by these computational methods, were in good accordance with previous results obtained by Laane and co-workers.²² The small energy differences and the low magnitude of the low frequency values for the stationary points clearly indicated a practically flat potential energy surface around the pseudorotational cycle. However, it should be noted that after adding the entropic and zero-point energies, the T shape became clearly favored (*ca.* 2 kcal mol^{-1} more stable than the E shape using the superfine grid; please see the ESI†).

Fluorocyclopentane (2). The introduction of a fluorine atom modified the conformational landscape in relation to that observed for cyclopentane. Early vibrational studies recognized that fluorocyclopentane should exist as a single stable conformer.^{11b} Later, the CNDO/2 calculations reinforced this proposal, suggesting that it should be envelope-equatorial (${}^1\text{E}$).²³ However, our calculations showed a different scenario (Fig. 3 and 4), with the global minima shifting towards the equivalent ${}^5\text{T}_4/{}^5\text{E}$ and ${}^2\text{T}_3/{}^2\text{E}$ conformations connected through the non-equivalent envelope-like transition structures (${}^1\text{E}$ and E_1). Notably, the E_1 conformation (showing a pseudo-axial fluorine) was 1.33 – 1.59 kcal mol^{-1} more stable than the corresponding ${}^1\text{E}$ analogue, with a pseudo-equatorial F atom, which was consistent with the axiality experienced by fluorine in the global minima conformation. It was previously found that pseudo-axial fluorine stabilizes the skews and boats in the cyclohexane derivative.⁵ In addition, the energies of the lower barrier between the two minima (through ${}^1\text{E}$) showed high similarities among the three methods under study (0.15 –

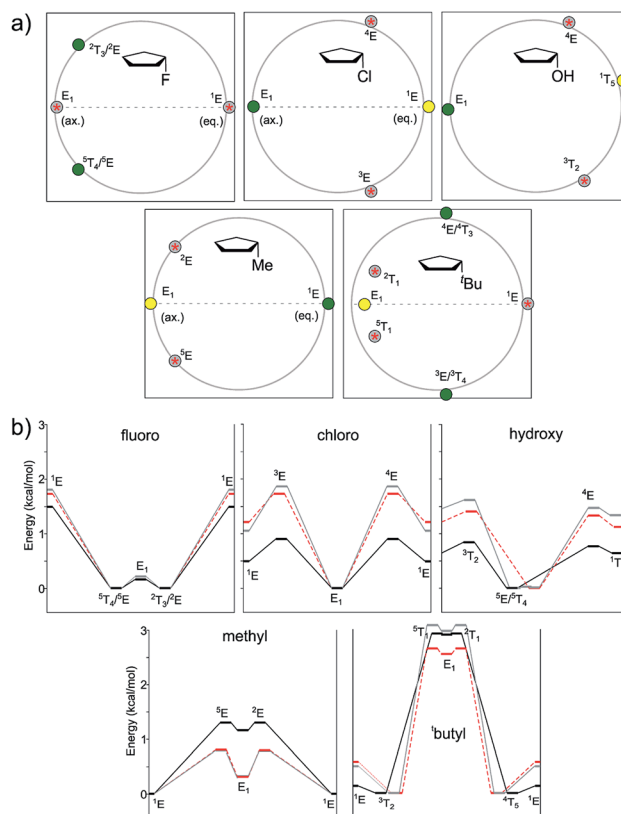

Fig. 3 (a) Geometry representations of the Cremer–Pople puckering parameters of the minima (green, global minima; yellow, local minima) and transition states (grey circle with red star) computed for compounds 2–6 at the M06-2X level. Qualitatively similar graphs were observed for the other levels of theory (see the ESI†). (b) Energies of the conformational pathways for compounds 2–6 calculated at the B3LYP (black), M06-2X (red), and MP2 (grey) levels.

0.21 kcal mol^{-1}). These results were in clear agreement with the findings of During *et al.*, who, on the basis of IR and Raman spectroscopy and MP2 calculations, proposed that fluoro-cyclopentane should exist exclusively as a twisted C_1 conformer, with the two envelope forms being first-order saddle points.²⁴

Chlorocyclopentane (3). The replacement of the fluorine atom by a chlorine atom generated an interesting inversion in the conformational behavior of the system. In contrast, in the case of fluorine, the ${}^1\text{E}$ and E_1 conformations were transition structures connecting the minimum; in this case, both conformations were actually the two minima (Fig. 3 and 4). The E_1 conformer (pseudo-axial chlorine) was the global minimum, with the $\text{E}_1/{}^1\text{E}$ energy differences ranging from 0.49 kcal mol^{-1} (B3LYP) to 1.21 kcal mol^{-1} (M06-2X), which were closer to the MP2 estimation (1.05 kcal mol^{-1}). Despite the higher tendency of chlorine toward equatorality in cyclohexane systems,⁵ in the case of cyclopentane, the pseudo-axial location of chlorine tends to stabilize the resulting geometry, which was also suggested from earlier vibrational studies.²⁵ The two local minima were connected through envelope-like transition structures (${}^3\text{E}$ and the symmetry equivalent ${}^4\text{E}$). The B3LYP relative energy of

Fig. 4 Selected stationary points found for compounds 2–6 at the M06-2X/6-311+G** level of theory (TS: transition structure; GM: global minimum; LM: local minimum).

3E ($0.90 \text{ kcal mol}^{-1}$) was $0.83\text{--}0.97 \text{ kcal mol}^{-1}$ lower than those computed with M06-2X and MP2, indicating a tendency for B3LYP to underestimate the pseudo-axial stabilization exerted by the electronegative atoms attached to the cyclopentane moiety.

Cyclopentanol (4). The conformational behavior resembled that observed for chlorocyclopentane, though with the two minima slightly shifting south (global minima) and north. The symmetry observed in previous compounds was lost as the hydrogen atom of the hydroxyl group was directed towards one side of the molecule.

With M06-2X, the global minimum was found around E_1 , with a pseudo-axial orientation of the OH group; the other minimum featured the switched 1T_5 conformation, with the OH group being pseudo-equatorial (Fig. 3 and 4). Previous vibrational studies indicated that the conformational isomerism of cyclopentanol is dictated by two representative shapes featuring equatorial and axial OH groups,^{25b} which is in agreement with our findings. According to B3LYP and MP2, the global minimum shifted south (around $^5E/^5T_4$). The preference towards envelope shapes with the hydroxyl group located at an axial position at the fold of the envelope (3E) was previously found by Abraham *et al.*²⁶ The B3LYP energy difference between both conformations ($0.64 \text{ kcal mol}^{-1}$) was lower than that observed with the other methods ($1.12 \text{ kcal mol}^{-1}$ for M06-2X and $1.33 \text{ kcal mol}^{-1}$ for MP2). The transition geometries were located at 4E and 3T_2 (closer to 3E), with the relative energies of $0.76 \text{ kcal mol}^{-1}$ (B3LYP) and $1.33\text{--}1.47$ (M06-2X and MP2,

respectively) for the former and $0.84 \text{ kcal mol}^{-1}$ (B3LYP) and $1.41\text{--}1.62 \text{ kcal mol}^{-1}$ (M06-2X and MP2, respectively) for the latter. The tendency of B3LYP to underestimate the pseudo-axial stabilization of electronegative atoms was also reflected in these calculations. When using MP2, an additional minimum (at E_1) and the corresponding TS to reach it (around 5T_1) also appear. Nevertheless, PES was flat in the studied region, showing negligible energy difference ($0.02 \text{ kcal mol}^{-1}$ between the minimum and TS, Fig. 3). All attempts to locate such conformations using B3LYP were met with no success as was observed with other common DFT functionals such as B3PW91 and PBE1PBE.

Methylcyclopentane (5). The larger steric hindrance exerted by the methyl group coupled with its low electronegativity has important conformational consequences in the conformational landscape of the corresponding cyclopentane derivative. As in the case of chlorine, the two local minima showed perfect envelope conformations (1E and E_1). However, in this case, the global minimum was 1E (featuring a pseudo-equatorial methyl group), reverting the trend observed for relatively small and electronegative substituents (F, Cl, and OH). The relative energy of the E_1 conformation, with the methyl group adopting a pseudo-axial position, depends largely on the level of theory employed (Fig. 3 and 4). In contrast, B3LYP predicted a relatively large energy difference between the two minima ($1.16 \text{ kcal mol}^{-1}$); the gap was considerably lower with both M06-2X and MP2 (0.31 and $0.33 \text{ kcal mol}^{-1}$). An NMR study of the 3J coupling values of different deuterated methylcyclopentanes suggested that the pseudorotation path is displaced to conformations featuring equatorial methyl groups,²⁷ which was in line with a previous ^{13}C NMR study of the β and γ effect.²⁸ Needless to say, a non-negligible contribution of conformations with the pseudo-axial methyl group should be expected. In spite of this, to the best of our knowledge, the $^1E/E_1$ energy gap has not been measured yet, but it can be roughly estimated as $0.53 \text{ kcal mol}^{-1}$, which is the energy difference between *cis*-1,3-dimethylcyclopentane (with the two pseudo-equatorial methyl groups) and the *trans*-counterpart (with one pseudo-equatorial methyl group and the other one pseudo-axial, *vide infra*).²⁸ Our calculations also showed that the two envelopes were interconverted through a pseudorotational path involving the other envelopes (5E and the symmetry analogue 2E) as transition structures. The relative energy of such structures was again overestimated by B3LYP ($1.30 \text{ kcal mol}^{-1}$ vs. $0.79 \text{ kcal mol}^{-1}$ computed for M06-2X and MP2).

***t*-Butylcyclopentane (6).** A classical case of two minima, two transition structures was noticed (Fig. 3). In this case, the larger size of the *t*-butyl group shifted the position of the global minimum more than that observed for the smaller methyl group. When using B3LYP, 54° displacement from a perfect 1E envelope occurred, affording 3T_2 geometry (or the symmetry equivalent 4T_5) with the *t*-butyl group close to a pseudo-equatorial position. This displacement was higher with M06-2X and MP2, leading to geometry near 3E . In all cases, the 1E envelope was now a “soft” transition structure connecting the twisted conformers. This TS had almost the same energy as the global minima at the B3LYP level ($\Delta E = 0.13 \text{ kcal mol}^{-1}$), and it

slightly increased compared to the other two model chemistries (0.57–0.68 kcal mol⁻¹). The other local minimum was located at E₁ (as in the previous case), with the *t*-butyl group adopting almost perfect pseudo-axiality. As expected, all the quantum methods predicted a significant energy rise in that conformation ranging from 2.55 kcal mol⁻¹ (M06-2X) to 2.90 kcal mol⁻¹ (B3LYP). The pseudorotational interconversion of E₁ occurred through a transition structure of almost the same energy with twisted ⁵T₁ (or the symmetry equivalent ²T₁) geometry. The pseudo-axial location of the bulky group accounted for the high energy content of this conformation.

Cyclopentanone (9). Our calculations showed that the only minimum found for cyclopentanone occurred at the ³T₄ conformation (or the symmetry equivalent ⁴T₃), with the carbonyl group on the main plane (Fig. 5). The other stationary points were located at perfect E₁ and ¹E envelopes, both equivalent by symmetry, corresponding to transition structures with a marked tendency to flatness (a low puckering degree, Fig. 3a). The barrier between ³T₄ and E₁ (by flattening C3) required a considerable amount of energy (2.66 kcal mol⁻¹ in the case of B3LYP), which was similar to the ³T₂/E₁ difference computed for *t*-butylcyclopentane. A close behavior was

predicted with M06-2X and MP2 though with higher barriers (3.19 kcal mol⁻¹ and 3.57 kcal mol⁻¹, respectively). These calculations were in good agreement with the permanently twisted shape of cyclopentanone found experimentally by Kim and Gwinn using microwave spectroscopy.²⁹

Oxolane (THF, 7). Given the symmetry exerted by the oxolane ring, only three characteristic shapes could be found: two equivalent envelopes (⁰E and E₀), two equivalent twists (⁴T₃ and ³T₄), and four equivalent E/T (²E/²T₃, E₅/⁴T₅, ⁵E/⁵T₄ and E₂/³T₂) geometries (Fig. 5). All these conformations exhibited negligible energy differences as a consequence of the extreme flatness of the potential energy surface (as occurred with cyclopentane). However, an interesting trend was noticed when comparing the results obtained at different levels of theory. In the case of B3LYP, the T shapes were the global minima, with the E shapes only 0.02 kcal mol⁻¹ higher in energy, and the E/T geometries were the transition structures connecting these minima (showing almost negligible energy difference as well). Interestingly, at the MP2 level, the exact opposite behavior was observed: the E/T intermediates were the global minima, and the E and T shapes corresponded to the transition structures. The dependence of PES on the level of theory employed during the calculations was consistent with the findings of Rayón and Sordo.³⁰ The relative energies were again very low (0.2 kcal mol⁻¹ and 0.04 kcal mol⁻¹). Finally, M06-2X showed intermediate results: the T shapes were the global minima, and E and E/T were the transition structures computed at 0.29 and 0.44 kcal mol⁻¹, respectively. This behavior was, however, anomalous as there was no minimum when passing from E to E/T. We speculate that this could be a calculation artifact resulting from the extremely flat energy surface.

Pyrrolidine (8). The conformational study of pyrrolidine has received considerable attention in recent years, and ambiguous conclusions have been drawn as well. Using microwave spectroscopy, Caminati *et al.* proposed that the most stable conformation of pyrrolidine should be envelope with the NH axial (E₁).³¹ This proposal was next verified by electron diffraction studies coupled with *ab initio* calculations at the HF/4-21G level.³² More than a decade later, Caminati *et al.* retracted their initial findings by proposing that the equatorial H(N) structure was 0.6 kcal mol⁻¹ more stable than the axial one based on rotational free jet analysis.³³ The conformational preference of the NH hydrogen was theoretically investigated by Carballeira *et al.* using a wide variety of Hartree–Fock, post-Hartree–Fock (MP2, CC, CI, *etc.*), and DFT methods.³⁴ A more recent report using femtosecond degenerate four-wave spectroscopy reinforced the higher stability of the E₁ shape but with a lower energy gap (0.08 kcal mol⁻¹) than that found by Caminati *et al.*³⁵ As in the case of oxolane, our calculations showed that the conformational landscape of pyrrolidine depends on the level of theory employed, which is in line with Carballeira's findings (Fig. 5).³⁴ For instance, in the case of B3LYP, the ¹E conformation (bearing an equatorial NH) was the global minimum and was 0.80 kcal mol⁻¹ more stable than the corresponding E₁ (with the axial NH) geometry. However, this trend was reversed when including the entropic component as the Gibbs free energy of ¹E was 1.95 kcal mol⁻¹ higher than that of E₁. Both

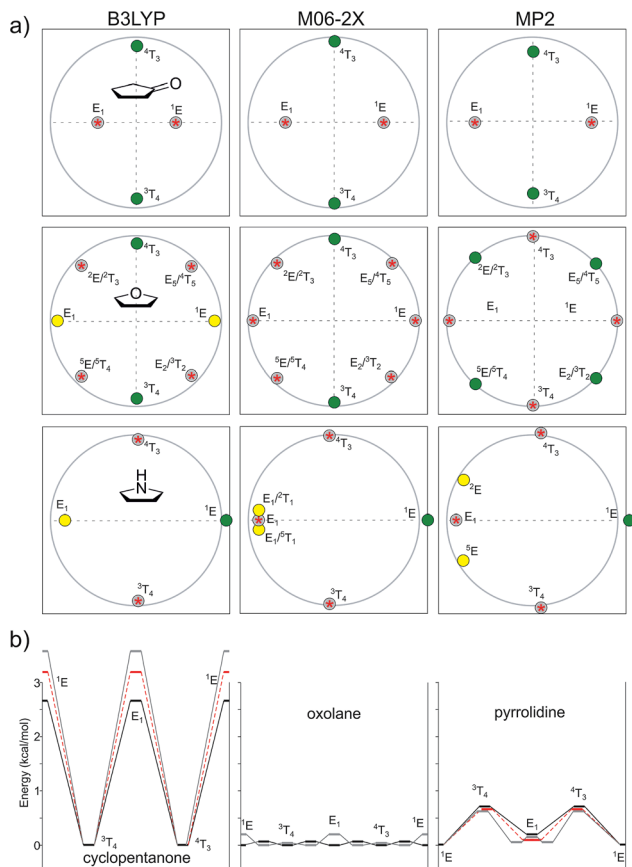

Fig. 5 (a) Geometry representations of the Cremer–Pople puckering parameters of the minima (green, global minima; yellow, local minima) and transition states (grey circle with red star) computed for compounds 7–9. (b) Energies of the conformational pathways for compounds 7–9 calculated at the B3LYP (black), M06-2X (red) and MP2 (grey) levels.

MP2 and M06-2X agreed with B3LYP in finding the global minimum at 1E , though they found the inverted E_1 shape as a low-energy transition structure connecting 1E with a close-by minimum of almost the same energy located around 5E . Moreover, M06-2X free energy calculations identified this last structure as the global minimum, whereas the 1E conformation was still the most stable one according to the free energy calculations at the MP2 level. A second transition structure around 3T_4 was located at the three levels of theory. The transition structure corresponding to nitrogen inversion was found at higher energy (3.4–4.4 kcal mol $^{-1}$), which was in agreement with previous observations.^{34,35} Hence, according to our calculations, the stable conformers of pyrrolidine should interchange following a pseudorotational process rather than N inversion, which is exactly the opposite situation found in the case of piperidine.⁵

Dimethylcyclopentanes (10–13). Using B3LYP, the *cis*-1,3-, *trans*-1,2- and *trans*-1,3-dimethylcyclopentanes exhibited just one minimum and one TS located on the antipodes of the circle and given as symmetry predicts (Fig. 6a). In all cases, the axiality or equatoriality of the methyl groups defined the conformational features, as previously discussed for methylcyclopentane. The *trans*-1,2 compound showed the global minimum at 1T_2 , with two pseudo-equatorial methyl groups. The corresponding TS was located 2.19 kcal mol $^{-1}$ above with a flipped 2T_1 geometry featuring a pseudo-axial arrangement of the substituents. A similar behavior was noticed in the case of the *cis*-1,3 product,

with the minimal conformation located at E_2 , allowing the required equatoriality of the methyl groups, and the TS adopted a flipped 2E shape. Noticeably, this TS showing the two pseudo-axial methyl groups was almost 2 kcal mol $^{-1}$ higher in energy (relative to the global minimum) than that computed for the 1,2-*trans* system (Fig. 6b). In the case of the 1,3-*trans* compound, the preferred equatoriality of the methyl groups was better achieved at 4T_5 , being 1.83 kcal mol $^{-1}$ more stable than the corresponding flipped 5T_4 shape found for the transition structure. The use of other model chemistry methods afforded different results. For instance, for the *trans*-1,2 compound, according to MP2 and M06-2X, the 2T_1 geometry is not TS connecting with the 1T_2 global minimum but instead a local minimum located at about 1.1 kcal mol $^{-1}$. However, all efforts to locate any transition structure were met with no success with these levels of theory. For the *trans*-1,3 system, a two-minima, a two-TS scenario was produced by MP2 or M06-2X: 4T_5 became TS instead of a minimum, and the global minimum shifted slightly to 4T_3 and its “enantiomer” 1T_5 . The three methods agreed when dealing with the *cis*-1,2 compound, giving two equivalent minima at ${}^1T_2/E_2$ (equivalent to ${}^2T_1/{}^2E$), characterized by one pseudo-equatorial methyl group and the other pseudo-axial methyl group. The two non-equivalent TSSs were observed at 4E and E_4 , with the two methyl groups taking isoclinical positions.

As stated above, the *cis/trans* energy difference was estimated experimentally as 0.53 kcal mol $^{-1}$ for 1,3-dimethylcyclopentane.²⁸ According to our computational results, the three levels of theory agreed with the higher stability of the *cis* isomer, though with lower energy gaps (0.28 kcal mol $^{-1}$ for B3LYP, 0.19 kcal mol $^{-1}$ for M06-2X, and 0.14 kcal mol $^{-1}$ for MP2).

2-Methylcyclopentanol (14–15). According to our results with monosubstituted cyclopentanes, the conformational preference is dictated by the trend of the electronegative and alkyl groups to become pseudo-axial and pseudo-equatorial, respectively. In an effort to explore this interesting effect, we next evaluated the conformational landscape of the *cis* and *trans* isomers of 2-methylcyclopentanol bearing one type of substituent of each kind (Fig. 7). Since the dihedral angle of the OH group imposes additional conformational freedom, we evaluated the two types of conformers resulting from the orientation of the OH group relative to the methyl fragment: “out” with OH pointing away from the methyl group and “in” with OH pointing inside. The need to consider the role of exocyclic groups when building conformational landscapes has been emphasized by Beckham and co-workers.³⁶ According to them, avoiding this effect would result in over- or underestimation of the puckering barriers.

In the case of the *cis* isomer, several minima and TSSs shifted slightly depending on the method used. In all cases, the global minimum was found near 2T_1 , with pseudo-equatorial and pseudo-axial methyl and OH groups, respectively. Although the energy of the “out” conformer was lower using MP2, it was slightly higher using the DFT methods. In any case, the two-minima, two-TS pattern was observed for all the methods and OH conformers. The other minimum was located near E_2 , with the exact opposite orientations of the substituents (OH pseudo-equatorial, Me pseudo-axial). The energy difference with the

Fig. 7 (a) Geometry representations of the Cremer–Pople puckering parameters of the minima (green, global minima; yellow, local minima) and transition states (grey circle with red star) computed for compounds 14–15 at the M06-2X level. Qualitatively similar graphs were observed for the other levels of theory (see the ESI†). (b) Energies of the conformational pathways for compounds 14–15 calculated at the B3LYP (black), M06-2X (red), and MP2 (grey) levels.

global minimum was quite high (1.31–1.69 kcal mol⁻¹), reinforcing our previous observations. The transition structures were located near ³T₄ and ¹T₅, the second being the most stable one. The barriers changed with the level of theory and orientation of the OH group (in vs. out). In general, the corresponding “in” TS was more stable than the analogous “out” one, with energy differences ranging up to 0.22 kcal mol⁻¹. The differences between ³T₄ and ¹T₅ were in the range of 0.67–0.81 kcal mol⁻¹ for all levels of theory.

In the case of the *trans* isomer, the pattern was more complicated, with three minima and three TSs, and the shapes depended on the orientation of the OH group as well. In the case of the “out” conformations, according to B3LYP, the global minima were located near ¹T₂, featuring a pseudo-equatorial arrangement of both groups. The flipped ²T₁ conformation (with pseudo-axial substituents) was 0.87 kcal mol⁻¹ higher in energy, whereas the E₄ shape with staggered groups was slightly more energetic than ¹T₂ (0.22 kcal mol⁻¹). The three transition structures connecting these minima had envelope structures (³E, E₁ and E₃) with energy gaps of 0.26 kcal mol⁻¹, 0.89 kcal mol⁻¹ and 1.56 kcal mol⁻¹, respectively. The preferred pseudo-equatorial orientation of the methyl group was also observed in TSs, with ³E (with pseudo-equatorial methyl group) being the most stable one. However, M06-2X and MP2 depicted a different scenario. In these cases, the most stable conformation (with the “out” OH group) was ²T₁ (with a *trans*-diaxial arrangement of the substituents), and it was 0.23 kcal mol⁻¹ (M06-2X) and 0.38 kcal mol⁻¹ (MP2) lower in energy than ¹T₂

(the global minimum according to B3LYP). In fact, this last shape was the least stable local minimum according to M06-2X and MP2. The third conformation, with the energy lying between those calculated for ¹T₂ and ²T₁, had a ⁵E/⁵T₄ shape. The lowest energy TS had the ⁵E shape, with pseudo-axial and staggered OH and methyl groups, respectively. Here, again, these results suggest that B3LYP underestimates the relative stabilization exerted by pseudo-axial electronegative substituents. The analysis of the “in” conformations allowed a similar approach. The B3LYP minimum was again ¹T₂, whereas the other two local minima slightly shifted to north (E₄ moved to ⁵T₄, and ²T₁ moved to ²E), with relative energies of 0.62 and 0.69 kcal mol⁻¹, respectively. M06-2X and MP2 showed that ²E was the global minimum, with a *trans*-diaxial arrangement of the substituents. The ²E/²T₁ gap was larger for MP2 (0.81 kcal mol⁻¹) than that for M06-2X (0.46 kcal mol⁻¹). TSs also slightly shifted than those computed for the “out” conformations.

1,2-Dimethoxycyclopentanes (16–17). These compounds were chosen instead of cyclopentane diols to avoid the effect of H-bond interactions. As in the previous case, two groups of conformations were available depending on the relative position of the methoxy groups: “in-out” (one OMe pointing inside, and the other outside) and “out-out” (both OMe pointing outside). However, “in-in” could not exist because of a steric clash. Moreover, “out-out” was symmetrical, whereas the former was not. Nevertheless, both types of conformations displayed similar pseudorotational behaviors and for this reason, the analysis focused on the asymmetric systems, which afforded lower energies (Fig. 8).

As in the case of *cis*-2-methylcyclopentanol, the global minimum of 1,2-*cis*-dimethoxycyclopentane was located at ¹T₂ (featuring one pseudo-axial methoxy group and the other pseudo-equatorial methoxy group). The other minima were found with the ²T₁ shape at 0.53–0.77 kcal mol⁻¹ at all levels of theory under study. The two transition structures connecting these minima had ⁴E and E₄ geometries (both with staggered OMe groups), with the barriers significantly increasing when passing from B3LYP to M06-2X to MP2 (1.46 kcal mol⁻¹, 1.93 kcal mol⁻¹, and 2.62 kcal mol⁻¹ for ⁴E; 2.27 kcal mol⁻¹, 2.58 kcal mol⁻¹ and 3.17 kcal mol⁻¹ for E₄). This trend could be explained on the basis of the gradual extra stabilization of the ¹T₂ shape.

The 1,2-*trans* isomer afforded more complex results. The symmetric conformers (“out-out”) exhibited by B3LYP afforded a six-conformation cycle, with three minima and three TSs, whereas M06-2X gave a simpler perspective (two maxima and two minima, very close in geometry). In the case of MP2, both related geometries converged into a single minimum (²T₁) and maximum in the antipodes (¹T₂). Interestingly, although *sym*-²T₁ was the global minimum for the MP2 calculations (with the two pseudo-axial methoxy groups), the B3LYP global minimum was around *asym*-E₄, with the two methoxy groups staggered. This reinforced the previous analysis regarding the underestimation of B3LYP to effectively account for the pseudo-axial stabilization exerted by electronegative groups. For the asymmetric conformations (“in-out”), the behavior was even

Fig. 8 (a) Geometry representations of the Cremer–Pople puckering parameters of the minima (green, global minima; yellow, local minima) and transition states (grey circle with red star) computed for compounds 16–17 at the M06-2X level. Qualitatively similar graphs were observed for the other levels of theory (see the ESI†). (b) Energies of the conformational pathways for compounds 16–17 calculated at the B3LYP (black), M06-2X (red) and MP2 (grey) levels.

more complex, with both B3LYP and MP2 showing a three minima-two maxima pattern (*i.e.*, missing one transition state) and M06-2X correctly locating this TS around ${}^1T_2/{}^1E$. In the case of B3LYP, the three minima were located at E_4 (global minima), 5T_1 ($\Delta E = 0.26$ kcal mol $^{-1}$), and 4E ($\Delta E = 0.25$ kcal mol $^{-1}$). M06-2X and MP2 showed similar patterns but with the envelope conformations displaced towards twisted ones (3T_4 and ${}^4E/{}^4T_5$).

1,3-Dimethoxycyclopentanes (18–19). The conformational analysis of these compounds was even more complex than that discussed for the corresponding 1,2-disubstituted analogues as three different types of conformations were observed regarding the relative orientation of the two methoxy groups. Both the "out-out" and "in-in" conformations were symmetrical, whereas the "in-out" conformation was asymmetrical in nature (Fig. 9 and 10).

In the case of the 1,3-*cis* isomer, B3LYP and MP2 exhibited a classical four-conformer pattern for the "out-out" system, whereas according to M06-2X, one of the TSs became a minimum, and two close-by TSs appeared, affording a six-conformer pattern. A four-conformer pattern was also observed with B3LYP, M06-2X, and MP2 for the "in-out" conformations though one of the TSs was missing with B3LYP and MP2 (hence, it was actually a three-conformer pattern), whereas M06-2X succeeded in finding the left-out TS around 3T_2 . Regarding the "in-in" type of conformations, the DFT

Fig. 9 (a) Geometry representations of the Cremer–Pople puckering parameters of the minima (green, global minima; yellow, local minima) and transition states (grey circle with red star) computed for compounds 18–19 at the M06-2X level. Qualitatively similar graphs were observed for the other levels of theory (see the ESI†). (b) Energies of the conformational pathways for compounds 18–19 calculated at the B3LYP (black), M06-2X (red), and MP2 (grey) levels.

methods encountered a six-conformer pattern, but MP2 converted the 1T_2 minimum and its surrounding TSs into just one TS, thus conforming a four-conformer pattern. The E_5 "in-out" is usually the global minimum and it was shifted by the MP2 calculation toward E_3 . In such conformations, one methoxy group is pseudo-equatorial and the other one is staggered. The 2E conformation, featuring the two methoxy groups in a pseudo-axial position, was located as TS at a relatively high energy content for all levels of theory (2.41–2.89 kcal mol $^{-1}$ for "out-out" conformations, 1.77–1.97 kcal mol $^{-1}$ for "in-out" conformations, and 1.89–2.04 kcal mol $^{-1}$ for "in-in" conformations). The corresponding flipped structure (E_2) with the two pseudo-equatorial OMe groups was also found as a TS or as a relative minimum depending on the level of theory and conformation of the methoxy groups. For instance, B3LYP predicted E_2 as a TS for the "out-out" conformations and a relative minimum for the "in-in" conformations. M06-2X described a relative minimum in both cases, whereas MP2 anticipated a TS. When comparing the relative energies of 2E vs. E_2 , the last ones were considerably lower ($\Delta E = 0.86$ – 1.99 kcal mol $^{-1}$). Here, again, the ΔE values

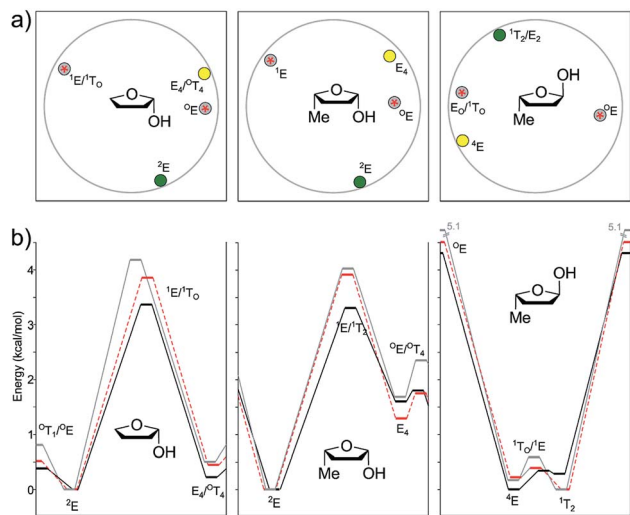

Fig. 10 (a) Geometry representations of the Cremer–Pople puckering parameters of the minima (green, global minima; yellow, local minima) and transition states (grey circle with red star) computed for compounds 20–22 at the M06-2X level. Qualitatively similar graphs were observed for the other levels of theory (see the ESI†). (b) Energies of the conformational pathways for compounds 20–22 calculated at the B3LYP (black), M06-2X (red), and MP2 (grey) levels.

were lower for MP2 than that for B3LYP, which was consistent with our previous findings.

In the case of the *trans*-1,3 compound, when dealing with the “out-out” system, B3LYP gave just one minimum at 5T_4 and one TS at the inverted 4T_5 (1.00 kcal mol $^{-1}$ higher in energy). M06-2X afforded a similar behavior, whereas MP2 turned it into a four-conformer pattern; however, one of the TSs was very close to its surrounding minima, and they all had very low frequencies (<10 cm $^{-1}$). In all levels of theory, the global minima were found near 5T_4 , with one pseudo-axial and one staggered OMe group. For “in-out”, B3LYP gave a four-conformer pattern, with the most stable conformation again near 5T_4 ($E_{\text{rel}} = 0.19$ kcal mol $^{-1}$) and the other one close in energy at 1T_5 ($E_{\text{rel}} = 0.60$ kcal mol $^{-1}$). The two transition structures connecting the minima were computed at 4E ($\Delta E = 0.86$ kcal mol $^{-1}$) and E_2 ($\Delta E = 0.71$ kcal mol $^{-1}$). M06-2X and MP2 afforded a simpler two-conformer pattern, with geometries depending on the level of theory. The minimum and TS were near 5T_4 and E_5 according to M06-2X and shifted toward E_4 and 4T_5 according to MP2. Finally, for the “in-in” type of conformations, a four-conformer pattern was observed for B3LYP, with two local minima (5T_4 and 1T_5) closer in energy (0.50 and 0.71 kcal mol $^{-1}$, respectively) and two transition structures connecting both minima at 2T_1 and 4T_5 . MP2 also showed a four-conformer pattern, but it was completely different to that of B3LYP, with different conformers at hand (5T_4 and $E_4/{}^3T_4$ as the local minima and E_4 and 4T_5 as TS). M06-2X afforded a cleaner scenario, with one minimum at 5T_4 and one maximum at 4T_5 .

2-Hydroxy-THF (20). As a model structure for furanoses, the conformational landscape of 2-hydroxy-THF represents an interesting case to be disclosed. As in other compounds, the stationary points found with B3LYP slightly differed from those

located with MP2 and M06-2X (Fig. 10). For instance, the former predicted a global minimum at almost perfect 2E ³⁷ bearing a pseudo-axial OH group, whereas in the last two methods, a minor shift south toward ${}^2T_1/{}^2E$ was observed. In both cases, the energetic preference should be well understood considering the anomeric effect. The other minimum featured E_4 geometry with an isoclinal OH group at 0.22–0.50 kcal mol $^{-1}$. The most stable transition structures were located at 0E , with low barriers (0.38–0.81 kcal mol $^{-1}$). Interestingly, the other transition structure featuring 1E (B3LYP and M06-2X) or $E_0/{}^1E_0$ (MP2) geometry was computed to be much higher in energy (3.36–4.17 kcal mol $^{-1}$), which could be explained given that the pseudo-equatorial orientation of the OH group precludes anomeric stabilization.

***cis*- and *trans*-5-Methyl-2-hydroxy-THF (21–22).** The conformational analysis of furanoside-containing compounds has received considerable attention due to their relevance in different fields of chemistry and biology.¹³ Besides 2-hydroxy-THF disclosed above, we thoroughly explored the *cis*- and *trans* 5-methylated analogues as model structures for pentofuranoses (Fig. 10).

In the case of the *cis* isomer, the conformational landscape was quite similar to that observed for 2-hydroxy-THF disclosed above. The global minimum was located at 2E in all cases, which was consistent with the stabilization exerted by the pseudo-axial OH group as a consequence of the anomeric effect. The other minima were computed near E_4 , with pseudo-axial and isoclinal methyl and hydroxyl groups, respectively. The energy difference between both minima was significant (1.29–1.69 kcal mol $^{-1}$), suggesting that the equilibrium should be cleanly displaced towards 2E at room temperature. The transition structures were found near those observed for 2-OH-THF, with the most stable one at 0E and the other one at 1E . The first TS (0E) featured a pseudo-diaxial arrangement of the two substituents, with barriers higher than those computed for the previous related system and underestimated by the DFT methods regarding MP2 (1.77–1.80 vs. 2.36 kcal mol $^{-1}$). The most unstable transition structure showed 1E geometry, with a pseudo-equatorial OH group and an isoclinal methyl group. Here, again, higher energy barriers were estimated with the three methods under study (3.30 kcal mol $^{-1}$ for B3LYP, 3.91 kcal mol $^{-1}$ for M06-2X, and 4.02 kcal mol $^{-1}$ for MP2).

The *trans* isomer reflected an excellent model study to illustrate the dependence of the conformational landscape with the relative orientation of the substituents and the level of theory employed during the calculations. The B3LYP global minimum was found at 4E , with a pseudo-equatorial methyl group and an isoclinal OH group. However, according to M06-2X and MP2, the global minima shifted towards 1T_2 with a pseudo-axial OH orientation, showing once again that the stabilization exerted by pseudo-axial electronegative groups is underestimated by B3LYP. Nevertheless, the ${}^4E/{}^1T_2$ energy difference was quite low for the three levels of theory (0.17–0.29 kcal mol $^{-1}$), indicating that the two type of conformations should be expected to occur in real systems. Interestingly, none of the theoretical models agreed on the structure of the most stable TS connecting both minima (1E for B3LYP, 1T_0 for M06-

2X, and E_O for MP2), with similar energy barriers in all cases (0.34–0.59 kcal mol⁻¹). The relative stabilization of these structures was due to the pseudo-axial orientation of the OH group. The other TS, much higher in energy, was found at 0E , with a pseudo-OH group. The selected stationary points of 21 and 22 found at the B3LYP/6-311+G** level of theory are shown in Fig. 11.

The conformational preferences calculated for these two simplified models for pentofuranoses showed good correlation with the landscape found for more complex furanose compounds shown in Fig. 12.³⁸ For instance, Cros *et al.* explored methyl- β -D- and - α -L-arabinofuranosides (*ent*-23 and 24, respectively) with the MM3 force field.³⁹ They observed that the conformations of the two compounds were distributed in two deep low-energy wells (consistent with the two minima-two maxima reported herein). In the case of 23, the two minima were found near 3T_2 and 2T_3 , whereas the stationary points of 24 were located at $^1T_2/E_2$ and E_3 . Later, Dowd *et al.* employed MM3 to build the conformational maps of the furanosyl rings of β - and α -D-ribose (*ent*-25 and *ent*-26, respectively) and their 2-deoxy counterparts (*ent*-27 and *ent*-28, respectively).⁴⁰ In the case of ribose (25 and 26), the northern (3T_2 and E_2 , respectively) and southern ($E_3/^2T_3$ and 4T_3 , respectively) minima were located closer to the proposal made by Cros *et al.* for arabinofuranosides. The same trend was also noticed for the 2-deoxyribose analogues 27 (3E and 2T_3) and 28 (E_2 and 4T_3). More recently, Lowary and co-workers carried out a detailed examination of the stable conformations of twelve β - and α -methyl furanosides of D-arabinose (*ent*-23 and *ent*-24), D-lyxose (*ent*-29 and *ent*-30), D-ribose (*ent*-31 and *ent*-32), and D-xylose (*ent*-33 and *ent*-34) at the B3LYP/6-31+G**//B3LYP/6-31G* level of theory.⁴¹ In the cases of β -arabinose and β -ribose (23 and 31, respectively), the northern minima located at E_4 shifted by $\sim 50^\circ$ southwest from the MM3 calculations by Cros *et al.* and Dowd *et al.* The southern minima found at 2E and E_3 slightly shifted from the MM3 results. In the case of α -series, the minima of 24 and 32 occurred at 1E and E_3 and E_2 and 4E , respectively, which were again closer to the MM3 results.

The remaining compounds (31–34) exhibited similar trends but with some disturbances in the southern region. Taking

Fig. 11 Selected stationary points found for (a) *cis*-5-methyl-2-hydroxy-THF, and (b) *trans*-5-methyl-2-hydroxy-THF at the M06-2X/6-311+G** level of theory (TS: transition structure; GM: global minimum; LM: local minimum).

Fig. 12 Scatter plot of the CP phase angle (amplitude not considered) of the local minima found for compounds 23–24 (Cros *et al.*), 25–28 (Dowd *et al.*), and 23*–24* and 29–34 (Lowary and co-workers). Light gray and dark gray circles represent the minima off the southern and northern regions, respectively, and the green arrow indicates the results of our calculations with the simplified model. The asterisks in 23 and 24 are provided to differentiate the results obtained by Cros *et al.* (no asterisk) from those reported by Lowary and co-workers (with asterisk).

collectively the results reported by Cros *et al.*, Dowd *et al.*, Lowary and coworkers, and us (Fig. 12), insightful relationships can be drawn. The conformational landscape of furanoses is governed by a 2-minima system, with one stationary point at the north and the other at the south of the rotational map. The northern region is mainly populated between 3T_2 and E_4 for the 1,4-*cis* isomers and between 1E and E_2 for the 1,4-*trans* counterparts. In the same way, in the southern region, these conformations between $E_3/^2E$ (1,4-*cis*) and $^4E/E_3$ (*trans*) are favored. The results of our calculations on a simplified model correlated well with these interesting trends, suggesting that the conformational preference of furanoses is strongly dictated by the C-1/C-4 relative configuration. Naturally, the presence of other substituents at the ring might introduce additional steric and electronic interactions, hence affecting the location of minima. Including the solvent effect in the calculations might also generate a different outcome provided by gas phase calculations. For instance, the southern minima of 31, 32, and 34 were found at E_1 , 2E , and E_O , respectively, which were slightly different from the above-mentioned range. In these cases, the formation of intramolecular H-bonds accounted for the shifts in the southern region.

Conclusions

The conformational pathways of several mono- and disubstituted five-membered rings were thoroughly explored with three

different quantum methods (B3LYP, M06-2X, and MP2). The results of these calculations showed that the conformational preference of a given compound is intimately linked with its own structural characteristics (type and number of substituents, substitution pattern, type of the heteroatom in the ring, etc.). Despite the case that in some systems the relative energies of different conformations fell within the limit provided by the levels of theory under study, interesting trends could be drawn. We found an interesting preference of electronegative substituents (chlorine, OH, etc.) and alkyl groups to take pseudo-axial and pseudo-equatorial positions, respectively. In addition, the conformational landscape computed for many systems showed dependence on the level of theory employed for the calculations. In this regard, we observed a higher correlation between the results provided by MP2 with M06-2X than that with B3LYP, which clearly underestimated the preferences for the pseudo-axial position of electronegative groups. In most cases, free energy calculations confirmed the results obtained using electronic energies. However, in a few cases, such as that for pyrrolidine, PES changed drastically by taking entropic effects into account.

Experimental section

Computational methods

Quantum mechanical calculations were performed using Gaussian 09W (rev. C.01)⁴² with the standard basis sets and default minimization methods and termination conditions, with the exception of the Tight keyword and the use of an Ultrafine grid for the optimizations. All the minima and transition states had zero or one imaginary frequency, respectively, as appropriate. For the transition states, it was verified that this frequency corresponded to the conformational pathway searched for. The transition states were obtained either by the traditional Berny algorithm or by using the QST2 procedure. Free energies were calculated at 298 K, as reported in the Gaussian output file, without scaling. For substituted cyclopentanes, the IUPAC numbering scheme was used, with the substituent facing down when numbering clockwise observed from above. The heterocycles were numbered following the usual carbohydrate convention, with C1 clockwise to the heteroatom (which is equivalent to atom 5).

- 37 The naming of the different conformers for 2-hydroxyTHF and its 5-methylated counterparts follows the nomenclature used in sugar chemistry, *i.e.*, C-1 for the anomeric atom, C-4 for the last carbon in the cycle, and O for the ring oxygen.
- 38 Most of the studies have been carried out with furanoses of D-series. However, the configurations exhibited by **21** and **22** are consistent with furanoses of L-series. Hence, to facilitate the comparison we have inverted (rotated by 180°) the results obtained for furanoses of D-series (*i.e.* the E₁ in D-series is identical to ¹E for L-series).
