# Glyme–Li salt equimolar molten solvates with iodide/triiodide redox anions†

 Keisuke Shigenobu, Azusa Nakanishi, Kazuhide Ueno,  \* Kaoru Dokko   
and Masayoshi Watanabe 

Room-temperature-fused Li salt solvates that exhibit ionic liquid-like behaviour can be formed using particular combinations of multidentate glymes and lithium salts bearing weakly coordinating anions, and are now deemed a subset of ionic liquids, viz. solvate ionic liquids (SILs). Herein, we report redox-active glyme–Li salt molten solvates consisting of tetraethyleneglycol ethylmethyl ether (G4Et) and lithium iodide/triiodide,  $[\text{Li}(\text{G4Et})\text{I}]$  and  $[\text{Li}(\text{G4Et})\text{I}_3]$ . The coordination structure of the complex ions and the thermal, transport, and electrochemical properties of these molten Li salt solvates were investigated to diagnose whether they can be categorized as SILs.  $[\text{Li}(\text{G4Et})]^+$  and  $\text{I}_3^-$  were found to remain stable as discrete ions and exist as well-dissociated forms in the liquid state, indicating that  $[\text{Li}(\text{G4Et})\text{I}_3]$  can be classified as a good SIL. This study also clarified that the  $\text{I}^-$  and  $\text{I}_3^-$  counter anions exhibit an electrochemical redox reaction in the highly concentrated molten Li salt solvates. The redox-active molten Li solvates were further studied as a highly concentrated catholyte for use in rechargeable semi-liquid lithium batteries. Although the cell constructed using  $[\text{Li}(\text{G4Et})\text{I}_3]$  failed to charge after the initial discharge step, the cell containing  $[\text{Li}(\text{G4Et})\text{I}]$  demonstrates reversible charge–discharge behaviour with a high volumetric energy density of  $180 \text{ W h L}^{-1}$  based on the catholyte volume.

## 1. Introduction

Molten salt solvates and highly concentrated electrolyte solutions with increased salt concentration near their saturation limit are in the limelight as possible replacements for conventional organic electrolyte solutions used in electrochemical devices because they afford improved thermal stability, reduced vapor pressure, and enhanced electrochemical stability.<sup>1–3</sup> Moreover, certain concentrated electrolytes have been reported to show improved performance in Li-ion batteries, such as higher rate capability and enhanced stable charge–discharge cycling of the high-voltage cathode and metallic Li anode when compared to conventional organic liquid electrolytes.<sup>4–9</sup>

Glyme-based molten Li salt solvates are of particular interest and have been intensively studied because certain stoichiometric mixtures of glymes and Li salts are found to behave like ionic liquids (ILs).<sup>10,11</sup> Molten Li salt solvates with long-lived  $[\text{Li}(\text{glyme})]^+$  complex cations are deemed a new family of ILs, solvate ionic

liquids (SILs).<sup>12</sup> Numerous combinations of glymes and metal salts have been examined; however, only limited cases using multidentate glymes and metal salts with bulky and weakly coordinating anions, such as bis(trifluoromethanesulfonyl)amide ( $[\text{TFSA}]^-$ ), act as good SILs.<sup>13</sup> However, these conventional anions only compensate for the positive charge on the Li ions and may have a less active role in the electrochemical properties even though they account for approximately half of the dense electrolyte material weight. In this respect, it is of great research interest to introduce an electrochemically-active functionality into the counter anions used in SILs. The redox-active, “two-in-one” SILs wherein the  $[\text{Li}(\text{glyme})]^+$  complex cation is responsible for Li ion transport and the redox-active anion imparts reversible redox activity have a potential to be used as a component of catholyte for semi-liquid rechargeable lithium batteries when Li metal is combined as the anode.

In a recent study, one of the authors employed a metal complex anion, tetrabromoferrate ( $[\text{FeBr}_4]^-$ ), to demonstrate redox-active glyme–Li salt SILs consisting solely of metal complex ions, in which the  $[\text{FeBr}_4]^-$  complex anion undergoes reversible redox reaction (*i.e.*,  $[\text{Fe}^{\text{III}}\text{Br}_4]^- + \text{e}^- \rightleftharpoons [\text{Fe}^{\text{II}}\text{Br}_4]^{2-}$ ) at  $\sim 3 \text{ V vs. Li/Li}^+$ .<sup>14</sup> However, the SIL with  $[\text{FeBr}_4]^-$  needs to be diluted with another SIL for use as a SIL-based catholyte due to its relatively high melting point, which leads to low energy density ( $37 \text{ W h L}^{-1}$  based on the catholyte volume) as a consequence of the reduced  $[\text{FeBr}_4]^-$  concentration.

The highly reversible redox activity of the  $\text{I}^-/\text{I}_3^-$  couple has long been utilized in a variety of electrochemical devices,

including dye-sensitized solar cells,<sup>15,16</sup> metal-I<sub>2</sub> batteries,<sup>17–19</sup> and flow batteries.<sup>20–22</sup> In recent studies, the I<sup>−</sup>/I<sub>3</sub><sup>−</sup> couple has also been employed as a redox mediator to improve the charge-discharge performance of high-energy-density Li–O<sub>2</sub><sup>23,24</sup> and Li–S<sup>25,26</sup> batteries. Extensive studies on IL-based electrolytes used for dye-sensitized solar cells have shown that iodide-based ILs have a relatively low melting point and are prone to exist as super-cooled liquids without crystallization.<sup>27–29</sup> In this study, we have prepared novel redox-active glyme–Li salt solvates based on the I<sup>−</sup>/I<sub>3</sub><sup>−</sup> couple in anticipation of melting point depression and anti-crystallization of the glyme–Li salt solvates. The thermal properties, coordination structure, and transport properties of redox-active glyme–Li salt solvates based on the I<sup>−</sup>/I<sub>3</sub><sup>−</sup> couple were investigated. Furthermore, the two-electron transfer reaction of the I<sup>−</sup>/I<sub>3</sub><sup>−</sup> couple (*i.e.*, I<sub>3</sub><sup>−</sup> + 2e<sup>−</sup> ⇌ 3I<sup>−</sup>) offers an increase in the theoretical capacity of the redox-active SIL when compared to the SIL-based catholyte prepared with [FeBr<sub>4</sub>]<sup>−</sup>. This study also reports the use of the neat redox-active SIL as a highly concentrated catholyte (~3 mol dm<sup>−3</sup>) in semi-liquid rechargeable lithium batteries.

## 2. Experimental

### 2.1 Materials

Purified tetraethyleneglycol ethylmethyl ether (G4Et, water content <50 ppm) was kindly supplied by Nippon Nyukazai and lithium bis(trifluoromethanesulfonyl)amide (Li[TFSA], >99.9%, water content <100 ppm) was provided by Solvay Japan. Lithium iodide (LiI, >99.9%, Sigma Aldrich) and iodine (I<sub>2</sub>, >99.8%, FUJIFILM Wako) were used as received without any further purification. All glyme–Li salt complexes were prepared in an argon-filled glove box ([H<sub>2</sub>O] <1 ppm; [O<sub>2</sub>] <1 ppm). G4Et and LiI were mixed in a 1 : 1 molar ratio at 45 °C to form [Li(G4Et)]I. [Li(G4Et)]I and iodine were mixed in an equimolar ratio and heated at 60 °C to form [Li(G4Et)]I<sub>3</sub>.

### 2.2 Measurements

The melting point (*T*<sub>m</sub>) and glass transition temperature (*T*<sub>g</sub>) were determined using differential scanning calorimetry (DSC7020, Hitachi High-Tech Science). All samples were hermetically sealed in aluminium pans in an argon-filled glove box. The sample pans were first pre-heated to 100 °C to erase thermal history. Then they were cooled to −150 °C, and heated to 100 °C at a heating rate of 5 °C min<sup>−1</sup> under a nitrogen atmosphere. Both *T*<sub>m</sub> and *T*<sub>g</sub> were calculated from the onset temperatures of the second heating thermograms. The thermal stabilities of the samples were investigated using isothermal thermogravimetric analysis (isothermal TGA) on a TG/DTA STA7200 instrument (Hitachi High-Tech Science) at 100 °C for 140 min under a nitrogen atmosphere.

The viscosity and density of [Li(G4Et)]I were measured simultaneously on a Stabinger viscometer (SVM300, Anton Paar). The viscosity and density of [Li(G4Et)]I<sub>3</sub> were measured on a density meter (DA-100, Kyoto Denshi Kogyo) and rheometer (Physica MCR 301, Anton Paar), respectively.

Raman spectra were recorded on a laser Raman spectrometer (NRS-4100, JASCO equipped with a 27 mW, 785 nm laser) at a resolution of ~4 cm<sup>−1</sup> and calibrated using a polypropylene standard. The samples were enclosed in a capillary tube to avoid moisture adsorption during the measurement. The sample temperature was adjusted to 30 °C for G4Et and [Li(G4Et)]I, and 60 °C for [Li(G4Et)]I<sub>3</sub> using a Peltier microscope stage (TS62, INSTEC) equipped with a temperature controller (mk1000, INSTEC). For the low wavenumber region (100–300 cm<sup>−1</sup>), [Li(G4Et)]I<sub>3</sub> was diluted to 1 mol dm<sup>−3</sup> with acetonitrile in order to reduce fluorescence interference. The UV-vis spectra were recorded on a UV-vis spectrometer (UV-2700, Shimadzu) using a cell with an optical path length of 10 mm.

The ionic conductivity was measured using the complex impedance method in the frequency range of 500 kHz to 1 Hz at an alternating voltage amplitude of 200 mV (VMP2, Biologic). Two platinum black electrode cells, whose cell constant was determined using a 0.01 M KCl aqueous solution at 25 °C prior to the measurements, were soaked in each sample and thermally equilibrated at each temperature for at least 1 h within a thermostat chamber.

Cyclic voltammetry was performed on a potentiostat/galvanostat (ModuLab XM ECS, Solartron Analytical) using a three-electrode cell consisting of a platinum disk micro electrode (*ca.* 10 μm in diameter) as the working electrode, platinum wire as the counter electrode, and lithium metal soaked in 1 mol dm<sup>−3</sup> Li[TFSA] in triglyme (G3) as the reference electrode. The diameter of the microelectrode was calibrated using a standard electrolyte solution (0.1 mol dm<sup>−3</sup> *n*-tetrabutylammonium hexafluorophosphate in acetonitrile solution containing 2 mmol dm<sup>−3</sup> ferrocene). The Li/Li<sup>+</sup> reference electrode was separated from the sample solution by a liquid junction with a Vycor glass frit.

Pulsed field gradient nuclear magnetic resonance (PFG-NMR) measurements were performed on a ECX400 spectrometer (JEOL) equipped with a 9.4 T (400 MHz) narrow bore superconducting magnet, a pulse gradient probe (JEOL), and current amplifier to clarify the self-diffusion coefficients of each component in the sample mixtures, G4Et (<sup>1</sup>H, 399.7 MHz) and lithium cation (<sup>7</sup>Li, 155.3 MHz). The experimental procedure for PFG-NMR was described in detail in our previous report.<sup>30</sup>

The charge and discharge tests were performed using a two-compartment cell separated by a lithium-ion conductive glass ceramic (OHARA, LICGC, 19 mm in diameter), and the iodide/triiodide-based SIL electrolyte used as the catholyte. Carbon paper (TGP-H-060, TORAY, 13 mm in diameter) coated with Ketjen black (EC-600JD, LION) was used as the current collector for the catholyte and the Li metal disk electrode (13 mm in diameter) was used as the anode. For the lithium metal anode, 1 mol dm<sup>−3</sup> Li[TFSA] in G4Et was also used as the anolyte to avoid direct contact between the lithium metal and LICGC. A porous glass filter paper (Advantec, GA55, 17 mm in diameter) was employed to retain the catholyte and anolyte in each compartment. Li|anolyte|LICGC|catholyte cells were assembled in an argon-filled glove box. The galvanostatic charge and discharge tests were performed on an automatic charge and discharge instrument (HJ1001SM8A, Hokuto Denko) at 60 °C, and the cut-off voltages were set at 2.2 V and 3.3 V for the

discharge and charge steps, respectively. For the cell constructed using the  $[\text{Li}(\text{G4Et})]\text{I}_3$ -based catholyte, the charge and discharge cycles were started from the discharge step.

### 2.3 Density functional theory (DFT) calculations

DFT calculations were performed using the Gaussian 09 program.<sup>31</sup> The geometries of the  $[\text{Li}(\text{G4Et})]^+$  complex cation were fully optimized at the B3LYP/6-311+G\*\* level of theory. Vibrational analysis of the optimized geometry was also carried out at the same level of theory.

## 3. Results and discussion

### 3.1 Thermal properties

In a previous work,  $\text{LiI}$  was found to form a 1 : 1 crystalline solvate with G3 or tetraglyme (G4), but their melting points were higher than room temperature ( $T_m = 96^\circ\text{C}$  and  $60^\circ\text{C}$  for  $[\text{Li}(\text{G3})]\text{I}$  and  $[\text{Li}(\text{G4})]\text{I}$ , respectively).<sup>32</sup> We previously reported that introducing asymmetry into each end group of the glyme molecules effectively reduces the  $T_g$  and  $T_m$  of SILs.<sup>33</sup> The entropy of fusion increases upon increasing the chain length of the alkyl terminal group in the asymmetric glyme molecules since the conformational degrees of freedom upon melting increases.<sup>33,34</sup> Thus, we expected that a low melting 1 : 1 solvate of  $\text{LiI}$  may be formed using asymmetric G4Et. The  $T_m$  and  $T_g$  values of the studied samples are summarised in Table 1.  $[\text{Li}(\text{G4Et})]\text{I}$  was prone to remain as a supercooled liquid in the sample vial over several days, which allowed us to perform further measurements in the liquid state at room temperature, however,  $[\text{Li}(\text{G4Et})]\text{I}_3$  readily crystallized at room temperature although  $T_m$  was lower than that of  $[\text{Li}(\text{G4Et})]\text{I}$ . As expected, the  $T_m$  of  $[\text{Li}(\text{G4Et})]\text{I}$  was lower than that of  $[\text{Li}(\text{G3})]\text{I}$  and  $[\text{Li}(\text{G4})]\text{I}$ , but still higher than room temperature.  $T_m$  of  $[\text{Li}(\text{G4Et})]\text{I}_3$  is lower than that of  $[\text{Li}(\text{G4Et})]\text{I}$ , and the reduction of  $T_m$  upon the addition of solid  $\text{I}_2$  to  $[\text{Li}(\text{G4Et})]\text{I}$  suggests that the cation–anion interaction is weakened *via* the formation of the charge-delocalized  $\text{I}_3^-$ . Indeed, it is known that the addition of a Lewis acid (e.g.,  $\text{AlCl}_3$ ) to imidazolium halide salts significantly reduces  $T_m$  and  $T_g$ , and gives room temperature ionic liquids consisting of the imidazolium cation and weakly coordinating Lewis acid–base adduct anions, such as  $[\text{AlCl}_4]^-$ .<sup>35,36</sup> Likewise, room temperature ionic liquids with polyiodide  $[\text{I}_m]$  ( $1 \leq m \leq 8$ ) can be formed upon the addition of  $\text{I}_2$  to imidazolium iodide salts.<sup>37,38</sup>

The thermal stability of the solvates was studied using isothermal TGA at  $100^\circ\text{C}$ , as shown in Fig. 1.  $[\text{Li}(\text{G4Et})]\text{I}$  shows discernible weight loss, indicating the gradual evaporation of

Fig. 1 Isothermal thermogravimetric data obtained for G4Et,  $[\text{Li}(\text{G4Et})]\text{I}$ ,  $[\text{Li}(\text{G4Et})]\text{I}_3$ , and  $[\text{Li}(\text{G4Et})][\text{TFSA}]$  at  $100^\circ\text{C}$ .

G4Et at  $100^\circ\text{C}$ . On the contrary, the weight loss was negligible for  $[\text{Li}(\text{G4Et})]\text{I}_3$  and its thermal stability was almost the same as that observed for a prototypical SIL,  $[\text{Li}(\text{G4Et})][\text{TFSA}]$ , under the same conditions.<sup>33</sup> The higher thermal stability of  $[\text{Li}(\text{G4Et})]\text{I}_3$  was attributed to the enhanced interaction between the Li ions and G4Et. The formation of charge-delocalized  $\text{I}_3^-$  results in the reduced interaction with Li ions, which in turn enhances the stability of the  $[\text{Li}(\text{G4Et})]^+$  complex cation.

### 3.2 Coordination structure

The Li ion coordination structure has been studied for a series of glyme–Li salt solvates in crystalline and molten states, and a variety of glyme conformations, such as helical polymeric  $[\text{Li}_n(\text{glyme})_n]^{n+}$ , dimeric  $[\text{Li}_2(\text{glyme})_2]^{2+}$ , and crown-ether-like monomeric  $[\text{Li}(\text{glyme})]^+$ , and has been found to be dependent on the chain length of the glyme molecules and the counter anion of the Li salt used.<sup>39–41</sup> In the molten state of G3 and G4-based 1 : 1 solvates with Li salts, the glyme molecules were found to adopt a crown-ether like conformation to form monomeric  $[\text{Li}(\text{glyme})]^+$ .<sup>42</sup> Fig. 2a shows the Raman spectra of the liquid samples, G4Et,  $[\text{Li}(\text{G4Et})]\text{I}$ , and  $[\text{Li}(\text{G4Et})]\text{I}_3$ , in the wavenumber range  $800\text{--}900\text{ cm}^{-1}$ , where the bands can be ascribed to the mixed mode of  $\text{CH}_2$  rocking and C–O–C stretching vibrations of the glyme molecules.<sup>43,44</sup> Except for the neat G4Et, a strong band emerges at  $\sim 870\text{ cm}^{-1}$  along with weaker bands in the range of  $800\text{--}850\text{ cm}^{-1}$ . The strong band observed at  $\sim 870\text{ cm}^{-1}$  can be assigned to the symmetric ring breathing mode of the  $[\text{Li}(\text{G4Et})]^+$  complex cation with a crown ether-like conformation, similar to the previously reported  $[\text{Li}(\text{G3})]^+$  and  $[\text{Li}(\text{G4})]^+$  complex cations.<sup>43</sup> A comparison between the experimental and calculated Raman bands confirms the presence of a crown ether-like  $[\text{Li}(\text{G4Et})]^+$  cation (Fig. 2b); the calculated Raman bands of the optimized  $[\text{Li}(\text{G4Et})]^+$  complex cation can explain the experimental Raman bands observed for  $[\text{Li}(\text{G4Et})]\text{I}$  and  $[\text{Li}(\text{G4Et})]\text{I}_3$  although the calculated bands appear at a slightly higher wavenumber when compared to the corresponding experimental bands.

Table 1  $T_g$  and  $T_m$  of G4Et,  $[\text{Li}(\text{G4Et})]\text{I}$  and  $[\text{Li}(\text{G4Et})]\text{I}_3$ <sup>a</sup>

Sample	$T_g$ [ $^\circ\text{C}$ ]	$T_m$ [ $^\circ\text{C}$ ]
G4Et	n.d.	–29
$[\text{Li}(\text{G4Et})]\text{I}$	–56	47
$[\text{Li}(\text{G4Et})]\text{I}_3$	n.d.	38

<sup>a</sup> n.d. = not detected.

Fig. 2 (a) The experimental Raman spectra recorded for G4Et, [Li(G4Et)]I, and [Li(G4Et)]I<sub>3</sub> at 60 °C and (b) the calculated Raman spectrum of the optimized [Li(G4Et)]<sup>+</sup> complex cation.

The formation of I<sub>3</sub><sup>−</sup> anions was also studied using Raman and UV-vis spectroscopy. Fig. 3a illustrates the Raman spectrum of 1 mol dm<sup>−3</sup> [Li(G4Et)]I<sub>3</sub> in acetonitrile in the wavenumber range of 125–180 cm<sup>−1</sup>. The bands observed at 125, 150, and

180 cm<sup>−1</sup> can be assigned to the asymmetric triiodide stretching vibration, Fermi resonance, and I–I stretching of the ion pair (namely, [Li(G4Et)]<sup>+</sup> I<sub>3</sub><sup>−</sup> in this work), respectively, as previously reported.<sup>45</sup> In Fig. 3b, the UV-vis spectra of [Li(G4Et)]I and [Li(G4Et)]I<sub>3</sub> diluted with acetonitrile also show characteristic splitting bands from 200 nm to 250 nm for I<sup>−</sup>, and 290 nm to 360 nm for I<sub>3</sub><sup>−</sup>, respectively. Consequently, the above results confirm that the stable complex ions, [Li(G4Et)]<sup>+</sup> and I<sub>3</sub><sup>−</sup>, were successfully formed in the liquid state of [Li(G4Et)]I<sub>3</sub>.

### 3.3 Transport and electrochemical properties

The viscosity and ionic conductivity of [Li(G4Et)]I and [Li(G4Et)]I<sub>3</sub> are listed in Table 2 along with the density and Li salt concentration at 60 °C. The viscosity of [Li(G4Et)]I<sub>3</sub> is one order of magnitude lower than that of [Li(G4Et)]I. This suggests that I<sub>3</sub><sup>−</sup> has a much weaker cation–anion interaction with the complex cation due to charge delocalization. The lower viscosity is responsible for the higher conductivity of [Li(G4Et)]I<sub>3</sub>, though the salt concentration associated with the number of charge carriers is lower with an equimolar addition of I<sub>2</sub>.

The redox response of the I<sup>−</sup>/I<sub>3</sub><sup>−</sup> couple was studied in the molten Li salt solvates and the cyclic voltammograms obtained for the Pt microelectrode in [Li(G4Et)]I and [Li(G4Et)]I<sub>3</sub> at 60 °C are shown in Fig. 4. In either case, the I<sup>−</sup>/I<sub>3</sub><sup>−</sup> redox couple shows a two-electron charge transfer reaction in the molten salt solvates. A typical sigmoidal curve with a limiting current of 0.24 μA was observed at a half wave potential (*E*<sub>1/2</sub>) of 3.10 V vs. Li/Li<sup>+</sup> for [Li(G4Et)]I, corresponding to the oxidation reaction, 3I<sup>−</sup> → I<sub>3</sub><sup>−</sup> + 2e<sup>−</sup> (Fig. 4a). For [Li(G4Et)]I<sub>3</sub>, the reverse reduction reaction of the I<sup>−</sup>/I<sub>3</sub><sup>−</sup> couple, I<sub>3</sub><sup>−</sup> + 2e<sup>−</sup> → 3I<sup>−</sup>, was detected with a limiting current of 0.32 μA at a more negative *E*<sub>1/2</sub> value of 2.75 V vs. Li/Li<sup>+</sup> (Fig. 4b). A relatively large difference of the *E*<sub>1/2</sub> values indicates rather slow kinetics of these redox reactions. In a previous study by Bentley *et al.*, the formal potential of the I<sup>−</sup>/I<sub>3</sub><sup>−</sup> couple, *E*<sup>o</sup> (I<sup>−</sup>/I<sub>3</sub><sup>−</sup>), was found to change depending on solvent polarity: more positive *E*<sup>o</sup> (I<sup>−</sup>/I<sub>3</sub><sup>−</sup>) value was observed in high polarity and Lewis acidic media in which highly Lewis basic I<sup>−</sup> is more stabilized.<sup>46</sup> The oxidation of I<sup>−</sup> is more

Fig. 3 (a) The Raman spectrum recorded for 1 mol dm<sup>−3</sup> [Li(G4Et)]I<sub>3</sub> in acetonitrile. (b) The UV-vis spectra recorded for 1 mmol dm<sup>−3</sup> [Li(G4Et)]I and [Li(G4Et)]I<sub>3</sub> in acetonitrile.

**Table 2** The density ( $d$ ), Li salt concentration ( $c$ ), viscosity ( $\eta$ ), and conductivity ( $\sigma$ ) of [Li(G4Et)]I and [Li(G4Et)]I<sub>3</sub> at 60 °C

	$d$ [g cm <sup>-3</sup> ]	$c$ [mol dm <sup>-3</sup> ]	$\eta$ [mPa s]	$\sigma$ [mS cm <sup>-1</sup> ]
[Li(G4Et)]I	1.33	3.58	233	1.7
[Li(G4Et)]I <sub>3</sub>	1.86	2.98	23	8.6

energetically difficult in [Li(G4Et)]I, since the concentration of strong Lewis acidic Li ions (*i.e.*, Li salt concentration,  $c$ ) is higher for [Li(G4Et)]I. Another possible reason for the more negative value of  $E_{1/2}$  in [Li(G4Et)]I<sub>3</sub> is rather slow kinetics of the redox reaction. It is known that I<sub>2</sub> and I<sub>3</sub><sup>-</sup> are adsorbed onto Pt electrode surface, giving rise to the large cathodic overpotential.<sup>47</sup> The adsorption of I<sub>2</sub> and I<sub>3</sub><sup>-</sup> is more likely to occur in [Li(G4Et)]I<sub>3</sub>, and thereby the  $E_{1/2}$  value may become more negative by a kinetic reason. The subsequent redox response around a potential more positive than 3 V vs. Li/Li<sup>+</sup> in [Li(G4Et)]I<sub>3</sub> may be assigned to the reaction of triiodide/iodine, I<sub>3</sub><sup>-</sup> → 3/2 I<sub>2</sub> + e<sup>-</sup> (Fig. 4b). In our preliminary study, we found the subsequent redox reaction of I<sub>3</sub><sup>-</sup>/I<sub>2</sub> at higher potential in a solvate ionic liquid [Li(G4)](TFSA) containing 5 mmol dm<sup>-3</sup> [Li(G4)]I as shown in Fig. S1.†

### 3.4 Stability of the complex cations

In our previous studies, low-melting glyme-Li salt complexes were categorized into two electrolyte groups, SILs and concentrated solutions with the stability of the [Li(glyme)]<sup>+</sup> complex cations being key to discriminating between the two liquid states.<sup>48</sup> The presence of robust complex cations was found to be associated with IL-like properties of the molten salt solvates. The stability of the [Li(G4Et)]<sup>+</sup> complex cation was assessed using the ratio of the self-diffusion coefficients of the glyme molecules and Li ions ( $D_G/D_{Li}$ ), as shown in Fig. 5. The diffusivity data for G4Et and the Li ions were obtained using PFG-NMR measurements and the self-diffusion coefficients,  $D_G$  and  $D_{Li}$ , listed in Table S1.† Similar to our previous study,<sup>48</sup>  $D_G/D_{Li}$

was plotted as a function of the molar conductivity ratio (so-called, ionicity of ILs),  $\Lambda/\Lambda_{NE}$ . Here,  $\Lambda$  is the experimental molar conductivity, whereas  $\Lambda_{NE}$  was calculated from the self-diffusion coefficients of the Li ions and anions, assuming the absence of any correlated motions of the ions on the basis of the Nernst-Einstein equation,  $\Lambda_{NE} = F^2(D_{Li} + D_{anion})/RT$ , where  $F$  is the Faraday constant,  $R$  is the gas constant, and  $T$  is the absolute temperature. Therefore,  $\Lambda/\Lambda_{NE}$  represents the proportion of ions that contribute to actual ionic conduction from all the diffusing ionic components and reflects the correlation of ionic motions affected by ion-ion interactions.<sup>49–51</sup> Because the self-diffusion coefficient of I<sup>-</sup> and I<sub>3</sub><sup>-</sup> is not measurable using PFG-NMR, the chemical diffusion coefficients determined from the limiting current values ( $|I_{lim}|$  in Fig. 4) were used to calculate the  $\Lambda_{NE}$  values for [Li(G4Et)]I and [Li(G4Et)]I<sub>3</sub> (see ESI, Table S1†). In Fig. 5, the data reported for the G3 and G4-based molten Li salt solvates with different anionic structures ([Li(G3)]X and [Li(G4)]X) are also displayed for comparison.<sup>33,48</sup> If  $D_G/D_{Li}$  is unity, the glyme molecules and Li ions are considered to diffuse together in the form of long-lived [Li(glyme)]<sup>+</sup> complex cations. Thus, such a molten Li salt solvate can be classified as an SIL. On the other hand, molten Li salt solvates with  $D_G/D_{Li} > 1$  are not considered to be as an SIL, but a concentrated solution since the occurrence of a fast ligand exchange between the unstable [Li(glyme)]<sup>+</sup> complex cations and counter anions, and the presence of non-coordinating free glyme molecules are suggested. For [Li(G4Et)]I, the relatively low  $\Lambda/\Lambda_{NE}$  value (0.27) corresponds to the strong attractive interaction and correlated motion (or ionic association) of Li<sup>+</sup> and I<sup>-</sup>. A  $D_G/D_{Li}$  value slightly higher than 1 suggests that the [Li(G4Et)]<sup>+</sup> complex cations are not long-lived and non-coordinating G4Et molecules are present to some extent. Thus, [Li(G4Et)]I is classified as a concentrated solution based on the above classification approach. By contrast, for [Li(G4Et)]I<sub>3</sub>, both the  $\Lambda/\Lambda_{NE}$  value and  $D_G/D_{Li}$  are close to unity. This is indicative of more uncorrelated ionic motions resulting from the weaker interactions observed between Li<sup>+</sup> and I<sub>3</sub><sup>-</sup>, and the formation of stable [Li(G4Et)]<sup>+</sup> complex cations in molten [Li(G4Et)]I<sub>3</sub>. The extraordinary high

**Fig. 4** The cyclic voltammogram obtained for (a) [Li(G4Et)]I and (b) the reduction of [Li(G4Et)]I<sub>3</sub> on the Pt microelectrode at a scan rate of 1 mV s<sup>-1</sup> at 60 °C.

Fig. 5 The correlation between  $D_G/D_{Li}$  and ionicity. Data for  $[Li(G4Et)]I$  and  $[Li(G4Et)][TFSA]$  were obtained from ref. 48 and 33 respectively.

$\Lambda/\Lambda_{NE}$  value exceeding 1 may imply Grotthuss-like charge transfer, which involves the exchange of a covalent bond between the  $I_3^-$  anions, as discussed for ionic liquid electrolytes containing  $I_3^-$ .<sup>52–54</sup> Consequently, these results and the high thermal stability shown in Fig. 1 support that  $[Li(G4Et)]I_3$  may be classified as a SIL.

### 3.5 Charge–discharge test

Redox-active SILs containing the  $I^-/I_3^-$  couple were studied as the liquid cathode material in 3 V-class semi-liquid rechargeable lithium metal batteries. Recently, stable charge–discharge of lithium polysulfide semi-liquid batteries has been achieved without an ion-selective membrane; the polysulfide shuttle effect that deteriorates the cell performance is eliminated by a passivation layer formed on the lithium metal anode.<sup>55</sup> For a commercialized lithium iodine ( $Li-I_2$ ) primary battery, direct contact of  $I_2$  with lithium metal instantaneously forms  $LiI$  on the lithium electrode as a  $Li$  ion conducting passivation layer.

Thus, the further reduction reaction of  $I_2$  causing self-discharge can be prevented.<sup>56</sup> We envisaged that the redox shuttle of  $I_3^-$  in the semi-liquid battery may also be mitigated by the  $LiI$ -based passivation layer formed initially on the lithium metal anode. However, the cell voltage of a membrane-free  $Li|[Li(G4Et)]I_3|KB$ -coated carbon paper cell gradually decreased before discharging the cell, indicating that the stable  $LiI$ -based passivation layer was not formed in the catholyte and  $I_3^-$  was continuously reduced to  $I^-$  on the lithium anode surface (Fig. S2†). Hence,  $Li$  ion conductive glass ceramic (LICGC) was employed in order to physically block the  $I_3^-$  redox shuttle.

Fig. 6a illustrates the initial discharge curve of the  $Li|[Li(G4Et)][TFSA]|LICGC|[Li(G4Et)]I_3$  cell at a low constant current density of  $100 \mu A cm^{-2}$  at  $60^\circ C$ . The cell delivers a low initial capacity of  $17 mA h g^{-1}$  based on the mass of  $[Li(G4Et)]I_3$ , which is only 20% of its theoretical capacity ( $85.9 mA h g^{-1}$ ), and no capacity was obtained in the subsequent charge cycle, even though the redox shuttle effect was no longer a problem. Given the total electrochemical reaction during discharge,  $[Li(G4Et)]I_3 + 2Li \rightarrow [Li(G4Et)]I + 2LiI$  (or a more concentrated complex  $3[Li(G4Et)]_{1/3}I$ ), the high-melting point products,  $LiI$  ( $T_m = 459^\circ C$ ) or  $[Li(G4Et)]_{1/3}I$  ( $T_m = 181^\circ C$ , see Fig. S3†), may be saturated and solidified/precipitated in the highly concentrated SIL catholyte since the G4Et solvent cannot be transferred between the anolyte and catholyte separated by the LICGC. This will cause a significant increase in the resistance of the catholyte, leading to a high overvoltage in the cell and low utilization of the catholyte. Unlike the cell constructed using  $[Li(G4Et)]I_3$ , a similar two-compartment cell with neat  $[Li(G4Et)]I$  as the initial catholyte enables repeated charge–discharge cycles with an average cell voltage of 2.9 V because the catholyte phase is diluted with the concomitantly generated G4Et during the initial charge step;  $3[Li(G4Et)]I \rightarrow [Li(G4Et)]I_3 + 2G4Et + 2Li$  for the total charge reaction (Fig. 6b). The initial discharge capacity reaches  $47.2 mA h g^{-1}$ , which is 98% of the theoretical capacity of  $[Li(G4Et)]I$  ( $48.3 mA h g^{-1}$ ), although the capacity gradually decreased upon charge–discharge cycling. The capacity fading was attributed to the further oxidation of  $I_3^-$  to form  $I_2$  that

Fig. 6 The charge–discharge curves obtained for the (a)  $Li|[Li(G4Et)][TFSA]|LICGC|[Li(G4Et)]I_3$  and (b)  $Li|[Li(G4Et)][TFSA]|LICGC|[Li(G4Et)]I$  cells at a constant current density of  $100 \mu A cm^{-2}$  at  $60^\circ C$ .

occurs at a higher potential during charging with a charging cut-off voltage of 3.3 V (*i.e.*, less reversible  $I_3^-/I_2$  redox and precipitation of  $I_2$ ) as suggested by a coulombic efficiency of  $\sim 98\%$ . The volumetric energy density during the initial cycle was calculated to be  $\sim 180 \text{ W h L}^{-1}$  based on the catholyte volume. Due to the high concentration of the redox component in the catholyte, this energy density is approximately five times higher than that of the previously reported semi-liquid lithium battery using the glyme-based SIL catholyte with  $[\text{FeBr}_4]^-$ .<sup>14</sup> To further study the effects of the salt concentration and charging cut-off voltage on the charge–discharge performance, such as catholyte utilization and cycle life, we also examined the cell with a diluted catholyte, 1 mol  $\text{dm}^{-3}$   $\text{LiI}_3$  in G4Et with a lower charging cut-off voltage of 3.2 V. As shown in Fig. S4a,† 32.6 mA h  $\text{g}^{-1}$  was achieved during the initial cycle with an average cell voltage of 3.0 V. The cell shows relatively stable charge–discharge behaviour and the coulombic efficiency was maintained at 100% over 20 cycles although the volumetric energy density decreased to  $110 \text{ W h L}^{-1}$  (Fig. S4b†). As a consequence, suppressing the solidification/precipitation of the reduction products in the catholyte under the optimized cut-off voltage conditions was found to be effective towards improving the cycle ability, coulombic efficiency, and energy density of the semi-liquid Li-polyiodide batteries. To achieve this using thermally stable SIL-based catholytes, the solvent structure and polyhalide composition of the redox active SIL needs to be further optimized. It has been reported that a non-stoichiometric composition of  $I^-$  and  $I_2$  can suppress crystallization in imidazolium polyiodide ILs.<sup>38</sup> Increasing one terminal alkyl chain length in the glyme molecules and the use of heteropolyhalides may also hamper the crystallization process, and thereby widen the liquid temperature range of redox-active SILs. Such attempts will allow for long-life operation of semi-liquid lithium metal batteries with high thermal stability and high energy density.

## 4. Conclusions

Redox-active glyme–Li salt molten solvates,  $[\text{Li}(\text{G4Et})]\text{I}$  and  $[\text{Li}(\text{G4Et})]\text{I}_3$ , were studied in terms of their coordination structures and thermal, transport, and electrochemical properties.  $[\text{Li}(\text{G4Et})]\text{I}$  was excluded from the category of SILs because of its non-negligible volatility at  $100^\circ\text{C}$ , low  $A/A_{\text{NE}}$ , and  $D_G/D_{\text{Li}}$  value exceeding 1, wherein rigid ion-pairs and non-coordinating volatile G4Et were suggested to be present to some extent. In contrast,  $[\text{Li}(\text{G4Et})]\text{I}_3$  was thermally stable similar to the SIL,  $[\text{Li}(\text{G4Et})][\text{TfSA}]$ . The crown-ether like  $[\text{Li}(\text{G4Et})]^+$  and  $\text{I}_3^-$  were found to be stable in the liquid state of  $[\text{Li}(\text{G4Et})]\text{I}_3$ . The high  $A/A_{\text{NE}}$  value close to unity implied weak interaction between uncorrelated ionic motion of  $[\text{Li}(\text{G4Et})]^+$  and  $\text{I}_3^-$ . All these data support that  $[\text{Li}(\text{G4Et})]\text{I}_3$  can be regarded as a good SIL.  $[\text{Li}(\text{G4Et})]\text{I}$  and  $[\text{Li}(\text{G4Et})]\text{I}_3$  underwent two electron oxidation and reduction reactions in the molten Li salt solvates, respectively, and the redox properties were exploited as a catholyte in semi-liquid rechargeable lithium batteries. Whereas the cell constructed using  $[\text{Li}(\text{G4Et})]\text{I}_3$  did not operate as a rechargeable battery due to solidification/precipitation of reduction products

of the neat catholyte during discharge, the cell containing  $[\text{Li}(\text{G4Et})]\text{I}$  exhibited relatively stable charge–discharge behaviour with an initial volumetric energy density of  $180 \text{ W h L}^{-1}$ . However, the volumetric energy density of this cell decreased to  $110 \text{ W h L}^{-1}$  after 20 cycles. The present SIL-based catholytes still have room for improvement in their liquid temperature range and cycle stability. However, this study may provide guidelines for applying such concentrated catholytes for semi-liquid lithium batteries with flow battery-like scalability toward large-scale electric energy storage.
