An efficient conversion of rutin to the corresponding anthocyanin, cyanidin 3-*O*-rutinoside, was established. Clemmensen-type reduction of rutin gave a mixture of flav-2-en-3-ol and two flav-3-en-3-ols, which were easily oxidised by air to give the anthocyanin. The interconversion reactions of these flavonoids provide insight into their biosynthetic pathway.

Introduction

Because anthocyanins are attractive plant pigments with beautiful colours¹ and beneficial functions for human health,² it is important to supply large amounts of the compounds, which can be problematic. Currently, almost all the anthocyanins for commercial demand and research needs are prepared from plants as a mixture, or purified by very expensive repeated column chromatography. Only simple anthocyanins, anthocyanidin mono- or di-glucosides, are synthesised using the classical Robinson's method *via* aldol condensation.³ The disadvantage of Robinson's route is that the alkaline reaction conditions in the last step are drastic and the yield is not very good, especially in the case of delphinidin derivatives (yield approximately below 20%).³ A Clemmensen-type reduction of flavonol glycosides to the corresponding anthocyanins by a metal or hydride reagent is another option for the synthesis of anthocyanins.^{3c,4,5} This route is short, does not need protecting groups, and is easy to carry out at large scale. However, it still has problems with low yield; previous attempts gave only a 20–30% yield of pigment.^{4,5} Another advantage to the Clemmensen-type reduction over Robinson's method is that acylated anthocyanins can be synthesised. We reported the synthesis of cyanidin 3-*O*-6''-*O*-acetyl-β-D-glucopyranoside from kaempferol 3-*O*-6''-*O*-acetyl-β-D-glucopyranoside according to Brouillard's Zn–Hg reduction.⁵ However, the yield was not satisfactory, being

only 10% with a deacylated anthocyanin (15%).⁵ To improve the reaction, we analysed the detailed reaction procedure of the reduction, and found that non-toxic dried Zn powder can replace Zn–Hg.⁶ Furthermore, we found that the reaction proceeded in two steps: in the first step, flavonol was reduced to give a mixture of flav-2-en-3-ol and two flav-3-en-3-ol derivatives; in the second step, these flavenols were oxidised to the anthocyanin.⁶ The intermediate flavenols are highly reactive and easily oxidised under acidic conditions without any reagent other than the oxygen in the air.

In the well-accepted biosynthetic pathway of Cy3G **1**, one of the simplest and most abundant anthocyanins in plants, the last colourless compound is *cis*-leucocyanidin, and this precursor is oxidised by anthocyanidin synthase (ANS) to give a coloured cyanidin, followed by glucosylation at 3-OH to give **1** (Scheme 1).⁷ Inspired by this route, we previously designed a *cis*-leucocyanidin derivative and tried an oxidation reaction in the total synthesis of **1**.⁸ However, this compound did not give a cyanidin chromophore. We then transformed the *cis*-leuco compound to a flav-3-en-3-ol 3-*O*-glucoside derivative by dehydration, which had the same oxidative level as the *cis*-leuco compound. Air oxidation of the flav-3-en-3-ol 3-*O*-glucoside derivative gave **1**. Furthermore, flav-2-en-3-ol 3-*O*-glucoside (**2**) has been found in the seed-coat of immature black soybeans.⁹ Combining these findings strongly suggested that **2** is a new anthocyanin precursor, and that one should pay attention to the interconversion of the labile flavonoids involved in anthocyanin redox potentials and biosynthetic pathways. In addition, the mechanism of ANS and the oxidation–reduction relationship of flavonoids should be re-examined. Herein, we report the Zn reduction of rutin (**3**) followed by air oxidation to cyanidin 3-*O*-rutinoside (**4**). To determine the absolute stereostructure of the intermediates, we carried out electronic circular dichroism (ECD) spectra calculations and the synthesis of catechin

derivatives. We anticipated that the obtained chemical characteristics and reactivity would add to the understanding of flavonoid biosynthesis.

Results and discussion

In the previously reported Clemmensen-type reduction of 3, all the reactions were carried out in air.^{3c,4c} Therefore, we first examined the reactions under the same conditions. Rutin (3) was dissolved in dried MeOH. Zn powder and then dried HCl–MeOH were added and the mixture stirred vigorously. The mixture was red at the beginning of the reaction, but quickly became colourless. The colourless reaction mixture was filtered with a cartridge filter (pore size: 0.45 μM) to remove Zn powder and analysed by HPLC. The obtained chromatogram showed peaks for two colourless intermediates 5 and 6, and, interestingly, a sample solution for HPLC analysis without Zn turned red within a couple of minutes. The HPLC chromatogram of the red solution showed a decrease in the colourless peaks and the formation of 4. This strongly indicated that the reduction of 3 does not give 4 directly, but other colourless compounds 5 and 6 as intermediates. To analyse these intermediates in detail, we tried the Zn reduction under argon atmosphere and detected the three colourless compounds 5–7 with a small amount of 4 (Fig. S1†). Compound 7 could not be detected under air reaction conditions because 7 is very sensitive to oxidation. After removing the Zn powder by filtration, the solution was allowed to stand at room temperature under air overnight, whereupon the solution became red. At this point, compounds 5–7 had disappeared and only 4 was detected by HPLC (Fig. S1†).

To determine the structure of 5–7, a Zn reduction of 3 (1 g, 1.64 mmol) in dried HCl–MeOH under argon atmosphere at –20 °C was performed (Scheme 2). After removal of Zn by filtration, the reaction mixture was diluted with water and adsorbed on an Amberlite XAD-7 column, then eluted with aq. CH₃CN. The obtained fraction containing 5–7 was evaporated and purified using preparative HPLC eluted with neutral aq. CH₃CN. Pure samples of 5–7 were obtained in 14%, 55%, and 3% yield, respectively. The HR-ESI-MS peaks of 5–7 were consistent with the theoretical values (Calcd for C₂₇H₃₁O₁₅ [M – H][–] 595.1668, found 5: 595.1665; 6: 595.1668; 7: 595.1671). After analysis using various 1D and 2D NMR techniques, 5 and 6 were both determined to be 3,5,7,3',4'-pentahydroxyflav-3-en-3-ol 3-O-rutinoside with differences in the absolute configuration of C2. The structure of 7 was determined to be 3,5,7,3',4'-pentahydroxyflav-2-en-3-ol 3-O-rutinoside (Scheme 2).

To confirm the role of these intermediates, the air oxidation of isolated 5–7 to cyanidin 3-O-rutinoside (4) was examined (Scheme 2). Compounds 5–7 were each dissolved in dried HCl–MeOH and stirred in air at room temperature. All the solutions became red and were converted to 4, although the reaction rate was different for each compound; the conversion rate of 7 was significantly higher than that of 5 and 6. If water was present in the oxidation reaction, the yield of 4 was lower. Finally, starting with 2 g of rutin (3), pure cyanidin 3-O-rutinoside (4) as the TFA salt was obtained in 50% yield (1.175 g).

To determine the absolute configuration at C2 in intermediates 5 and 6, quantum chemical calculations for ECD spectra

Scheme 2 Conversion of rutin (3) to cyanidin 3-O-rutinoside (4) by Zn reduction and air oxidation.

were performed,¹⁰ as explained in detail in the ESI.† Optimised conformations of model compounds with 2*S* and 2*R* configurations derived from **5** and **6**, respectively, were obtained by density functional theory (DFT) calculations. Then, the ECD curve, $\Delta\epsilon$, of each conformer was computed by time-dependent DFT calculations. In these calculations, we simplified the structure by replacing the rutinoside moiety with OMe to reduce the number of plausible conformations and hence to reduce the computational cost. Eight conformers were considered for both the 2*S* and 2*R* structures of the model compounds (Fig. S2†). As shown in Fig. 1, the computed UV absorption spectra reasonably agree with the experimental spectra of **5** and **6** (Fig. 1), verifying that the replacement of ORut with OMe should not significantly affect the electronic character in the main skeleton of **5** and **6**. To highlight the absolute configurations at C2, the computed $\Delta\epsilon$ values at ~ 273 nm were examined in detail. As explained in the ESI,† the excited state at this region is attributed to the π - π^* transition. The calculated ECDs were compared with those of the experimental data (Fig. 1). This comparison between the theoretical and experimental results shows that the positive and negative Cotton effects around 280 nm are assigned to the *S* and *R* absolute configurations at C2, respectively. Note that, as seen in Fig. S4† in the ESI,† all the 2*R* conformers show a negative Cotton effect in the $\Delta\epsilon$ and the 2*S* conformers show a positive Cotton effect. This result further supports the above assignment.

The chirality at C2 of **5** and **6** was also confirmed by derivatization to the corresponding flavanols by hydrogenation (Scheme 3) and comparison with authentic compounds which were synthesised from (+)-catechin (**11**) and (-)-epicatechin (**12**). Compound **5** was dissolved in MeOH and reduced by H₂/Pd-C at room temperature to give a single product **8** in 52% yield with a 2,3-*cis*-configuration (H₂: broad singlet). The same reduction of **6** gave **9** and **10** in 16% and 23% yield, respectively. NMR analysis indicated that **9** has a 2,3-*cis*-configuration ($J_{2,3} = 2.0$ Hz) and **10** has a 2,3-*trans*-configuration ($J_{2,3} = 6.5$ Hz). Hydrogenation of **7** gave only **8** in 36% yield. Flavan-3-ol 3-

Scheme 3 Hydrogenation of 5–7.

rutinosides (**10**) were synthesised as shown in Scheme S1.† After selective benzylation of (+)-catechin (**11**),¹¹ glycosylation of 3-OH with rutinosyl immediately followed by deprotection gave **10** in 21% overall yield. All the physicochemical data of this product were consistent with the reductant **10** obtained from **6**. Using a similar procedure, (-)-epicatechin (**12**) was transformed to **9** and all characterisation data of this product were also consistent with the reductant **9** obtained from **6** (Scheme S1†). From these results, the chirality at C2 of **6** was determined to be the *R* configuration, whereupon the other 2,3-*cis*-flavan-3-ol 3-rutinoside **8** must have an *ent-epi* structure, and therefore C2 of **5** was determined to have an *S* configuration. Thus, ECD computational calculations for determining the chiral centre of flav-3-ene compounds were proven to be correct. This methodology is promising to the structure determination of chiral natural compounds.

To further confirm the interconversion reaction in flavonoids intermediates, we reduced the anthocyanin. At first, we attempted the Zn reduction of **4** in HCl-MeOH. HPLC analysis showed that **4** gave a mixture of 5–7 with a similar ratio as that obtained by the Zn reduction of rutin (**3**). However, hydrogenation of **4** by H₂/Pd-C in MeOH at room temperature gave a different result (Scheme 4). Two flavanols were obtained and identified as the major product **8** (55%) and the minor product **9** (2%). This indicated that hydrogenation occurs selectively, possibly a result of the steric hindrance of rutinoside. A similar

Scheme 4 Reduction of **4**.

stereoselective reduction was found in the hydrogenation of 5 and 7; therefore, hydrogenation of 4 might involve 5, 7, or both as an intermediate. We also attempted the reduction of 4 with a hydride reagent, NaBH₃CN, which can be used in acidic conditions (Scheme 4). Compound 4 was dissolved in MeOH, 3 eq. of NaBH₃CN was added, and the mixture stirred at -20 °C for 30 min. The result was different from that of the Zn reduction; the major product was 2-flavenol 7 with small amounts of 5 and 6. Purification by preparative ODS-HPLC with 10% aqueous CH₃CN solution gave pure 7 in 70% yield.

In the above conversion of flavonols to their corresponding anthocyanins, protection of the 3-OH was essential. Treatment of quercetin 3-O-glucoside gave 1; however, quercetin did not give cyanidin.^{6,12} It is not necessary for the 3-OH to be glycosylated; an alkyl-protected 3-O-methylquercetin was transformed to 3-O-methylcyanidin using the same reaction.¹³ These findings can explain the existence of 2 in immature black soybeans and raises a new hypothesis that glucosylation at 3-OH occurs first, following which oxidation by ANS gives 1. Recent reports have proposed a role and mechanism of the enzymatic reaction of ANS as oxidation at C3, and predicted 3,3-diol as an intermediate.^{7,c,f} However, according to our experimental results, oxidation to the anthocyanidin chromophore is not possible from these intermediates.

Conclusion

In summary, we studied the conversion of rutin (3) to cyanidin 3-O-rutinoside (4) by a Clemmensen-type reduction using Zn in dried HCl–MeOH. The reaction proceeded in two steps: the first step was reduction to a mixture of flavenol compounds 5–7, and in the second step, 5–7 were oxidised to anthocyanin 4. Removal of Zn before the second step improved the reaction yield and reproducibility. This reaction can be easily scaled up to gram-scale anthocyanin synthesis. For this conversion reaction, protection of 3-OH was essential.^{6,12,13} We also studied the reduction of 4 under various conditions and obtained chemical information about the anthocyanin–flavenols–flavanols inter-conversion. In the biosynthetic pathway of these flavonoids, sequential oxidation–reduction reactions were observed, and our findings should aid in the understanding of those reactivities and conversions in plants.

Elhabiri, P. Figueiredo, A. Fougerousse and R. R/Brouillard, *Tetrahedron Lett.*, 1995, **36**, 4611–4614: Elhabiri *et al.* reported the yield was 60%. However, we re-examined the reduction of rutin under HCl–MeOH with zinc amalgam, zinc powder, or magnesium powder and obtained cyanidin 3-O-rutinoside in less than 30% yield under the optimised conditions. This might be because the value of the molar absorption coefficients for cyanidin 3-O-rutinoside reported by Elhabiri *et al.* (7000 at 510 nm) is too low compared with the theoretical value (around 20 000 in our results); therefore, they miscalculated the yield.
