15N labeling and analysis of 13C–15N and 1H–15N couplings in studies of the structures and chemical transformations of nitrogen heterocycles

Sergey L. Deev, Igor A. Khalyymbadzha, Tatyana S. Shestakova, Valery N. Charushina and Oleg N. Chupakhin

This review provides a generalization of effective examples of 15N labeling followed by an analysis of 13C–15N (JCN) and 1H–15N (JHN) coupling constants in solution as a tool to study the structural aspects and pathways of chemical transformations (e.g., rearrangements and ring-chain tautomerisms) in monocyclic and fused nitrogen heterocycles. This approach allows us to significantly expand and supplement the scope of NMR techniques for heterocyclic compounds. Moreover, methods for the incorporation of 15N atoms into the cores of various N-heterocycles have been collected in this work.

1. Introduction

Nitrogen heterocycles are a ubiquitous class of organic compounds that include azine, azetidine, azole, azine and azepine derivatives and their fused analogs. These structures are inherent in drug design1–7 and natural compounds,8,9 in catalysis for cross-coupling and asymmetric synthesis reactions,10,11 in materials science as metal complexes with luminescent properties,12–14 in ligands for the separation of lanthanides15 and in high-density energy materials.16,17

At first glance, it seems that establishing the structure of poly-nitrogen-containing compounds can be achieved by general NMR methods suitable for carbon-containing compounds; however, this statement is not correct. It should be noted that heterocycles have low densities of hydrogen and carbon atoms. Therefore, the application of conventional NMR methods (1D 1H and 13C spectroscopy, 2D HMOC, HMBC, INADEQUATE, etc.) might be ineffective for the structural estimation of poly-nitrogen compounds. Another important consequence of an increased nitrogen atom content is a decrease in the aromaticity and the tendency to undergo ring-chain transformations. Thus, the confirmation of the structure can be complicated by the azide–tetrazole equilibrium, ANOROC (Addition of Nucleophile, Ring Opening, Ring Closure) reaction, Dimroth rearrangement, etc., which are observed in the azolo and azine series under the action of nucleophilic reagents and solvents. In this case, researchers usually use X-ray crystallography or comparison of UV-vis and 1H and 13C NMR spectra with the data of model compounds with unambiguously confirmed structures. Unfortunately, the first approach gives information about the structure of compounds only in the solid state and is not suitable for the analysis of mixtures of compounds. The second method allows for the determination of structural characteristics in solution, but it can lead to incorrect conclusions.18 There are several approaches to solve these issues. For example, the use of 2D H–(C)–N multiple bond correlation (HCNMC) experiments was described for the structural confirmation of N-alkylated azolo derivatives based on the natural 15N abundance.19,20 However, these NMR procedures rely on magnetization transfer through 13C–15N J-coupling, and although they allow the determination of some other structures of simple monocyclic azoles, they cannot be considered as general.

The selective 15N-labeling of organic molecules leads to the appearance of additional 1H–15N and 13C–15N spin–spin coupling constants (SSCCs) that significantly expand the application of NMR methods in the determination of molecular structures. This approach is widely used in the chemistry of proteins and nucleic acids.21–24 Although 15N-labeling and the subsequent analysis of JHN and JCN couplings in structural studies of nitrogen heterocycles have been described in a few articles, such a method can be effective for the determination of the structure and studying of the mechanism of chemical transformations of azoles, azines and their fused derivatives. Most of these articles were presented in early published review papers and books that described the highlight achievements in various areas of chemistry.

However, the incorporation of a 15N atom into structures leads to the appearance of isotope shifts.25 These data may only be considered as additional features to confirm the structure. The chemical shifts of labeled nitrogens in 1D 15N NMR spectra
can also be used as additional characteristics of enriched compounds. However, information on chemical shifts is relative and can only be used in the context of the already obtained detailed data. In contrast, the measurement of $^{13}$C--$^{15}$N and $^1$H--$^{15}$N coupling constants provides unambiguous information about the molecular structures.

Despite the great opportunities for selective $^{15}$N incorporation followed by an analysis of $J_{HN}$ and $J_{CN}$ couplings, no systematic review devoted to this tool for structural studies of heterocycles has been presented until today. This is the first attempt to generalize the literature data on $^{15}$N-labeling and show the capacity of the usage of $J_{HN}$ and $J_{CN}$ couplings for the determination of the molecular structure and the chemical transformations of nitrogen-containing heterocycles. The relevance of the topic has been confirmed by a recently published article describing the Dimroth-type ring transformation of an azine fragment in the imidazo[1,2-a]pyrimidine scaffold, which is of significant interest for modern medicinal chemistry. The authors showed the efficiency and universality of the use of $^{15}$N-labeling and the analysis of $^1$H--$^{15}$N coupling constants for ring-chain transformations, which require more detail to determine the structures of heterocyclic compounds. It was this work that drove us to summarize the more detail to determine the structures of heterocyclic coupling constants for ring-chain transformations, which require

2. Use of $J_{HN}$ and $J_{CN}$ for establishing methods for the heterocyclization of azole, azine or azepine to azole and azine fragments and studying ring-chain tautomerism in a series of heterocycles

A combination of $^{15}$N-labeling and an analysis of $J_{HN}$ and $J_{CN}$ couplings is one of the approaches for the confirmation of the structure of a fused heterocyclic system that can be formed by different methods for the cyclization of an azole, azine or azepine ring to various five- or six-membered heterocycles. Moreover, this method may be effective for the study of ring-chain tautomerisms that are observed in various classes of heterocycles.

2.1. Determination of methods of heterocyclization based on an analysis of $^1$H--$^{15}$N and $^{13}$C--$^{15}$N spin–spin interactions

The measurement of $^{13}$C--$^{15}$N and $^1$H--$^{15}$N spin–spin interactions can be used for the determination of alternative heterocyclization pathways, including monocyclic derivatives. This method can be efficient even for the analysis of isotopomer mixtures. For example, the interaction of 4,5-dicyanoimidazole with $^{15}$N-guanidine led to compounds $3^*$a and $3^*$b (Scheme 1). It should be noted that the reaction could give tautomers $3^*$a–i and isomers $4^*$a–c. Nonetheless, the registration of the signals of the two labeled nitrogen nuclei as a triplet and singlet in the $^{15}$N NMR spectrum provided solid evidence of the formation of isotopomers $3^*$a and $3^*$b and excluded the formation of tautomers $3^*$c–i. Furthermore, structure $3^*$a was confirmed by observation of the single $^1$H--$^{15}$N spin–spin coupling ($J_{HN} = 90$ Hz) between a $^{15}$N atom and the protons of an NH$_2$ group in the $^1$H NMR spectrum. If a mixture of compounds $4^*$a–c were produced, additional $J_{HN}$ splitting for the $^{15}$NH imino group would appear in both the $^1$H and $^{15}$N NMR spectra. However, such $^1$H--$^{15}$N SSCCs were absent, which excluded the formation of $4^*$a–c. This result also showed that the measurement of $J_{HN}$ couplings can be effective in the

![Scheme 1](image-url) Establishing the structure of the condensation product of 3,4-dicyanoimidazole with guanidine. The observed $J_{HN}$ couplings in the $^1$H NMR spectra are shown by blue arrows. The expected couplings ($J_{HN}$) in the excluded structures are indicated by dashed arrows.
The determination of the structure of prototropic tautomers instead of an analysis of the chemical shifts of $^{13}$C and $^{15}$N atoms in the NMR spectra.  

An analysis of direct $^{13}$C-$^{15}$N coupling constants allowed for the determination of the method of cyclization in the reaction of guanosine with glycidaldehyde. Two methods were used for the incorporation of $^{15}$N atoms in the pyrimidine fragment of guanosine. The first procedure was based on the treatment of compound 5 with $[^{15}$N]-ammonia (Scheme 2). This approach gave an isotopomeric mixture containing $75\%$ $6^a$ and $15-20\%$ $6^b$. Another synthesis of $6^a$ and $6^b$ that included obtaining the $^{15}$N-labeled amide $5^a$ by the interaction of $[^{15}$N]-benzoyl isothiocyanate and imidazolecarboxamide derivative 7 is depicted in Scheme 3. The reaction of compound $5^a$ with ammonia yielded a mixture containing $6^a$ (15-20%) and $6^b$ (75%).

The use of the mixture of $^{15}$N-guanosines $6^a/6^a$ and $6^b/6^b$ in a reaction with glycidaldehyde led to obtaining samples that had different concentrations of isotopomers $8^a$ ($^{15}$N, 75%)/$8^a$ ($^{15}$N, 15-20%) and $8^b$ ($^{15}$N, 15-20%)/$8^b$ ($^{15}$N, 75%) (Scheme 4). Differences in the enrichment of products $8^a/8^a$ and $8^b/8^b$ allowed for the direct measurement of $^{13}$C-$^{15}$N coupling constants ($J_{C7-N8}$ 9 Hz and $J_{C8-N9}$ 11 Hz) and the assignment of the C6 and C7 signals in the $^{13}$C NMR spectra.

The values of $J_{C7-N8}$ and $J_{C8-N9}$ were obtained from the carbon spectra of compounds $8^a$ and $8^b$ with 75% $^{15}$N enrichment. This characteristic permitted the determination of sites for the attachment of the hydroxymethyl group in compounds $8^a$ and $8^b$. However, the alternative isomers $9^a/9^a$ and $9^b/9^b$ were not observed (Fig. 1).

The values of the $^1H$-$^{15}$N and $^{13}$C-$^{15}$N couplings can be applied as diagnostic features for confirmation of the ring closure of heterocycles. This approach was described in 1986 by Villarasa et al., where a $^{15}$N-labeled derivative of diazaole 11 was prepared. The synthesis comprises the diazotation of 2-aminoimidazole 10 with Na$_{15}$NO$_2$ having 25% $^{15}$N enrichment (Scheme 5). The following reaction between compound $11^*$ and 1,1-dimethoxyethene 12 can lead to either open-chain azalkene $13^*$ or fused azoloazine $14^*$. It should be noted that compound $14^*$ is the product of the cyclization of $13^*$. The observed $J_{CN}$ of 2.3 Hz and $J_{HS}$ of 14.2 Hz for the obtained compound were in good agreement with the NMR spectral data of pyridine and other azines. Thus, they confirmed the formation of bicycle $14^*$ in the reaction of imidazole $11^*$ with dimethoxyethene compound 12.

The use of labeled azole derivatives in the synthesis of fused heterocycles is one method for the incorporation of $^{15}$N atoms in the azoloazine series. Obtaining $^{15}$N-azoles can require several steps. For example, the synthesis of $[2-^{15}$N]-5-amino-1,2,4-triazole 18 began by the interaction between labeled potassium nitrate (87%, $^{15}$N) and guanidine sulfate 15 (Scheme 5). Then, the N-nitrated product $16^*$ was reduced to $^{15}$N-aminoguanidine bicarbonate $17^*$, which was transformed into $[1-^{15}$N]-3-amino-1,2,4-triazole $18^*$ by reaction with formic acid.
Alternative isomers $9^a$/$9^b$ and $9^b$/$9^a$.

Scheme 5 The choice between open chain azoalkene $13^a$ and fused azoloazine $14^a$. The observed $J_{CN}$ and $J_{CH}$ couplings are shown by red and blue arrows, respectively.

Compound $18^a$ ($\sim 87\%$, $^{15}$N) with one equivalent of unlabeled 3-amino-1,2,4-triazole was used in a condensation reaction with 2-benzylidene-2-fluoroacetyl ester $19$ (Scheme 6). The analysis of the $J_{CN}$ couplings showed that a $^{13}$C$–^{15}$N spin–spin interaction was observed for the C7 atom bonded to a phenyl fragment ($J_{CN} = 4.7$ Hz). Moreover, a $J_{CH-N}$ of 15.3 Hz was detected in the $^1$H NMR spectrum of compound $20^a$. These data unequivocally prove the formation of structure $20^a$ ($\sim 43\%$,$^{15}$N). In the case of obtaining the alternative product $21^a$, $^{13}$C$–^{15}$N splitting should be observed for the signal of the carbon atom coupled with a CF$_3$ group.

The use of $^{15}$N-phenylhydrazine $23^a$ in the interaction with nitroenamine $22$ allowed for the determination of a reaction pathway that can be route A or B (Scheme 7). According to pathway A, product $25^a$ is formed through $24^a$, while the alternative pathway B involves the formation of compound $26^a$ that transforms into resulting pyrazole $27^a$. The comparison of the detected $J_{HN}$ of 9.2 Hz with the early described amplitudes of the $^1$H$–^{15}$N SSCCs for the pyrazole series showed that the observed coupling is a vicinal one. Thus, it was found that the reaction between $22$ and $23^a$ gave compound $25^a$. Moreover, the formation of azole $27^a$ would lead to the appearance of $J_{C5-N1}$ with values of 8–11 Hz, whereas a carbon coupled with a hydrogen did not show the splitting of $^{13}$C$–^{15}$N due to the small amplitude of $J_{C3-N1}$ ($\sim 2$ Hz). The weak $^{13}$C$–^{15}$N constant was used as an additional criterion for the confirmation of the structure of $25^a$.

2.2. Study of ring-chain tautomerism using $J_{CN}$ and $J_{CH}$ coupling constants

Aminoguanidine bicarbonate $17^a$ ($^{15}$N, 86%) was also applied as a labeled starting material for the incorporation of $^{15}$N atoms in aminotetrazole $28^*$ (pathway A, Scheme 8). The synthesis of $28^*$ was based on the Thiele method, which includes the interaction of aminoguanidine salts with nitrous acid produced in situ from potassium nitrite and nitric acid.

The reaction of $^{15}$N-potassium nitrite ($^{15}$N, 86%) with unlabeled aminoguanidine $17$ is an alternative method that is suitable for obtaining compound $28^*$ (pathway B, Scheme 8).

The use of $^{15}$N-aminoguanidine bicarbonate $17^a$ and $^{15}$N-potassium nitrite allowed for the incorporation of two stable isotopes into aminotetrazole $28^{*\star}$ (Scheme 9).

Compounds $28^*$ and $28^{*\star}$ were used for the synthesis of labeled tetrozolo[1,5-$a$]pyrimidines and tetrozolo[1,5-b][1,2,4]triazines. Because $^{15}$N-aminotetrazole $28^*$ exists in two tautomeric forms in solution, $28^a$ and $28^b$, the reaction of this compound should result in the formation of a mixture of...
isotopomers (Scheme 10)\(^\text{39}\). As expected, the condensation of tetrazole \(^{28}\text{a}\) with 1,1,3,3-tetramethoxypropane \(^{29}\) led to a mixture of tetrazolopyrimidines \(^{30}\text{aT}\) and \(^{30}\text{bT}\) in a 1:1 ratio.

A similar result was obtained by the reaction of 2-hydrazinopyrimidine \(^{31}\) with \(^{15}\text{N}\)-enriched nitrous acid that was generated from labeled potassium nitrite in acetic acid (Scheme 11)\(^\text{37}\). A mixture of isotopomers \(^{30}\text{aT}\) and \(^{30}\text{bT}\) in a 5:1 ratio was obtained. The Dimroth rearrangement is one of the most likely sources of the observed isomerization.

The NMR spectra of the isotopomer mixture in DMSO-\(\text{d}_6\) solution showed that the tetrazole forms \(^{30}\text{aT, bT}\) prevail over the azides \(^{30}\text{a, bA}\), which were detected in trace amounts (~5%). The detection of \(J_{\text{CN}}\) couplings for the C2, C5, and C6 nuclei (Scheme 11 and Table 1) proved the formation of a fused tetrazole (Scheme 10). Interestingly, small amounts of the azide forms \(^{30}\text{a, bA}\) (~5%) were detected in both the \(^{13}\text{C}\) and \(^{1}\text{H}\) NMR spectra. Similarly, \(J_{\text{CN}}\) splitting, which was only observed for the C2 nucleus, confirmed the azide structure of \(^{30}\text{a, bA}\). In TFA solution, the azide–tetrazole equilibrium was rapidly shifted toward the azides \(^{30}\text{a, bA}\). As expected for the azide forms \(^{30}\text{a, bA}\), the presence of \(^{13}\text{C}\)–\(^{15}\text{N}\) \(J\)-couplings was detected only for the C2 nucleus (Scheme 11 and Table 2).

The cyclization of the diazonium salt \(^{34}\text{a}\), derived from \(^{15}\text{N}\)-labeled aminotetrazole \(^{28}\text{a}\), with ethyl formylphenylacetate \(^{35}\) gave a mixture of tetrazolo[1,5-b][1,2,4]triazines \(^{37}\text{aT}\) and \(^{37}\text{bT}\) at a 1:1 ratio (Scheme 12). Similarly, a 1:1 isomeric mixture of tetrazolo[1,5-b][1,2,4]triazines \(^{40}\text{aT}\) and \(^{40}\text{bT}\) was obtained by the reaction of \(^{34}\text{a}\) with ethyl cyanacetae \(^{38}\) (Scheme 12).

Compounds \(^{37}\text{a, bT}\) were only registered in the tetrazole form in DMSO-\(\text{d}_6\). The observation of the \(^{13}\text{C}\)–\(^{15}\text{N}\) splitting for the C2 and C5 carbon signals in the 1D \(^{13}\text{C}\) NMR spectra of \(^{37}\text{a, bT}\) unambiguously confirmed the [1,5-b] fusion between the tetrazole and 1,2,4-triazine rings.

A small amount of the azide forms \(^{40}\text{a, bA}\) (~4%) in DMSO-\(\text{d}_6\) solution was detected in the \(^{13}\text{C}\) and \(^{1}\text{H}\) NMR spectra for the sample that was obtained by the interaction of compounds \(^{34}\text{a}\) and \(^{38}\) (Table 2). The low concentration of the azide form did not allow for the detection or measurement of the corresponding \(J_{\text{CN}}\) couplings. This form was only characterized by an easily large downfield shift of the C2 resonance. Moreover, the main tetrazole isomers \(^{40}\text{a, bT}\) were characterized by \(J_{\text{CN}}\) couplings for signals C2 and C5. These characteristics allowed for the determination of the type of fusion between the tetrazole and 1,2,4-triazine rings in heterocycles \(^{40}\text{a, bT}\) as [1,5-b].

\(\text{a}\) Unless otherwise stated, the listed \(J_{\text{CN}}\) values represent the average between two independent measurements using \(^{13}\text{C}\) line-shape analysis and amplitude-modulated spin-echo experiments. 
\(\text{b}\) The mixture of isotopomers \(^{30}\text{aT, bT}\) (5:1) synthesized by Scheme 11 was used for the \(J_{\text{CN}}\) measurements. 
\(\text{c}\) The \(J_{\text{CN}}\) value was measured only by \(^{13}\text{C}\) line-shape analysis. 
\(\text{d}\) The \(J_{\text{CN}}\) coupling constant was not detected, probably due to the low abundance of the \(^{30}\text{b}\) isotopomer. 
\(\text{e}\) Measurements of the \(J_{\text{CN}}\) couplings were impossible due to the significant broadening of the corresponding \(^{13}\text{C}\) resonance. 
\(\text{f}\) The \(J_{\text{CN}}\) values were estimated from the \(^{13}\text{C}\) line-shape analysis. Precise measurements were impossible due to the fast conversion of tetrazoles \(^{40}\text{a, bT}\) to azides \(^{40}\text{a, bA}\) in TFA solution.

### Scheme 10

The formation of two isotopomeric \(^{15}\text{N}\)-labeled azides \(^{30}\text{A}\) and tetrazoles \(^{30}\text{T}\) in the reaction of aminotetrazole \(^{28}\text{a}\).

### Scheme 11

The Dimroth rearrangement of tetrazolopyrimidines \(^{30}\text{aT}\) and \(^{30}\text{bT}\). The azide–tetrazole equilibrium is shifted to the tetrazole/azide form in DMSO-\(\text{d}_6\)/TFA-\(\text{d}\) solution. The observed \(J_{\text{CN}}\) couplings from the \(^{15}\text{N}\)7 and \(^{15}\text{N}\)8 nuclei are shown by red arrows. The expected coupling (\(^2\)\(J_{\text{CN}}\)) is indicated by a dashed arrow. The measured \(J_{\text{CN}}\) values are presented in Tables 1 and 2.
The NMR spectral parameters of compounds 37\textsuperscript{a},38\textsuperscript{b} were determined in TFA immediately after dissolving the tetrAZole form and 30 days after the preparation of the solution. During this period of time, the relative population of the azide forms of 37\textsuperscript{a},38\textsuperscript{b} increased from 0% to 60%. Significant broadening of the C2 signal observed in the \textsuperscript{13}C spectra of 37\textsuperscript{a},38\textsuperscript{b} in TFA did not allow for the identification of the \textit{J}_{CN} couplings from this carbon atom (Table 1). The \textsuperscript{3}J\textsubscript{C5-N7} and \textsuperscript{4}J\textsubscript{C5-N8} values for the C5 nucleus were measured easily. The obtained values of 1.6 and 0.7 Hz, respectively, correspond nicely to the \textit{J}_{CN} coupling observed for the C5 carbon of \textsuperscript{37}a,\textsuperscript{38}b in DMSO-d\textsubscript{6} solution (1.6 and 0.9 Hz, respectively). This similarity confirms the retention of the bicyclic structure with a [1,5-b] type of fusion between the azole and azine fragments for \textsuperscript{37}a,\textsuperscript{38}b in TFA (Scheme 12). An analysis of the \textsuperscript{13}C multiplets of \textsuperscript{37}a,\textsuperscript{38}b in the 1D NMR spectra revealed the presence of \textit{J}_{CN} interactions only for the C2 nucleus, which confirmed the azide structure of this compound (Table 2 and Scheme 12).

The rearrangement of \textsuperscript{40}a,\textsuperscript{40}b to \textsuperscript{38}a,\textsuperscript{39}b in TFA solution was relatively fast when compared to that of compounds \textsuperscript{40}a,\textsuperscript{40}b. The \textsuperscript{13}C NMR spectra were measured 1, 2 and 12 h after dissolving \textsuperscript{40}a,\textsuperscript{40}b in TFA, and the concentrations of the azide forms \textsuperscript{40}a,\textsuperscript{40}b were 18%, 40% and 97%, respectively. The \textit{J}_{CN} couplings for the C2 and C5 carbon atoms of tetrAZoles \textsuperscript{40}a,\textsuperscript{40}b were observed in the \textsuperscript{13}C NMR spectra (Scheme 12 and Table 1), thus proving that the tetrAZole structure was retained and that the [1,5-b] type of fusion for \textsuperscript{40}a,\textsuperscript{40}b occurred. The precise measurement of the \textit{J}_{CN} values for \textsuperscript{40}a,\textsuperscript{40}b was impossible due to the fast conversion of tetrAZoles to azides. A simplified line-shape analysis, however, revealed that the \textsuperscript{3}J\textsubscript{C2-N7} and \textsuperscript{4}J\textsubscript{C2-N8} interactions in \textsuperscript{40}a,\textsuperscript{40}b have significantly lower values in TFA than in DMSO-d\textsubscript{6} (Table 1). The azides \textsuperscript{40}a,\textsuperscript{40}b in TFA solution were characterized by the presence of \textsuperscript{13}C-\textsuperscript{15}N \textit{J}_{CN} coupling constants for only the C2 carbon (Scheme 12 and Table 2).

The use of double-labeled aminotetrazole \textsuperscript{28}** is one way to avoid the formation of isotopomeric mixtures. For example, the

\textsuperscript{a} Unless otherwise stated, the listed \textit{J}_{CN} values represent the average between two independent measurements using \textsuperscript{13}C line-shape analysis and amplitude-modulated spin-echo experiments. \textsuperscript{b} The mixture of isotopomers \textsuperscript{30}a,\textsuperscript{30}b (5 : 1) synthesized by Scheme 11 was used for the \textit{J}_{CN} measurements. \textsuperscript{c} The \textit{J}_{CN} value was measured only by \textsuperscript{13}C line-shape analysis. \textsuperscript{d} The measurement of the \textit{J}_{CN} coupling was impossible due to the low abundance of the \textsuperscript{30}b isomer. \textsuperscript{e} Signals from the azide forms \textsuperscript{37}a,\textsuperscript{38}b were not observed in DMSO-d\textsubscript{6} solution. \textsuperscript{f} The measurement of \textit{J}_{CN} was impossible due to the low concentration of the azide forms \textsuperscript{40}a,\textsuperscript{40}b in DMSO-d\textsubscript{6} solution.

Scheme 12  The azide–tetrAZole equilibrium in the series of azido-1,2,4-triazines. The azide–tetrAZole equilibrium is shifted to the tetrAZole/azide form in DMSO-d\textsubscript{6}/TFA-d solution. The observed \textit{J}_{CN} couplings from the \textsuperscript{15}N7 and \textsuperscript{15}N8 nuclei are shown in red. The expected but unobserved couplings (\textsuperscript{2}J\textsubscript{CN} and \textsuperscript{3}J\textsubscript{CN}) are indicated by dashed arrows. The measured \textit{J}_{CN} values are presented in Tables 1 and 2.
reaction of diazonium salt **34**, obtained from **28**, with ethyl
z-formylphenylacetate **35** gave compound **36**, which underwent cyclization in acetic acid (Scheme 13). As a result, **15**N-substituted tetrazolo[1,5-b][1,2,4]triazine **37** was synthesized. An analysis of the J_HN couplings confirmed the type of fusion between the tetrazole and 1,2,4-triazine rings in compound **37** (Scheme 1 and Scheme 13).

A similar approach was applied for the incorporation of two **15**N atoms in the structure of tetrazolo[1,5-a]pyrimidine derivatives. The interaction of **28** with benzoylacetonone **41** led to product **42** (Scheme 14). The structure of compound **42** in DMSO-d_6 was determined by the analysis of the long-range **1**H–**15**N coupling constants (4 and 5) and **3**J_HN–**15**N couplings, which were measured by spin-echo experiments with the selective inversion of **15**N nuclei. The observed **4**J_HN values are presented in Table 3. The **4**J_HN–**15**N and **5**J_HN–**15**N couplings can only be observed in the proton spectrum of compound **42** (Scheme 14). In the case of the formation of tetrazoloazine **42**, these spin–spin interactions should be absent.

This result indicated that the analysis of **4**J_HN and **5**J_HN can be used for the determination of the method of fusion betweenazole and azide fragments in tetrazolo[1,5-a]pyrimidines.

It was also found that tetrazole isomer **42** underwent complete rearrangement into the azide form **42** in TFA solution. This was confirmed by the disappearance of the long-range **1**H–**15**N coupling correlations in the proton spectrum.

In contrast to 2-hydrazinopyrimidine **31**, the reaction of compound **43** with **15**N-potassium nitrite (99%, 86%) in phosphoric acid led to the single isomer **44** (Scheme 15). Registration of the 1D **13**C NMR spectra of **44** in DMSO-d_6 showed **J_CN** splittings for the signals from the C2 and C5 nuclei (Scheme 15 and Table 1).

These spin–spin interactions confirmed the formation of a cyclic structure with a [1,5-b] type of fusion between the tetrazole and 1,2,4-triazine fragments. If the alternative isomer **44** was present, then additional **J_CN** splitting for the C4 signal should be observed in the carbon spectrum (Scheme 15). The azide–tetrazole equilibrium was shifted to the azide form **44** in TFA solution. The rearrangement of tetrazole **44** to the azide did not occur quickly.

The NMR spectra for compound **44** were measured in TFA-d solution immediately after dissolving the tetrazole form, after 16 days, and again after 30 days. During this period, the relative population of isomer **44** increased gradually from 0% to 87%. An analysis of the **J_CN** couplings allowed for the detection of both **44** and **44** in TFA-d (Tables 1 and 2).

Similar to compound **43**, the treatment of hetarylhydrazines **45** and **47** with labeled sodium nitrite (99%, 98%) in acetic acid selectively yielded compounds **46** and **48**, respectively (Schemes 16 and 17).

Compound **46** in DMSO-d_6 underwent a transformation to an isomeric mixture of 1,2,4-triazine derivatives **46** and **46** in a ratio of 79:12:9, respectively. The addition of TFA-d to DMSO-d_6 solution led to an increase in the relative concentration of the minor forms A and T.

In pure TFA, compound **46** underwent an almost complete rearrangement to yield the open-chain azide **46**. In this case, the minor isomer **46** was also found with a concentration of approximately 1%. The measurement of **4**J_HN for tetrazole **46** was possible in DMSO-d_6, TFA-d and different mixtures of these solvents (Table 3). The detection of **1**H and **15**N spin–spin interactions provides evidence for the [5,1-c] type of fusion between theazole and azide rings in **46**. It should be noted that other protons signals (H11 and H12) can be measured similarly.

Two tetrazole forms, **48** and **48**, in a ratio of 1:1 were detected upon dissolution of **48** in DMSO-d_6. The signals from azide **48** in the NMR spectra became detectable only in the mixture DMSO-d_6/TFA-d at a concentration of the acid of more than 50%. For example, in DMSO-d_6/TFA-d (3:1) solution, a 24:29:47 concentration ratio of **48** : **48** : **48** was found. In TFA-d, a mixture of the isomers **48** and **48** (96:4) was obtained. The observed **J_HN–**15**N and **J_HN–**15**N patterns enable the unambiguous determination of the cyclization method of theazole fragment in tetrazolopyrimidines **48** and **48** in
dinitrobenzofuroxan 50* permitted the determination of the specificity of the reaction with indene 51. The appearance of $J_{\text{H5-N6}} = 1.9$ Hz, $J_{\text{H7-N6}} = 3.1$ Hz and $J_{\text{H11-N6}} = 7.1$ Hz in the proton spectrum showed that the expected $\sigma$-adduct 52* underwent a transformation into N-oxide 53*. If the isomerization of 52* into 53* had not occurred, the $J_{\text{H11-N6}}$ coupling would have been absent.

The incorporation of the $^{15}$N isotope in structure 55* was achieved by the nitration of compound 54 with labeled nitric acid (Scheme 19).42 The appearance of the $^{15}$N atom provided the opportunity to study the interaction of 55* with sulfate ions (Scheme 19). It was found that the initial reaction occurs at the 5-position to give the $\sigma$-adduct 56*a, which was characterized by a geminal $^1$H-$^{15}$N coupling constant of 2.0 Hz. Then, isomerization of intermediate 56*a occurred to yield adduct 56*b carrying a sulfite at the 7-position. $J_{\text{H7-15N}} = 1.2$ Hz and $J_{\text{H6-15N}} = 1.2$ Hz were observed in the proton spectrum of compound 56*b. These $^1$H-$^{15}$N coupling constants showed that the authors observed the intramolecular Boulton–Katritzky rearrangement rather than the SO$_3^-$ transfer, which should lead to the formation of compound 56*c.

The use of $^{15}$N-labeled compounds allowed the examination of the interaction of 3-aryl-5-methylisothiazoles with 57a–f with aromatic nitriles in the presence of lithium diisopropylamide (LDA) (Scheme 20). The reaction between compounds 57b,c,e,f and nitriles with different aromatic fragments ($\text{Ar}_1 \neq \text{Ar}_3$)
afforded the formation of a mixture of isomers $58b,c,e,f$ and $59b,c,e,f$. In the cases where $Ar_1 = Ar_2$, the reaction gave a single product. The application of $^{15}$N-enriched $p$-chlorobenzonitrile in these experiments allowed the authors to study the structures of the obtained compounds and the mechanism of formation of these products.

The treatment of 3-(4-chlorophenyl)-5-methylisothiazole with LDA and $^{15}$N-labeled $p$-chlorobenzonitrile afforded a mixture of isotopomers $58^*d$ and $59^*d$ containing $^{15}$N atoms in the amino group and thiazole fragment, respectively (Scheme 21). The positions of the isotope label in heterocycles $58^*d$ and $59^*d$ were provided by the measurement of the corresponding direct $^{13}$C–$^{15}$N coupling constants (11.7 Hz and 6.9 Hz for $58^*d$ and $59^*d$, respectively). The value of $J_{HN} = 4.3$ Hz for the vinyl proton in isotopomer $58^*d$ showed that the obtained compound had a trans geometry with respect to the two aromatic rings $Ar_1$ and $Ar_2$.

For an explanation of the formation of the isotopemic mixture $58^*d$ and $59^*d$, the selectively labeled compound $58^*d$ was prepared, and the ring-chain transformation for this labeled structure was studied by NMR. Compound $58^*d$ was obtained by treatment of $60$ with $^{15}$N-labeled $p$-chlorobenzonitrile.

This procedure led to compound $61^*$, which then underwent desilylation to form isotopomer $58^*d$ (Scheme 22). Compound $60$ was obtained by the interaction of methylisothiazole with tert-butylmethylsilyl chloride in the presence of LDA. Then, heating the $C_6D_6$ solution of $58^*d$ at 50 °C for 50 h resulted in an equilibrium of a 1:1 mixture of isotopomers $58^*d$ and $59^*d$.

Hence, two possible mechanisms (A and B) for the reversible equilibrium between $58^*d$ and $59^*d$ were presented (Scheme 23). It should be noted that the key intermediate in each path is sulfurane–2, $62^*b$. Pathway A involved the formation of sulfurane–1, $62^*a$, which transformed into structure $62^*b$ via a $[1,5]$-sigmatropic hydrogen shift. Alternative pathway B suggests that thiazoles $63^*$ and $64^*$ are involved in the isomerization process.

Thus, the incorporation of $^{15}$N labels and the analysis of the $J_{CN}$ and $J_{HN}$ couplings allow the determination of the formation mechanism of different heterocyclic systems and the observation of ring-chain tautomerism in a series of heterocycles.

3. Analysis of $J_{CN}$ and $J_{HN}$ couplings as a method for the study of ring-chain transformations under the action of nucleophilic and electrophilic reagents

Some reactions of nitrogen heterocycles are simple at first glance, but they can hide a complex and completely unobvious mechanism. Isotopic labels allow a look deep inside into the details of such reaction mechanisms. Several heterocycles undergo ring transformations under the action of nucleophilic reagents (ANRORC, Dimroth rearrangement, etc.). Another type of recycilation is associated with intramolecular attack by the electron-deficient terminal atoms of the open-chain form on the ring system heteroatoms bearing a lone pair of electrons. It should be noted that ring opening or recycilation processes in both cases can occur and lead to the formation of a new type of heterocyclic structure. Additionally, determination of the structure of the obtained product always remains an important issue in organic chemistry. Moreover, solution of this task can help provide evidence for the mechanisms of ring-chain transformations.

3.1. Study of ANRORC and Dimroth rearrangements and similar chemical transformations by analysis of $J_{CN}$ and $J_{HN}$ couplings

The analysis of $J_{CN}$ and $J_{HN}$ is an efficient method for studying different rearrangements that include ring-chain and ring
opening transformations. It should be noted that the use of $^{15}$N labeling and the estimation of $^{13}$C-$^{15}$N and $^1$H-$^{15}$N coupling constants are a single approach for the determination of one-pot cascade reactions; for example, the study of the ANRORC mechanism in the reaction of N-oxide-1,2,4-triazine 65 with potassium cyanide (Scheme 24). The use of $^{13}$C$^{15}$N showed that the product of nucleophilic addition transformed into pyrazole through the formation of intermediates. The structure of compound was confirmed by the measurements of $J_{CN} = 17.8$ Hz and $J_{HN} = 91$ Hz. These characteristics show the unambiguous incorporation of the $^{13}$C atom in the pyrazole ring of product 70.

The application of double-labeled $^{13}$C, $^{15}$N-ethyl cyanoacetate 38 permitted the detection of the Dimroth rearrangement for nitro-1,2,4-triazolo[1,5-$a$]pyrimidine 71 (Scheme 25). It was found that $^{13}$C, $^{15}$N-ethyl cyanoacetate 38 demonstrated binucleophilic properties in the reaction with 6-nitro-1,2,4-triazolo[1,5-$a$]pyrimidine 71, and the mechanism of this reaction included several consecutive transformations (Scheme 25). The first step gave adduct 72*, which underwent isomerization into the open form 73* (pathway A) or structure 74* (pathway B). It should be noted that both intermediates 73* and 74* can transform into imine 75*. The following Dimroth rearrangement led to compound 76*. The usage of $^{13}$C- and $^{15}$N-
labeled atoms and the analysis of $^{13}$C–$^{15}$N coupling constants allowed for the detection of the C–$^{13}$C–$^{15}$N–C fragment in the pyridine ring of molecule 76*.

A similar result was obtained from the treatment of compound 79*a with a solution of sodium hydroxide in a mixture of EtOH and THF. In this case, the rearrangement was accompanied by hydrolysis of the ester group.

An unusual transformation was found from the study of Vorbriuggen glycosylation in a series of aminopyrimidines 82*a,b and 89*a–e using $^{15}$N-labeled regents (Schemes 28 and 29). It was revealed that the silylated 4-aminopyrimidines 83*a,b, 90*a–e after interaction with 84 yielded compounds 88*a,b and 94*b, which are products of the Dimroth rearrangement of nucleosides 85*a,b and 91*a–e in basic conditions. The mechanisms of these processes involve nucleophilic addition, ring opening and ring closure. Furthermore, the formation of structures 88*a and 94*a–e from 91*a–e imposes the nucleophilic substitution of a chlorine atom in open intermediates 92*a–e.

The synthesis of double-labeled diaminopyrimidine 82*b and the use of this compound in the glycosylation reaction led to product 88*b (Scheme 30). The observed $J_{HB-NS} = 93$ Hz, $J_{H2-H5} = 16$ Hz and $J_{H7-H11} = 3.9$ Hz unambiguously confirmed the structure of compound 88*b. These characteristics showed that the pyrimidine derivative 88*b was formed by the Dimroth rearrangement of the ribosylated azine 85*b. The mechanism presented in Scheme 29 was confirmed by the application of $^{15}$N-ammonium chloride in the process of the glycosylation of compound 89*a (Scheme 31). In this case, the incorporation of an isotope label in the pyrimidine ring was also observed. The values of the $^1$H–$^1$N coupling constants ($J_{H2-15N} = 15.1$ Hz and $J_{H7-15N} = 2.2$ Hz) unequivocally proved the incorporation of a $^{15}$N atom into a pyrimidine fragment in compound 88*a.b.
showed that the nucleophilic attack mainly occurs at the C4 atom of the uridine ring. Moreover, this interaction afforded ring-chain intermediate $97^*$, which transformed into compound $98^*$ in the presence of K$_2$CO$_3$ (Scheme 32). The production of structure $97^*$ was confirmed by analysis of the $^{13}$C–$^{15}$N coupling constants. Indeed, the $J_{CN}$ splittings were only detected for C4 ($J_{CN} = 16.4$ Hz) and C5 ($J_{CN} = 7.7$ Hz) atoms, which unambiguously proved the production of the ring opening product $97^*$. The formation of intermediate $97^*$ was monitored by an NMR experiment in CDCl$_3$ solution. This reaction is one example that allows the incorporation of a $^{15}$N-labeled atom in the core of a uridine derivative.

A previously mentioned article also describes the study of the features of the interaction of N-nitroinosine with an amine by using $^{15}$N-labeled benzylamine (Scheme 33). The reaction of 99 with PhCH$_2^{15}$NH$_2$ was monitored by NMR in CDCl$_3$ solution. It was shown that the attack of the amine takes place at the C2 atom of the inosine nitro derivative 99. This process leads to the ring opened intermediate $100^*$, which may follow two pathways, either $101^*$, or, in the presence of an excess of $^{15}$N-labeled benzylamine, compound $102^*$. In the 1D $^{13}$C NMR spectrum of $100^*$, the interaction $^{13}$C–$^{15}$N was only observed for signal C2 ($J_{CN} = 18.3$ Hz) and the carbon atom of the benzyl fragment ($J_{CN} = 9.8$ Hz). The signal of C6 did not show any $^{13}$C–$^{15}$N

---

The observed $^1$H–$^{15}$N coupling constants are shown by blue arrows.

The incorporation of $^{15}$N atom into the structure of the uridine derivative. The observed $^1$J$_{CN}$ couplings are shown by red arrows.

The three differently $^{15}$N-enriched 1,4-diphenylthiosemicarbazides 103*a–c in reaction with two different aryl chlorides 104 and 105 were used as labeled starting materials. Thiosemicarbazide 103*a was synthesized by treatment of phenylhydrazine with $^{15}$N-phenyl isothiocyanate, which was the product of the interaction between $^{15}$N-aniline, carbon disulfide and ethyl chloroformate (equivalent quantities). To obtain compound 103*b/103*c, it was necessary to use labeled hydrazine obtained by the diazotization of aniline/$^{15}$N-aniline with Na$^{15}$NO$_2$/NaNO$_3$ in the reaction with phenyl isothiocyanate and perform the subsequent reduction in a mixture of Na$_2$SO$_3$–Na$_2$S$_2$O$_3$. The formation of structures 106*a–c/107*a–c from compounds 108*a–c/109*a–c was observed by refluxing in pyridine solution. The measured values of $^1$J$_{CN}$ for heterocycles 106*a–c and 109*a–c were collected in Table 4.

The main characteristics confirming the formation of structures 108*a and 109*a were the appearance of three direct $^{13}$C$_5$–$^{15}$N coupling constants that were observed in the carbon spectra of isotopomers 108*a and 109*a. The starting heterocycles 106*a and 107*a were only characterized by two $^{13}$C$_2$–$^{15}$N and $^{13}$C$^6$–$^{15}$N spin–spin interactions. The detection of the $^1$J$_{C5-N1}$ couplings verified the transformation of compound 106/107 into 108/109 under reflux in pyridine.

3.2. Analysis of $^1$J$_{CN}$ and $^1$J$_{HN}$ couplings in the study of other ring-chain rearrangements and transformations occurring with changes to the heterocyclic scaffold

The analysis of the $^1$J$_{CN}$ value was used for the determination of the structure of the nitrosation product obtained from compound 110 (Scheme 35). The data from the 1D $^1$H and $^{13}$C NMR spectra did not permit the identification of the ring opening of the pyrrole fragment in 110 under the action of sodium nitrite in acetic acid. The use of the $^{15}$N-labeled sodium nitrite and analysis of the direct $^{13}$C–$^{15}$N coupling constant showed that the tetrazole derivative 111*a underwent

The incorporation of $^{15}$N atom into the structure of the hypoxanthine derivative. The observed $^1$J$_{CN}$ couplings are shown by red arrows.
additional splitting was observed for the protons from the CH dihydrofuro[3,2-a] structure of the benzoin product. 

The use of 15N-phenylhydrazine 23b in the reaction of 2,3-dihydrofuro[3,2-c]coumarin-3-one 114 is another example of the use of labeled compounds to study chemical conversions in a series of heterocyclic compounds (Scheme 36). The analysis of the 1H-15N coupling constants allowed the determination of the positions of the labeled atoms in product 118* and proved the mechanism of the transformation. In the proton spectrum of compound 118*, direct and long-range 1H-15N spin–spin interactions were detected for two signals of 15N-groups (JHN 89.7 Hz, JHN ~4 Hz and JHN 93.4 Hz, JHN ~4 Hz). Moreover, additional splitting was observed for the protons from the CH=N and NH-Ph fragments. Thus, compound 118* was formed by the double addition of 15NH=N-NH-Ph (23b) and the elimination of aniline in the last step of the reaction. This mechanism involves the formation of intermediates 115*-117* (Scheme 36).

The revision of the result for the reduction reaction of diazonium salt 120* that was obtained by the diazotization of amine 119 was described in another work. It was considered that the product of this transformation is 1,2,3-triazine 121 (Scheme 37), while the determination of structure 121 was based on the detection of two direct 1H-15N coupling constants (JHN-N2 and JHN-N6 = 97 Hz) in the 15N NMR spectrum of the unlabeled sample. However, using 15N-labeled diazonium salt 120* in the reaction with sodium sulfite seed light on the real method of this transformation. The signal from the 15N-nitrogen atom in the resulting compound was only characterized by one 1H-15N coupling constant, JHN = 8.2 Hz. Therefore, the 1,2,3-triazine structure of 121* was rejected, and it was shown that the reduction of compound 120* led to heterocycle 122*.

An unusual transformation was detected from the use of 15N-enriched compound 125* in a reaction with phenyltetrazole 126 (Scheme 38). The synthesis of chloride 125* included the interaction of benzoyl chloride and labeled ethylammonium chloride (15N, 99%) in the presence of triethylamine in dichloromethane. Then, amide 124* was treated with thionyl chloride. The interaction of 125* and 126 led to heterocycles 129* and 131*, which were characterized by 13C-15N and 1H-15N SSOCs.

These data confirmed the structures of compounds 129* and 131*. In the proton NMR spectra of 129* and 131*, the signals of the N-ethyl fragments showed additional splittings (JHN = 1.2 Hz, JHN = 2.9 Hz and JHN = 0.5–1.0 Hz, and JHN = 3.2 Hz, respectively). Moreover, in the 13C NMR spectra, the signals of the carbons of the tetrazole and 1,2,4-triazine fragments were detected as doublets with magnitudes of 12.2 Hz and 12.1 Hz, respectively. These results indicate that the formation of structures 129* and 131* occurred over two different mechanisms (pathways A and B, Scheme 38). However, these transformations started with the common intermediate 127*. Pathway A included the elimination of benzonitrile, obtaining azide 128*, which underwent cyclization into tetrazole 129*. Compound 131* may be formed according to the mechanism demonstrated by route B. In this case, structure 127* transformed into 130* by the elimination of nitrogen. Then, the isomerization of intermediate 130* led to 1,2,4-triazine 131*.

The incorporation of the 13C and 15N atoms in compound 136* allowed determination of the method of the photosensitized oxidation of imidazole derivatives (Scheme 39). This interaction with singlet oxygen was considered a model reaction for natural and biologically active structures containing the imidazole fragment (guanosine, xanthine, theophylline, histidine, etc.). The production of 136* involved heating a mixture of 15N2-urea 132* (13C, 99% and 15N, 98%) and 13C-formic acid 133* (13C, 99%) at 150 °C for 4 h (Scheme 39). Then, 13C-enriched benzoin 135* was introduced, and the reaction mixture was heated at 180 °C.

The synthesis of labeled benzoin 135* was based on coupling 2 mol of 13C-benzaldehyde (13C, 99%) in the presence of NaCN.

Scheme 35 Determination of the structure of the nitrosation product using a 15N label. The observed JCN couplings are shown by red arrows.
The photosensitized oxidation of $^{13}$C$_3$,$^{15}$N$_2$-labeled 4,5-diphenylimidazole 136* was carried out in an NMR tube. This experiment permitted the observation of the formation of several intermediates 137*–141* that were obtained from 136* under the action of singlet oxygen.

Oxidation of labeled imidazole 136* gave one intermediate 137* at $-100$ °C. The observation of splitting of C2 ($J_{C-N1} = 5.1$ Hz and $J_{C-N3} = 4.9$ Hz) showed that this carbon bonds with two nonequivalent, labeled nitrogen atoms. Moreover, a $^1H$–$^{15}$N SSCC of 69.7 Hz was detected in the proton spectrum for this intermediate. These data and an analysis of the chemical shifts of the labeled atoms with the measurement of $J_{CN}$ couplings confirmed the formation of 2,5-endoperoxide 137* in the reaction of 136* with singlet oxygen. This transformation occurred through the open form 140*. The formation of intermediates 138*–140* and 141*, 143* was monitored by $^1H$, $^{13}$C and $^{15}$N NMR spectroscopy.

It should be noted that the estimation of the $^{13}$C–$^{15}$N and $^1H$–$^{15}$N coupling constants with analysis of the chemical shifts for $^1H$, $^{13}$C and $^{15}$N NMR spectra and the measurement of the $^1H$–$^{13}$C spin–spin interaction allowed for the determination of the structures of these compounds. For example, the detection of only one $J_{CN} = 2.3$ Hz for C2 in the carbon spectra of 143* showed that one bond of C2–$^{15}$N was broken. The chemical shift of C4 was characteristic of a sp$^3$-carbon connected to two heteroatoms. These data indicated that C4 was bonded to an oxygen and the N1 nitrogen. Moreover, the signal from the amino group was observed as a triplet split by two bonded hydrogens ($J_{H-N1} = 74.0$ Hz) in the proton spectrum. This information suggested that the five-membered imidazole ring in 141* opened and reclosed to form intermediate 143*.

The application of $^{15}$N-azirine 146* ($^{15}$N, 50%) with one equivalent of unlabeled 2,2-dimethyl-3-(dimethylamino)-2$^H$-azirine 146 provided an opportunity to illustrate the capacity of $^{15}$N-labeling and $^1H$–$^{15}$N analysis in studying the mechanisms of chemical transformation in a series of three-
membranated heterocyclic compounds (Schemes 40 and 41).\textsuperscript{57} The synthesis of compound 146\textsuperscript{*} was based on the treatment of trimethyl-1-propenylamine 144 with enriched sodium azide (15N, 99\%). The interaction of 146\textsuperscript{*} (15N, 25–30\%) with 1,1-dioxo-1,2-benzothiazol-3-one (saccharine) 147 led to compound 150\textsuperscript{*}, which was characterized by \( J_{HN} = 89 \text{ Hz} \) (Scheme 40). This result confirmed the position of the 15N-labeled atom in 150\textsuperscript{*} and showed that the transformation of 144\textsuperscript{*} into 150\textsuperscript{*} occurs via aziridine 148\textsuperscript{*} and ring expansion to zwitterion 149\textsuperscript{*} (Scheme 40).

In the case of the reaction between azirine derivative 146\textsuperscript{*} and phthalimide, the tricyclic product 153\textsuperscript{*} was isolated. The structure of 153\textsuperscript{*} was identified by measurements of \( J_{C3-N2} = 7 \text{ Hz} \) and \( J_{C3-N2} = 8 \text{ Hz} \), which were registered for sp\(^3\)-hybridized carbon atoms (Scheme 41). Additionally, the \( J_{HN} \)-couplings were not detected in the 1D \(^1\text{H}\) and 13C NMR spectra. The authors suggested that compound 153\textsuperscript{*} is the product of the transformation of 2,3-dihydro-2,5-benzodiazocine-1,6-dione 152\textsuperscript{*}. Moreover, the analysis of chemical shifts for the carbon atoms and \( J_{C3-N2} \) coupling constants of signals C2 (\( J_{CN} = 5 \text{ Hz} \)) and C4 (\( J_{CN} = 5 \text{ Hz} \)) verified the formation 2-(4H-imidazol-2-yl)benzoic acid derivative 154\textsuperscript{*}, which was obtained by treatment of 153\textsuperscript{*} with methanol.

An interesting example of the use of 15N-labeled compounds for determining the ring open reaction pathway in a series of diazirines was reported by Creary and co-workers.\textsuperscript{58} The incorporation of 15N in the benzimidate 155 with enriched ammonium chloride (15N, 99\%) (Scheme 42). Then, oxidation of the resulting benzamidine 156\textsuperscript{*} with NaOBr yielded 15N-phenylbromodiazirine 157\textsuperscript{*}. Compound 157\textsuperscript{*} reacted with tetrabutylammonium azide to give a mixture of benzonitriles 160 and 160\textsuperscript{*} in a ratio of 1 : 1. The 13C NMR spectrum confirmed partial 15N labeling for the obtained product. The nitrile carbon of 160\textsuperscript{*} appeared as a doublet (\( J_{CN} = 17.8 \text{ Hz} \)), while the carbon of the cyano group of 160 registered as a singlet. A comparison of the intensity of these signals showed a 50% excess of the 15N isotope of 160\textsuperscript{*}. This result proved that the formation compounds 160 and 160\textsuperscript{*} from diazirine 157\textsuperscript{*} and BuN+N\(_3\)/C\(_0\) occurred via the structures 158\textsuperscript{a,b} and 159\textsuperscript{a,b}.

Thus, analysis of the literature shows that the measurement of the \(^1\text{H}\)-15N and 13C-15N coupling constants can be successful for the determination of different mechanisms of chemical.

transformation and rearrangement in nitrogen-containing heterocycles.

4. $^{13}$C–$^{15}$N and $^1$H–$^{15}$N coupling constants as an approach to the determination of structural reaction/isomerization products occurring without changes to the heterocyclic core

Nitrogen-enriched heterocycles are molecules containing several reaction centers. This class of compounds can exhibit dual behaviors, expressed by the fact that they can react with both nucleophilic and electrophilic reagents. As a result, such interactions often give a mixture of isomers even when the heterocyclic scaffold does not undergo rearrangement. This situation requires that researchers use different methods for the determination of structures obtained from similar products. One of the effective approaches that can be used to solve these problems is the measurement of the $J_{CN}$ and $J_{HN}$ couplings in $^{15}$N-labeled samples. In this part of the review, examples of $^{15}$N labeling and the use of the analysis of $^1$H–$^{15}$N and $^{13}$C–$^{15}$N coupling constants for the determination of functionalization methods that do not lead to changes in the heterocyclic core were collected. Such chemical transformations can be observed in reactions of N-alkylation, nitration, amination and obtaining azomethines based on different heterocycles.

4.1. Using $J_{CN}$ and $J_{HN}$ couplings for the investigation of N-alkylation reactions

The incorporation of $^{15}$N atoms in different positions of 5-phenyl-1,2,3,4-thiatriazole 163 allowed for determination of the structure of the products obtained by alkylation with triethylloxonium tetrafluoroborate (Scheme 43). The synthesis of isotopomers 163$a,b$ was based on the reaction of a sodium salt of carboxymethyl dithiobenzene 161 with $^{15}$N-hydrazine ($^{15}$N, enrichment 30%) and the subsequent interaction with nitric acid. A mixture of 15% isotopically labeled compounds 163$a,b$ was obtained.

Treatment of salt 161 with $^{15}$N-labeled sodium azide (95%, $^{15}$N) led to the formation of a mixture of compounds 163$a,b,c$ (15N, 47.5%) and 163$c$ (15N, 47.5%). The use of the mixture of 163$a$ and 163$b/c$ to determine $J_{HN}$ couplings in 164$a-c$ was determined by analysis of the $^1$H–$^{15}$N coupling constants. It should be noted that vicinal ($J_{HN}$) couplings were only registered in the proton spectra of 164$a-c$ and the expected geminal coupling ($J_{HH}$) was not detected by 1D $^1$H NMR spectroscopy due its small amplitude (approximately 1.2 Hz). For compound 164$a/164$c, $J_{HH-N2}/J_{HH-N2}$ was measured (Table 5). The detection of an additional splitting $J_{HH-N3}$ (3.7 Hz) for the methyl signal of 164$b$ unambiguously confirmed the structures of the products obtained by the interaction of compound 164$a-c$ with EtO$_3$BF$_4$ because the formation of the alternative isomers 164$d/e$ should lead to the appearance of $J_{HH-N2}$ and $J_{HH-N4}$ couplings, respectively (Fig. 2).

Moreover, the authors developed a selective synthesis for isotopomer 164$c$. This approach included the interaction of unlabeled 2-ethylthiobenzoylhydrazine 162 with $^{15}$N-nitric acid. Then, obtained 163$c$ underwent alkylation with triethylloxonium tetrafluoroborate (Scheme 44). The detection of $J_{CN}$ was 5.0 Hz further evidence for the binding of the N-ethyl fragment with the N2 atom in compounds 164$a-c$.

Another example of the application of $^{13}$C–$^{15}$N SSC has been presented for the determination of the structures of N-alkylated derivatives 172$a$ and 172$b$ that were obtained by the interaction of $^{15}$N-labeled 8-methylthioimidazo[4,5-g]quinazoline 171 with benzyl bromide. The synthesis of compound 171 included the treatment of 7-chloro-4-quinazolone 165 with $^{15}$N-nitric acid ($^{15}$N, 99%) (Scheme 45) to obtain $^{15}$N-labeled product 166$a$.

Scheme 45 through heterocycles 167*, 168*, 169* and 170*. The chosen method for the synthesis of 171* determined the position of the $^{15}$N-labeled atom.

The use of 171* in the N-benzylation reaction led to the formation of two isomers, 172*a and 172*b, that were separated by column chromatography. The determination of the site of the N-allyl fragments in compounds 172*a and 172*b was based on data from the proton-decoupled $^{13}$C NMR spectra. In the case of isomer 172*a, a signal of atom C1' of a benzyl moiety was registered as a singlet. The benzylic carbon of 172*b showed splitting and appeared as a doublet ($^3$J$_{CN} = 8.6$ Hz) due to the spin–spin interaction $^{13}$C1'–$^{15}$N1 (Scheme 45).

The obtained results allowed the authors to reach the conclusion that this method for determining the site of alkylation may well prove applicable in other heterocyclic systems where $^{15}$N can be selectively incorporated.

Indeed, the selective $^{15}$N-labeling of compound 178* and analysis of the $^{13}$C–$^{15}$N spin–spin interaction allowed the unambiguous determination of N-methylation sites in a series of imidazo[2,1-c][1,2,4]triazin-4-ones and related azolo[5,1-c][1,2,4]triazin-4-ones. In this work, compound 178* was prepared by the coupling of isopropylidene malonate (Meldrum’s acid) with diazooazole 174* (Scheme 46). The incorporation of the isotope label in structure 174* was based on the treatment of 2-aminoimidazole 173 with $^{15}$N-enriched sodium nitrite ($^{15}$N, 36%) in an acidic medium. The reaction between 175 and 174* gave product 176*. The heating of 176* in acetic acid led to azoloazole 178*. Cyclization and decarboxylation occurred in one pot, as shown in Scheme 46.

The methylation of compound 178* yielded isomers 179*a and 179*b, which were separated. The detection of the direct $^{13}$C–$^{15}$N coupling of 11.0 Hz for the signal of the carbon of the N-methyl group confirmed the formation of betaine-like structure 179*b in the alkylation reaction of imidazo[2,1-c][1,2,4]triazin-4-ones and their analogs.

It should be noted that today, for the determination of the site(s) of the benzyl/methylation of an unlabeled analog 171*/178*, it is possible to use conventional $^1$H, $^{13}$C-NMR methods because for the resulting products, the $^1$H–$^{13}$C spin–spin interactions between the protons of the N–CH$_3$/N–CH$_2$ fragment and the carbons of the heterocyclic part (8-methylthioimidazo[4,5-g]quinazoline/imidazo[2,1-c][1,2,4]triazin-4-one) can be identified. That is, these cases do not require $^{15}$N labeling and the analysis of $^3$J$_{CN}$ couplings. However, the determination of N-adamantylation site(s) in unenriched analogs of heterocycle 178* such as azolo[5,1-c][1,2,4]triazine, azolo[1,5-a]pyrimidine and related azoloazines using well-established $^1$H and $^{13}$C NMR methods (such as 1D, 2D COSY, HMQC, HMBc, and INADEQUATE spectra) are difficult because the heterocyclic moiety is covalently attached to the adamantane tertiary carbon that has no bond with hydrogen atoms. Nuclear Overhauser effect spectroscopy (NOESY or ROESY) also does not provide unequivocal structures for N-adamantylated derivatives. In this case, the application of $^{15}$N labeling and the measurement of $^{13}$C–$^{15}$N and $^1$H–$^{15}$N coupling constants allows for the determination of the N-adamantylation sites in the azolo-1,2,4-triazine and 1,2,4-triazolo[1,5-a]pyrimidine series.

The first time efficiency of this approach was shown in the study of the interaction of 6-nitro-1,2,4-triazolo[5,1-c][1,2,4]triazin-7-one 183* (Scheme 47). The synthesis of 183* was based on the treatment of amine-1,2,4-triazole 18* ($^{15}$N, 87%) with sodium nitrite in acidic medium and a subsequent interaction of compound 180* with ethyl nitroacetate 181.

Then, the resulting sodium salt 182* was transformed into azoloazine 183*, which was treated with adamantanol 184 in a solution of sulfuric acid. The adamantylation of 183* gave a mixture of isomers 185*a and 185*b. The appearance of the $^{15}$N label in structure 185*a permitted the determination of the conformation of the additional adamantane fragment in the N3-atom azole rings by the observation of the $^3$J$_{CN}$ couplings (0.5 Hz) in the carbon spectrum.

The structure of the adamantylated derivative 185*b was determined by $^{13}$C NMR spectroscopy via comparison with a model compound, N-methylated 1,2,4-triazolo[5,1-c][1,2,4]triazin-7-one. Moreover, the use of $^{15}$N-enriched azoloazine 183* in the investigation of adamantylation showed that compound 185*b is a product of the reversible isomerization of 185*a; this rearrangement occurs via the formation of an adamantyl cation and heterocyclic base 183*.

The selective incorporation of two $^{15}$N atoms in different positions of the 1,2,4-triazolo[5,1-c][1,2,4]triazin-7-ones and other nitrogen-containing heterocycles together with a combined analysis of the $^3$J$_{HN}$ and $^3$J$_{CN}$ coupling constants was more effective for the structural determination of heterocyclic N-adamantylated derivatives. For example, the use of this approach allowed for the determination of the structures of...
compounds 187**a and 187**b obtained by the coupling between 186** and 184 in trifluoroacetic acid (TFA) solution under reflux (Scheme 48).

The incorporation of two labeled atoms in compound 186** was based on the treatment of 15N-3-amino-1,2,4-triazole 18* (15N, 98%) with labeled sodium nitrite (15N, 98%). The reaction of 18* and 15N-sodium nitrite in an acidic medium allowed the in situ production of diazonium salt 180**, which reacted with ethyl nitroacetate 181 in a sodium carbonate solution. This reaction led to the formation of 15N2-1,2,4-triazolo[5,1-c][1,2,4]triazinone 182**. The interaction of 182** with hydrogen bromide generated from acetyl bromide and ethanol gave compound 186**.

It should be noted that the formation of an isomeric mixture in the adamantylation reaction of 186** could explain the rearrangement of the N3-isomer 170**a into the N4-isomer 170**b. This process could include the production of an adamantyl cation and the base of 186**. The structures of compounds 187**a,b were unambiguously confirmed by analysis of the JCN and JHN couplings. The detection of a single JCN coupling (0.4 Hz) for the adamantane carbon in compound 187**a indicated that the substituent group is attached to the N3 atom of the 1,2,4-triazole ring (Table 6 and Scheme 48).

The attachment of the adamantane fragment to the N4 atom of the triazine ring in compound 187**b led to a large set of observable JCN couplings, including geminal (JCN = 5.0 Hz) and vicinal (JCN = 1.7 Hz) (Table 6 and Scheme 45). The 15N-HMBC spectra of compounds 187**a,b allowed for JHN couplings of the nitrogen atoms at a natural isotopic abundance. The analysis of the 1H–15N spin–spin interactions also confirmed the structures of the products of adamantylation of 186** (Table 7 and Scheme 48). Moreover, the appearance of the 15N isotope in the azine ring of 187**b permitted the observation of the long-range 1H2–15N5 coupling constant (Table 7 and Scheme 48). This characteristic was additional evidence for the attachment of the adamantane substituent to the unlabeled N4 atom.

In the abovementioned work, the selective incorporation of two 15N atoms and combined analysis of JCN and JHN were also used for the determination of the adamantylation site of 1,2,4-triazolo[1,5-a]pyrimidine and tetrazolo[1,5-b][1,2,4]triazine derivatives (Schemes 49 and 50).

In the first case, double-labeled amino-1,2,4-triazole 18** was used for to incorporate 15N in the core of 1,2,4-triazolo[1,5-a]pyrimidine. Compound 18** was synthesized by the interaction of 15N3-hydrazine sulfate (98%, 15N) with S-methyl isothiourea sulfate 188 and the subsequent cyclization of 15N3-aminoguanidine 17** with formic acid (Scheme 49). The use of

Scheme 45 The use of 15N-labeled annulated imidazole to determine the site of alkylation. The observed 1JCN coupling is shown by a red arrow.

Scheme 46 The use of 15N-labeled triazine to determine the site of alkylation. The observed 1JCN coupling is shown by a red arrow.

Scheme 47 The use of 15N-labeled triazolotriazine to determine the site of adamantylation. The observed 3JCN coupling is shown by a red arrow.
In contrast to 190**, the adamantylation of tetrazolo-1,2,4-triazine 37**T in TFA solution led to N2- and N1-regioisomers (compounds 192**a and 192**b, respectively, Scheme 50). It was found that compound 192**b is the product of the reversible isomerization of 192**a. This process occurs via the formation of an adamantly cation and heterocyclic base 37**T.

Compounds 192**a was characterized by a set of 1H-15N coupling constants that were detected for the H2` (3/4 J(C1`,N2)=0.83/0.06 Hz), H3` (1/4 J(C1`,N2)=0.60/0.11 Hz) and H4` (1/4 J(C1`,N2)=0.23 Hz) atoms of the adamantane fragment (Table 7 and Scheme 50). These spin–spin interactions, with the exception of J(C1`,N3), were also observed in the 2D 15N-HMBC spectrum. However, analysis of the JHN couplings did not allow the determination of the adamantylation site. This problem was solved by measuring the 13C-15N coupling constant (Table 6 and Scheme 50). Observation of the direct J(C1`,N3) (6.5 Hz) and other 13C-15N interactions for the C1` (J(C1`,N3)=3.8 Hz), C2` (J(C1`,N3)=0.4 Hz and J(C1`,N3)=1.2 Hz), C3` (J(C1`,N2)=1.6 Hz and J(C1`,N3)=0.2 Hz) and C4` (J(C1`,N3)=0.3 Hz) atoms of the adamantane group in 192**a indicated that the initial adamantylation of 37**T occurred on the N2 atom of the tetrozole ring (Table 6 and Scheme 50).

A similar situation with the determination of the adamantylation site in isomer 192**b had arisen. The detected 13C-15N spin–spin interactions of the J(C1`,N2) (2.7 Hz), J(C1`,N2) (1.1 Hz), J(C1`,N3) (0.3 Hz) and J(C1`,N2) (0.3 Hz) couplings in the 1D 13C NMR spectra of 192**b revealed the attachment of the adamantane fragment to the N1 atom of the tetrozole ring (Table 6 and Scheme 50). However, an analysis of the 1H-15N coupling constants in the 15N-HMBC spectrum (J(C1`,N3) and J(C1`,N2) and the obtained values of JHN from spin-echo experiments in 1D 15N NMR did not allow the unambiguous establishment of the structure of 192**b (Table 7 and Scheme 50).

### 4.2. JCN and JHN coupling constants as an approach for the confirmation of the mechanisms of nitration

The application of 15N-labeled compounds and the measurement of the 1H-15N and 13C-15N coupling constants permitted the investigation of the mechanism for nitration in a series of different heterocycles. An unusual method for the incorporation of the nitro group into the core of 6-chloro-9-Boc-purine was found by using a mixture of trifluoroacetic anhydride (TFAA) with labeled tetrabutylammonium nitrate (Bu4N+15NO3−) and freezing the nitration reaction (Scheme 51).43

The transformation of intermediate 194** was detected at −50 °C by NMR spectroscopy. In the corresponding 1H spectrum, the signal of proton H8 was split (JH8N=2.7 Hz).

In the carbon spectrum of an experiment with Bu4N+15NO3−, the JCN (1.8 Hz) coupling was observed for C8, and the signal of the carbon of the carbonyl group for the trifluoroacetoxy fragment was characterized by a 1H8-13C spin–spin interaction (2.8 Hz). These results unambiguously confirmed the formation of intermediate 194**, which underwent rearrangement into structure 196** at −10°C. Notably, this process occurred via the formation of intermediate 195** (Scheme 51).
The use of $^{15}$N-enriched nitric acid in the nitration of nitroimidazole 197 allowed the detection of the rearrangement occurring in this process.\(^4\) It was found that the interaction of 197 with $^{15}$N-nitric acid led to N-$^{15}$NO$_2$ nitroimidazole 198*, which underwent isomerization into compound 199* in chlorobenzene at 115 °C (Scheme 52). It should be noted that the carbon NMR spectrum of dinitroimidazole 199* was only characterized by one direct $^{13}$C-$^{15}$N coupling constant at the C2 atom with a magnitude of 30.6 Hz (Scheme 52). Thus, the fact that a doublet was observed for the $^{13}$C resonance at the 2-position only confirms the assignment of the C-2 resonance but also excluded the formation of intermediate 200* in the process of the isomerization of 198* into 199*. If this transformation included the production of structure 200*, statistically only 50% of the $^{15}$N would move to the 2-position. Moreover, this result showed that the isomerization included a [1,3]-sigmatropic rearrangement.

### 4.3. Analysis of $^1$H–$^{15}$N and $^{13}$C–$^{15}$N constants for the confirmation of the structures of amine and imine derivatives

The appearance of labeled nitrogen atoms in different amines simplifies the determination of the structures of the reaction products exploiting the analysis of $^{13}$C–$^{15}$N and $^1$H–$^{15}$N coupling constants. In that vein, the specifics of the interaction of 2,3-diketopyrido[4,3,2-de]quinolines 201 with $^{15}$N-propylamine were studied\(^5\) (Scheme 53). The $^1$H NMR spectrum of the final product 206* showed signals from two protons that are attached to the $^{15}$N-labeled atom ($^1$H$_{HN}$ 92.5 Hz, Scheme 53). These data unambiguously confirmed the production of compounds 206*. Then, the author shed light on the mechanism of this transformation after the isolation of intermediate 203*. The structure of 203* was confirmed by $^1$H and $^{13}$C NMR spectroscopy. Indeed, the proton spectrum showed that proton H1' and an n-propyl group are attached to the $^{15}$N atom. The signal of atom H1' was characterized by a direct $^1$H–$^{15}$N1 coupling constant with a magnitude of 92.5 Hz (Scheme 53). The aliphatic C2' and the aromatic C4 are directly linked to the labeled nitrogen atom ($^1$H$_{C2'-N1}$ = 8.5 Hz and $^1$H$_{C4-N1}$ = 15.8 Hz, Scheme 53). This result suggested that the transformation of 201 into 206* under the action of $^{15}$N-propylamine includes an amination–elimination reaction that involves the formation of structures 202*–205* (Scheme 53).

![Scheme 50](image-url) Scheme 50 The use of double $^{15}$N-labeled triazolotetrazine to determine the site of adamantylation. The observed J$_CN$ couplings are shown by red arrows. The measured J$_HN$ couplings by amplitude-modulated 1D $^1$H spin-echo experiments and detected $^1$H–$^{15}$N spin–spin interactions in the 2D $^{15}$N-HMBC spectra are shown by blue, green and magenta arrows (see the legend in the scheme).
The selective incorporation of the $^{15}$N-label into diamino-2-quinoxalinol $^{210}$ permitted the analysis of the $^1$H–$^{15}$N coupling constants for the confirmation of the structure of product $^{212}$*, which was isolated from the reaction of $^{210}$* with salicylaldehyde $^{211}$ (Scheme 54).

A synthesis of compound $^{210}$* was based on several steps. Initially, an interaction occurred between compound $^{207}$ and $^{15}$N-labeled ammonium hydroxide ($^{15}$N, 98%), and then $^{208}$* was transformed into $^{209}$*. Oxidation of $^{209}$* led to diamine $^{210}$*, which had two amino groups with different reactivities. Next, reaction of compound $^{210}$* with aldehyde $^{211}$ could give an imine $^{212}$*a or the isomer $^{212}$*b. The observation of the $^1$H–$^{15}$N coupling constant for the proton signal of the imine group ($^2$J$_{HN}$ = 3.0 Hz) confirmed the formation of structure $^{212}$*a.

5. Conclusion

We have reviewed examples of the incorporation of $^{15}$N atoms and subsequent analyses of the $J_{HC}$ and $J_{CN}$ couplings in labeled samples. The above approach can be considered an effective, general, and convenient tool for establishing realistic structures of nitrogen-containing compounds in solution, including mixtures of compounds and equilibrium mixtures. The measurement of the $^1$H–$^{15}$N and $^{13}$C–$^{15}$N coupling constants allows the investigation of ring-chain tautomerism, the mechanisms of chemical transformation and other structural aspects of azoles, azines, azepines and their fused derivatives. Although this approach is not widely used, $^{15}$N labeling and estimation of the $^1$H–$^{15}$N and $^{13}$C–$^{15}$N spin–spin interactions may be a single method that can be efficient for the determination of the molecular structure or method of chemical transformation in the chemistry of poly-nitrogen heterocycles. In structural studies, two types of coupling constants are used, namely, long-range and near (direct, geminal, vicinal) constants. While early publications used only near constants, modern works exploit both long-range and near constants, as well as 2D spectra. For example, 2D $^1$H–$^{15}$N HMBC spectra and spin-echo experiments were used for the determination of the N-adamantylation site of azolo-1,2,4-triazines and confirmation of the structure of...
imidazo[1,2-α]pyrimidine. This situation is closely related to the development of the NMR technique. Thus, it can be expected that this approach will be expanded in the chemistry of nitrogen-containing compounds since $^{15}$N labeling and the analysis of the $^{13}C-^{15}$N and $^1H-^{15}$N spin–spin coupling constants shines light on new and known chemical transformations, rearrangements and ring-chain tautomerism in a series of nitrogen heterocycles.
