A facile approach to prepare crosslinked polysulfone-based anion exchange membranes with enhanced alkali resistance and dimensional stability

Chao Wang,^a Nengxiu Pan,^a Yuliang Jiang,^a Junbin Liao,^a Arcadio Sotto,^b Huimin Ruan,^a Congjie Gao^a and Jiangnan Shen^{id}*^a

Novel anion exchange membranes with enhanced ion exchange capacity, dimensional stability and alkali stability were prepared by a facile synthesis method. Internal crosslinking networks in the resulting membranes were achieved by reacting chloromethylated polysulfone with 4,4'-trimethylene bis(1-methylpiperidine) (BMP), where BMP was used as both a quaternization reagent and crosslinker without requirement of post-functionalization. In order to evaluate the alkali resistance and dimension stability performance of the resulting membranes, the molar ratio of BMP in the resulting membranes was fixed at four different contents: 40%, 60%, 80% and 100%. The obtained membranes were accordingly denoted as CAPSF-*N*, in which *N* = 40, 60, 80 and 100, respectively. Due to the dense internal network structure and spatial conformation of the six-membered rings, the resulting CAPSF-*N* AEMs showed enhanced dimensional structures (at 60 °C, the water uptakes and swelling ratios of CAPSF-*N* were 8.42% to 14.84% and 2.32% to 5.93%, respectively, whereas those for the commercial AEM Neosepta AMX were 44.23% and 4.22%, respectively). In addition, after soaking in 1 M KOH solution at 60 °C for 15 days, the modified membranes exhibited excellent alkaline stability. The CAPSF-100 membrane showed the highest alkali stability (retained 85% of its original ion exchange capacity and 84% of its original OH⁻ conduction after the alkaline stability test), whereas the non-crosslinked APSF broke into pieces. Additionally, compared to the commercial Neosepta AMX membrane under the same test conditions, the desalination efficiency of CAPSF-100 was enhanced, and the energy consumption was lower.

1 Introduction

Electrodialysis (ED) is a combination of an electrochemical process and a dialysis diffusion process. The ED process exhibits several operational advantages in terms of energy saving, environmental protection, and simple operation. It has been widely used in desalination and industrial production.^{1,2} For example, ED has been applied in demineralization of salt solution, desalination and reuse of sewage or industrial wastewater, and preparation of acids and bases by bipolar membrane ED from salt solution. The ion exchange membrane (IEM), as the core part of the ED, has the function of selecting specific ions to pass through. Cation exchange membranes (CEMs) and anion exchange membranes (AEMs) are two major types of IEMs which depend on the opposite charge of the fixed groups.³ Driven by the external direct current field, anions are induced to

move to the anode by AEMs, and cations are induced to move to the cathode through cation exchange membranes. According to the mechanism of the IEMs and their different environments, it is necessary to adjust the design of the substrate, the functional group types, and the polymer structures of these membranes.

Recently, the application of AEMs has become widespread, such as fuel cells,⁴⁻⁶ selective separation of different anions by electrodialysis⁷⁻¹⁰ and high pollution environments.^{11,12} For different applications of AEMs, they require high ion exchange capacity (IEC), low membrane surface resistance (*R*), low water uptake (WU), strong dimensional stability, strong physical and chemical stability, and strong alkali resistance. Theoretically, a high IEC value means that more active sites can be used for ion exchange in the membrane structure so as to ensure the full migration of ions.^{13,14} However, this will usually lead to excessive swelling of the membrane, and a “trade-off” phenomenon exists between WU and IEC.¹⁵ Dimensional stability and IEC are the key parameters for AEM performance. The existence of this “trade-off” limits the development of IEMs.

Alkali resistance is another important property that determines the overall performance of AEMs.^{2,16,17} Inevitably, in

complex chemical processes, practical applications in industrial wastewater treatment processes, and even in the process of membrane cleaning, the chemical environment will be complex and contain corrosive substances, such as alkaline species. Therefore, it is required that the membrane is resistant to basic substances. The lack of a simple and controllable method to achieve both good alkali stability and high ionic conductivity of AEMs hinders the widespread application of alkali-resistant AEMs. Due to the attack of hydroxide ions, the quaternary ammonium groups of AEMs follow two major degradation pathways:^{2,18} (1) Hofmann elimination and (2) nucleophilic substitution. OH⁻ attacks the nitrogen atom containing hydrogen atoms at the β position, and the quaternary ammonium group is eliminated; this is called Hofmann elimination. An SN₂ nucleophilic substitution reaction³ between OH⁻ and the α -position carbon atom of the ammonium group ultimately produces alcohols and amines; this is called nucleophilic substitution.

In conventional AEMs, different quaternary ammonium cations are densely grafted at the active sites of the backbone (quaternary ammonium AEMs,^{19,20} guanidine AEMs,^{21,22} quaternary phosphonium AEMs, imidazole AEMs²³); although AEMs can easily achieve a high IEC, the alkaline stability of this type of AEM tends to be poor, and Hofmann degradation and nucleophilic substitution reactions readily occur, leading to decreased ion exchange groups and even membrane rupture.^{4,18} Zhang *et al.*²³ prepared AEMs with chloromethylated polysulfone and 1-methylimidazole functional groups; although the AEMs exhibited enhanced overall performance, the quaternary ammonium groups densely grafted at the backbone afforded insufficient physical and chemical stability as well as degradation in alkaline environments.

In order to balance the dimensional stability, ionic conductivity and alkaline stability of AEMs, many researchers have focused investigations on this field. Dang *et al.*⁵ introduced long flexible hydrophobic side chains with multiple quaternary ammonium groups which had fewer active sites to a polymer; by controlling the hydrophobic chain length and the amount of hydrophilic quaternary ammonium groups, micro-phase separation could be achieved.^{5,24} With improved alkali resistance, a certain control of water uptake of the membrane was also achieved. Yang *et al.*²⁵ employed 1-(N',N'-dimethylamino)-6,12-(N,N,N-trimethylammonium) dodecane bromide as a substance for constructing hyperbranched structures; the ionic conductivity of the resulting AEMs was improved, while the chemical stability was enhanced. Guo *et al.*²⁶ used a cluster of alkyl branches containing three imidazolium cations with six methylene spacers grafted to fluorenyl poly(aryl ether sulfone) to form internal nanostructures in AEMs *via* a novel long flexible multi-cation spacer that facilitated ion migration (120 ms cm⁻¹ at 80 °C) and provided superior dimensional stability (12.0%, 30 °C). Although the above methods are helpful for improving dimensional stability, ion conductivity and alkali stability, complicated preparation processes and high preparation costs are involved.

Cross-linking is a simple method for preparing improved dimensionally stable and alkali-resistant AEMs. Particularly,

cross-linked AEMs with high IEC values can minimize swelling, increase steric hindrance of degradation in alkaline environments, and decrease the attack of OH⁻ on the polymer backbone or ion exchange groups, thus improving alkali stability.^{27,28} Cross-linked AEMs can be prepared by various methods, such as a series of end-linked cross-linked AEMs by “click chemistry”,²⁹ reacting halomethylated polymers with diols, dihalides, and diamines,^{30–34} ring-opening metathesis polymerization (ROMP),^{35,36} and thermal cross-linking.^{37,38}

Generally, preparation of cross-linked AEMs requires two steps, which are quaternization and cross-linking. Some reactions must be performed at high temperature and in other complicated environments; these complicated and time-consuming experimental procedures limit their potential for industrial application. Jiang *et al.*¹⁸ used 1-methylpyrrolidine as a quaternization reagent and 4,4-trimethylenedipiperidine (TMDP) as a crosslinker. The cross-linking agent did not provide any ion exchange sites and formed a complicated three-dimensional network structure that improved both the dimensional and alkali stability of the film; however, the preparation process was complicated and other factors influenced the stability of the preparation process and the AEMs, limiting their industrial application. Komkova *et al.*³¹ used N,N,N',N'-1,2-tetramethylethylenediamine, N,N,N',N'-tetramethyl-1,4-butanediamine and N,N,N',N'-tetramethyl-1,6-hexanediamine as both quaternization and cross-linking reagents under mild reaction conditions. In addition, studies have shown that some n-spiral ring quaternary ammonium salts have higher alkali stability; this can be attributed to the spatial conformation limit of the ring, which increases the energy barriers required for SN₂ nucleophilic substitution and Hofmann elimination and thus decreases the attack from OH⁻.³⁹

In view of these observations, this work aims to develop AEMs with enhanced dimensional stability, ion-exchange capacity and alkali resistance through a simple procedure. AEMs were fabricated by constructing an internal cross-linked network in the polymer backbone. Chloromethylated polysulfone (CAPSF) was selected as the polymer backbone; it has good physico-chemical stability. CAPSF was synthesized by avoiding the use of the carcinogenic reagent chloromethyl ether.⁴⁰ 4,4'-trimethylene bis(1-methylpiperidine) was selected as the quaternary ammonium and cross-linking agent due to the symmetric structure and ring conformation of the two piperidine rings. By controlling the content of 4,4'-trimethylene bis(1-methylpiperidine) in the casting solution, only one step is required to form the cross-networking structure with chloromethylated polysulfone at room temperature. The IEC, WU, swelling ratio (SR), alkali resistance, mechanical strength and desalination efficiency of the prepared AEMs with several cross-linking degrees were considered.

2 Experimental

2.1 Materials

Polysulfone ($M_w \sim 35\,000\text{ g mol}^{-1}$) and 4,4'-trimethylene bis(1-methylpiperidine) (99%) were bought from Sigma-Aldrich, China. PSF was dried at 80 °C in vacuum before use.

Chloroform (CHCl₃), stannic chloride, paraformaldehyde, trimethylchlorosilane, sodium chloride, dimethyl sulfoxide (DMSO), 1-methyl-2-pyrrolidone (NMP), dimethylacetamide (DMAc) and sodium sulfate were obtained from Aladdin, Co. Ltd. (Shanghai, China). The reagents purchased were all analytical reagents and were used directly. Commercial IEMs, Neosepta AMX and CMX were obtained from Fujifilm, Japan.

2.2 Membrane fabrication

2.2.1 Preparation of chloromethylated polysulfone (CAPSF). The preparation of CAPSF was carried out according to the literature.⁴⁰ Firstly, 10 g polysulfone was added to 500 mL chloroform in a three-necked flask. Then, paraformaldehyde (13.56 g), trimethylchlorosilane (57.36 mL) and stannic chloride (0.53 mL) were added to the flask in turn to form a transparent solution after sufficient mechanical stirring. After 60 hours of stirring at 50 °C, the filtered yellow transparent solution was poured into ethanol to form a white flocculent product, which was then fully dried in a vacuum oven at 60 °C for 24 hours to obtain CAPSF.

2.2.2 Synthesis of cross-linked AEMs. We used a solution-casting method to fabricate AEMs for the experiments. The cross-linking degree and anion exchange group (piperidine group) contents were adjusted using different amounts of 4,4'-trimethylene bis(1-methylpiperidine); the AEMs were named CAPSF-*N* (where *N* represents the molar ratio between the cross-linker and chloromethyl groups: CAPSF-20, CAPSF-40, CAPSF-60, CAPSF-80, and CAPSF-100 were obtained, respectively). Taking the preparation of CAPSF-80 as an example: a transparent casting solution was obtained by dissolving 0.5 g CAPSF in 7 mL NMP in a round-bottom flask at room temperature. Then, 0.104 g 4,4'-trimethylene bis(1-methylpiperidine) was added. In order to avoid gelation, the reaction time should be controlled within one hour at room temperature. Bubbles were removed under vacuum at 25 °C. A clean glass plate was prepared, and CAPSF-80 solution was casted on it. Then, the membranes were dried in a vacuum oven at 60 °C for 12 h.

2.2.3 Synthesis of AEMs. As shown in Scheme 1, non-crosslinked APSF casting solution was obtained *via* dissolving CAPSF (0.5 g) and 0.195 g trimethylamine (TMA) in 7 mL NMP and stirring for 24 h at room temperature. Then, bubbles were removed by allowing the casting solution to stand for 10 minutes. A clean glass plate was prepared and the APSF solution was casted. Then, it was dried in a vacuum oven at 60 °C for 12 h.

2.3 Membrane characterization

2.3.1 ¹H NMR, FTIR spectra. An NMR spectrometer (Bruker AVANCE III) was used to record the ¹H NMR spectra, operating at 500 MHz at 25 °C, using dimethyl sulfoxide-*d*₆ as the solvent. FTIR spectra of the prepared AEMs were acquired with a Nicolet 6700 spectrometer; the total spectral range of the spectrometer was 4000 to 400 cm⁻¹, and the resolution of the spectrometer was 2 cm⁻¹.

2.3.2 Ion exchange capacity. Potentiometric titration (Mettler Toledo, T50) was used to measure the IECs of the cross-linked membranes. Before the tests, the prepared AEMs were

fully dried and weighed precisely. Then, the AEMs were converted to Cl⁻ form by soaking in 0.5 M NaCl solution for 24 h, and deionized water was used to clean the surface of the AEMs. Cl⁻ ions were released for titration by soaking the membranes in 0.5 M Na₂SO₄ solution for 24 h. Eqn (1) shows the calculation method of IEC:

$$\text{IEC} = \frac{C \times V}{W_{\text{dry}}} \quad (1)$$

where *C* (mol L⁻¹) is the molar concentration of Cl⁻ tested by potentiometric titration, *V* (L) is the volume of Na₂SO₄ solution used to replace Cl⁻ in the Cl⁻-form AEMs, and *W* represents the dry weight of the sample.

2.3.3 Surface area resistance of membranes. As illustrated in Fig. 1, a home-made device (MEIEMP-I, Hefei Chemjoy Polymer Material Co., Ltd., China) was employed to test the membrane surface electrical resistance of the prepared AEMs. 0.5 M NaCl solution was fed to soak the AEMs for 30 min, and a balance was achieved. The electrode cell, dilute cell (DC) and concentrate cell (CC) were separated by a commercial cation exchange membrane (CEM, Neosepta CMX). In this device, the two electrode cells contained 0.3 M Na₂SO₄ solution, and intermediate compartments were filled with 0.5 M NaCl solution. Eqn (2) shows the calculation of the membrane area resistance:

$$R = \frac{U - U_0}{I} \times S \quad (2)$$

where *U* (V) is the voltage of the trans-membrane; *U*₀ (V) is the voltage when the intermediate device has no film (blank experiment); *I* (A) is a constant current applied to the device (0.04 A); and *S* (cm²) is the effective area of the tested AEMs (7.065 cm²).

2.3.4 Transport number and limiting current density (LCD). The transport numbers of the prepared AEMs were tested in a similar setup to that used during the surface area resistance tests. Firstly, equilibrium of the prepared AEMs was reached by soaking in 0.15 M KCl solution. During testing, 0.1 M and 0.2 M KCl solutions were cycled in the intermediate chambers which are next to the prepared AEMs in the device. A multimeter (DMM6000 Zhiyuan Electronics Co., Ltd.) was used to record the voltage (*E*_m) between the Ag/AgCl reference electrodes. According to eqn (3), *t* was calculated as

$$t = \frac{E_m - E_0}{2E_0} \quad (3)$$

t represents the transport number of the AEM; *E*₀ represents the difference between the potential values (V) of the standard 0.1 M KCl and 0.2 M KCl solutions; and *E*_m represents the potential (V) across the membrane.

Current-voltage (*C-V*) tests were used to obtain the ICD values of the membranes. A similar device was used to measure the surface area resistance of the membranes. Current-voltage curves of the prepared AEMs were obtained by recording the gradually increased applied current density (from 0 to 60 mA cm²) and the corresponding voltage change. The intermediate solution and the electrode solution were fed with 0.5 M NaCl solution and 0.3 M Na₂SO₄ solution, respectively.

Scheme 1 Preparation of cross-linked CAPSF and APSF membranes.

2.3.5 Water uptake (WU) and swelling ratio (SR). The WU and SR values of the prepared AEMs were calculated by measuring the weight and dimension changes. Firstly, the weights and dimensions of the dried IEM samples were recorded after the AEM samples were fully dried at 60 °C under vacuum for 24 h. Then, we placed the tested dried AEM samples in DI water at 25 °C, 35 °C, 50 °C and 60 °C for one day. After removing residual water on the surface of the samples, we quickly measured the weights and dimensions of the hydrated AEMs.

According to eqn (4) and (5), WU and SR were calculated:

$$\text{WU} = \frac{W_{\text{wet}} - W_{\text{dry}}}{W_{\text{dry}}} \quad (4)$$

$$\text{SR} = \frac{L_{\text{wet}} - L_{\text{dry}}}{L_{\text{dry}}} \quad (5)$$

where W_{wet} (g) and W_{dry} (g) represent the mass of the hydrated and dry AEM, respectively; L_{wet} (cm) and L_{dry} (cm) represent the length of the AEM before and after being hydrated, respectively.

2.3.6 Alkaline stability. The alkaline resistance ability of the prepared AEMs was measured by soaking the prepared AEMs in KOH solution (1 mol L⁻¹, 60 °C) for 3, 6, 9, 12 and 15 days, respectively. Then, the AEM samples were cleaned with DI water. The decreased IEC values of the prepared AEMs reflected the ability of the AEMs to resist alkaline attack.

The OH⁻ conductivity of the membranes was determined by an Autolab PGSTAT302N using a 4-probe technique and frequencies in the range of 1 Hz to 1 MHz. All tested membranes (4 cm in length, 1 cm in width) were submerged in 1.0 M KOH aqueous solution and soaked for a day. Before the test, the tested samples were rinsed thoroughly with DI water, and the OH⁻ conductivity (σ) was calculated by the following eqn (6):

Fig. 1 Schematic diagram of measuring device for surface area resistance test.

$$\sigma = \frac{L}{Rwd} \quad (6)$$

where R is the resistance of the membrane; L is the potential sensing electrode distance (cm); and w and d denote the width and thickness of the membrane, respectively.

2.3.7 Electrodialysis (ED) tests. As shown in Fig. 2, the home-made ED device was assembled with four compartments. In this work, the applied constant current density was 22.94 mA cm^2 , and the effective membrane area was 19.625 cm^2 . In the two electrode cells, $0.3 \text{ M Na}_2\text{SO}_4$ solution was cycled, and 0.5 M NaCl solutions were supplied in both the concentrated/dilute cells. The changes in the conductivity of the NaCl solution in the concentrated/dilute cells and the potential of the device were recorded every 10 min. In addition, the performance in the ED process, such as NaCl removal ratio, current efficiency and energy consumption, were assessed and compared; they were calculated using eqn (7)–(9), below:

$$R_w = \frac{\delta_0 - \delta_t}{\delta_0} \quad (7)$$

$$\eta = \frac{Z(C_t - C_0)V_t F}{NI t} \times 100\% \quad (8)$$

$$E = \int_0^t \frac{UI}{(C_t V_t - C_0 V_0) M_b} dt \quad (9)$$

where R_w is the desalination rate (%); δ_0 and δ_t are the initial and final conductivity of the NaCl solution after 2.5 h of the experiment; n is the current efficiency; C_t and C_0 are the concentrations of NaCl solution in the CC at time t and 0; Z is the absolute valence of the ions ($Z_{\text{Na}^+} = 1$); E (kW h kg^{-1}) is the energy consumption; V_t and V_0 are the volumes of the solution in the CC at times t and 0, respectively; F represents the Faraday constant (96485 C mol^{-1}); I represent the applied current, which is 0.45 A ; N represents the number of repeating units, which is 1; U is the voltage over the ED device; and M_b is the relative molecular mass of NaCl , $M_b(\text{NaCl}) = 58.5$.

3 Results and discussion

3.1 ^1H NMR and FTIR spectra

The chloromethylation of polysulfones (PSF) and the reaction of chloromethylated polysulfone and trimethylamine was studied by NMR spectroscopy. In the ^1H NMR spectrum of PSF (Fig. 2(b)), the signals with chemical displacements of 6.90 to 7.86 ppm can be attributed to the polyhydrogen (H1) on the phenyl group, while the peaks with chemical displacements of 1.72 ppm can be ascribed to hydrogens (H2, $-\text{CH}_3$) on the methyl group. In contrast, in the CAPSF spectrum (Fig. 2(a)), at 4.56 ppm, a new sharp signal appears; the chemical shift is ascribed to the hydrogen chloride (H3, $-\text{CH}_2\text{Cl}$) hydrogen. These observations confirmed the formation of the $-\text{CH}_2\text{Cl}$ group in CAPSF. The degree of chloromethylation (DC) of CAPSF was estimated to be 127% by means of the relative area ratio of the $-\text{CH}_2\text{Cl}$ and $-\text{CH}_3$ peaks, calculated by the equation $\text{DC} = 3S_{\text{H3}}/S_{\text{H2}}$ (ref. 41,42) (where S represents the integral area

Fig. 2 ^1H NMR spectra of CAPSF (a), PSF (b) and APSF (c).

of the proton peak). In the APSF ^1H NMR spectrum (Fig. 2(c)), in contrast with the ^1H NMR spectrum of CAPSF, a new signal appears at 2.98 to 3.15 ppm;⁴³ this can be attributed to the successful reaction of TMA and CAPSF.

The insolubility of the prepared CAPSF-*N* AEMs is due to the cross-linked reaction between 4,4'-trimethylene bis(1-methylpiperidine) (BMP) and CAPSF; it indicates that a cross-linked network was successfully formed.¹⁸ By comparing the FT-IR spectra of CAPSF-*N* and CAPSF, the cross-linked structure was further confirmed.

The FT-IR spectra of CAPSF and CAPSF-*N*^{18,41} are shown in Fig. 3. Because of the hydrophobic nature of CAPSF,¹⁸ it is difficult for CAPSF membranes to absorb water from the external environment. When BMP was successfully introduced, the CAPSF-*N* membranes obtained hydrophilic performance and absorbed external water, which is reflected in the characteristic peak of the stretching vibration of O-H groups at around 3375 cm^{-1} . With increasing content of BMP (from CAPSF-40 to CAPSF-100), the peak at 3375 cm^{-1} becomes sharper, which indicates the successful quaternization reaction.

3.2 Measurement of cross-linking degree

Measuring solubility is a facile way to assess the crosslinked structures inside membranes.^{44,45} As shown in Table 1, the prepared cross-linked AEMs (CAPSF-*N*) exhibited high mass retention ratios over 80%; also, they dissolved only slightly in NMP, DMAc, DMSO, and CHCl_3 after 7 days, suggesting their non-extractable nature. The three-dimensional network structures constructed inside the AEMs endow them with excellent solvent resistance ability. Conversely, the CAPSF membrane exhibited excellent solubility in these solvents and completely dissolved in the solutions.

3.3 Physico-chemical properties of different AEMs

As illustrated in Table 2, the prepared AEMs had similar thicknesses (53 to 61 μm) under the same environmental

Table 1 Solubility properties of prepared cross-linked membranes and mass retention of each membrane after being soaked in NMP/DMAc/DMSO/ CHCl_3 at 25 °C for 7 days

Membrane	Organic solvents			
	NMP	DMAc	DMSO	CHCl_3
CMPSF	0	0	0	0
CAPSF-40	88.3%	86.7%	80.6%	89.7%
CAPSF-60	95.1%	85.6%	94.9%	97.1%
CAPSF-80	94.5%	91.6%	95.7%	96.1%
CAPSF-100	99.2%	96.9%	98.9%	96.8%

conditions. Thus, we can easily compare the possible variation of other physico-chemical membrane properties as a result of the proposed modifications. BMP was used as both a cross-linker and quaternary ammonium reagent. As the cross-linked degree increases, the IEC shows a consistent upward trend because of the increasing number of ion exchange groups, and the experimental IEC value approaches the theoretical value.

As shown in Fig. 4(a) and (b), the water uptake (WU) is at a low level (8.42% to 14.84%); the enhanced IEC endows the CAPSF-*N* AEMs with higher WU. Usually, excessive membrane swelling can be effectively suppressed by reinforcing the crosslinked network. In this experiment, the effect of the water absorption ability provided by IEC is probably slightly stronger than the water resistance ability that the internal crosslinked structure provides. Tighter networks and enhanced interactions between adjacent polymer segments increased the resistance of water molecules to entering the cross-linked CAPSF-*N* AEMs. SR shows the positive correlation of this trend with the water content; with increasing cross-linking degree, the LER increases.

With increasing IEC value, the surface area resistance of the cross-linked AEMs decreases remarkably from 16.31 to 2.41 $\Omega\text{ cm}^2$. This phenomenon arises due to the conductive ion exchange groups produced by the reaction between the BMP groups and the chloromethylated polysulfone backbone. In the same test conditions, the membrane surface area resistance of the CAPSF-100 membrane (2.41 $\Omega\text{ cm}^2$) was lower than that of a commercial membrane (Neosepta AMX, 2.51 $\Omega\text{ cm}^2$). The transport numbers of the cross-linked CAPSF-*N* AEMs show an increasing trend from 0.91 to 0.98 with *N* from 40 to 100. The high transport number of CAPSF-100 (0.98) represents higher perm-selectivity, which is caused by its higher IEC as well as its denser interior network. Due to its lower membrane surface area resistance and high transport number, CAPSF-100 is more suitable for practical application in desalination.

3.4 Mechanical properties

Table 3 illustrates the mechanical properties of the cross-linked AEMs (CAPSF-*N*) and APSF AEM. Eb and Ts are significant factors in the mechanical properties of membranes. The cross-linked CAPSF AEMs show an incremental trend of tensile strength (Ts) from 20.4 MPa to 26.4 MPa. Conversely, the elongation at break (Eb) apparently decreases, from 120.1% to 47.8%; this suggests that the cross-linked network provided

Fig. 3 FT-IR spectra of CAPSF & CAPSF-*N* membranes.

Table 2 The physico-chemical properties of the various as-prepared AEMs and commercial Neosepta AMX

Membrane	IEC ^a mmol g ⁻¹	IEC ^b mmol g ⁻¹	Thickness μm	WU ^c %	LER ^d %	AR ^e $\Omega \text{ cm}^2$	Transport number
CAPSF-40	0.79	0.68	53	8.42	1.42	16.31	0.91

^a IEC, calculated values (DC is 1.27). ^b IEC, experimental values by potential titration. ^c WU, water uptake. ^d LER, linear expansion ratio. ^e AR, area resistance.

compact and stiff internal structures. Generally, the cross-linked CAPSF-100 AEM shows a mechanical strength of 26.4 MPa and an elongation at break of 47.8%. This behavior is due to the favorable balance obtained between high IEC and good mechanical properties. The excellent mechanical stability of the prepared AEMs suggests that they are feasible to use in ED processes.

3.5 Alkaline stability

It is critical for AEMs to have long-term alkali stability in alkaline environments. The degradation resistance that affects the alkaline stability of AEMs in some complicated operational environments is mainly provided by the functional groups and the polymer backbone. At high temperatures, strongly electrophilic functional groups are more likely to be attacked by OH^- .^{2,46} Thus, the IEC retention ratios and conductivity retention ratios of the cross-linked AEMs (CAPSF-*N*) and APSF membrane sample were tested to evaluate their alkaline stability by calculating the ratio of IEC and the conductivity of the tested AEMs before and after being soaked in 1 M KOH at 60 °C for 15 days.

As illustrated in Fig. 5(a), during the stability test, the CAPSF-*N* AEMs show high alkaline stability; this is confirmed by the slight decreases of their IEC values. It is worth noting that the non-crosslinked APSF membrane showed poor alkali resistance ability; after immersion in 1 M KOH for 3 days, it

Table 3 The tensile strengths and elongations at break of the prepared AEMs and Neosepta AMX

Property	CAPSF-40	CAPSF-60	CAPSF-80	CAPSF-100	APSF
Ts/MPa	20.4	22.1	21.0	26.4	14.3
Eb/%	120.1	84.8	60.6	47.8	173.5

started to break into pieces, rendering it useless for further tests. Comparatively, after an initial sharp drop stage, the ion conductivities of the CAPSF-*N* AEMs exhibited a nearly constant trend. After 15 days, over 70% IRR of the cross-linked CAPSF-*N* AEMs were retained, and as result of the cross-linked degree increase, the IRR increased. For example, the IRR of CAPSF-100 reached nearly 86%, while CAPSF-40 only retained 72% of its original IEC after the test. As illustrated in Fig. 5(b), the corresponding conductivity retention ratios show an almost consistent trend with the IEC retention ratios, as we predicted.

Because of the attack of OH^- anions, the brittle and fragile performance of the non-crosslinked AEM (APSF) is mainly due to the interaction of nucleophilic substitution and the Hofmann degradation mechanism;⁴⁷ the stable polymer system was broken, resulting in reduction of the ion exchange groups and electrochemical oxidative stress.

Fig. 4 (a) WU (b) SR of CAPSF-*N* and APSF membranes at different temperatures.

Fig. 5 (a) IEC retention ratios and (b) conductivity retention ratios of the tested AEMs, immersion in 1 M KOH at 60 °C for 15 days, respectively.

Although the polysulfone backbone is relatively inexpensive, it has been reported that it shows unstable performance in alkaline environments and is subject to hydrolytic cleavage of the quaternary groups due to the existence of aryl-ether bands in the polysulfone ammonium groups;⁴⁸ the added BMP readily alleviated this phenomenon, even in 1 M KOH at 60 °C for up to 16 days. On one hand, the densely crosslinked structure inside CMPSF-N increased the energy barriers of the Hofmann elimination and nucleophilic substitution reactions. On another hand, the limitation of the spatial conformation of the six-member ring increases the transition state energy of the substitution reaction and the elimination reaction.⁴⁹

3.6 Limiting current density (LCD) and desalination performance

LCD is also a key parameter for electro dialysis. When the operating current density approaches or exceeds the critical state, the concentration polarization phenomenon will occur. At this time, the electrolyte ion concentration on the membrane surface of the desalting chamber is much lower than that of the main solution, and the ion content on the membrane surface of the concentration chamber is much higher than in the main solution; this results in great hazards, such as significantly increased membrane resistance, decreased salt rejection rate, and decreased current efficiency. Therefore, the operating current density must be controlled at an appropriate level. C - V curves were used to investigate the limiting current density during the desalination process. Generally, three typical characteristic regions, (1) the ohmic region, (2) the limiting current region, and (3) the over-limiting region, are displayed in the C - V curves.^{50,51}

The cross-linked membranes were tested and, as expected, showed better electro dialysis performance (CAPSF-100, CAPAF-80) compared with APSF and the commercial AEM (Neosepta AMX). As shown in Fig. 6(a), the LCD values of all the membranes are higher than the applied current density (22.94 mA cm^{-2}), which guarantees the normal migration of ions, avoids hydrolysis

and leads to additional current consumption for transport of OH^- . The LCD of CAPSF-100 is higher than that of the commercial AEM (Neosepta AMX); CAPSF-100 can be feasibly operated at higher current densities with a low area resistance as well as a high LCD.

After a continuous-mode ED test, the change in conductivity of the NaCl solution in the DC and CC and the potential over the device during the test were recorded. As illustrated in Fig. 6(c), the conductivity decreased in the dilute chamber and increased in the concentrate chamber; this is ordinary behavior for ion transport through an ion exchange membrane driven by an electric field. Accordingly, as shown in Fig. 6(b), the potential over the stack with different AEMs increased continuously until the maximum power was reached, due to the decreased number of available ions for migration.

The cross-linked CAPSF-100 showed better desalination performance than commercial AEM (Neosepta AMX) for the 150 min ED test. As shown in Fig. 7(a) and (b), the NaCl removal ratio and current efficiency of cross-linked CAPSF-100 after a 2.5 h ED test were the highest (around 96.7%, 82.3% calculated) among the testing samples. Usually, the IEC, WU, and polymer structure play important roles in the ED performance. The collective effects of high LCD and good dimensional stability may lead to good desalination performance and high current efficiency of the CAPSF-100 AEM. The high dimensional stability of the CAPSF-100 AEM is expected to ensure good mechanical stability and can help maintain a stable desalination process throughout the electro dialysis process. On the other hand, the concentration polarization generated by the electro dialysis process also affects the transport and conduction of conductive ions at the interface and inside of the membrane. The low energy consumption can be ascribed to the suitable water uptake and low area resistance. Additionally, the energy consumption of the cross-linked CMPSF-100 AEM ($10.34 \text{ kW h per kg NaCl}$) is lower than that of the commercial membrane (Neosepta, AMX, $11.03 \text{ kW h per kg NaCl}$) due to its low membrane area resistance. Overall, the above properties of the CAPSF-100 AEM show promising potential in ED applications.

Fig. 6 In ED process: (a) limited current density test: C–V curves of CAPSF-100, CAPSF-80, APSF, and commercial AEMs; (b) change of potential over stack with different AEMs; (c) conductivity change in concentrate/dilute chamber.

Fig. 7 (a) NaCl removal ratio, (b) current efficiency and energy consumption after 2.5 h in ED.

4 Conclusions

A series of cross-linked anion exchange membranes (CAPSF-*N*) were synthesized by a facile method at room temperature. 4,4'-trimethylene bis(1-methylpiperidine) was used as both the quaternization reagent and crosslinker, and good dimensional stability and alkali resistance were obtained. Even at 60 °C, CAPSF-100 showed strikingly suppressed water uptake (15.6%) and swelling ratio (5.2%). A test of the alkaline stability of CAPSF-*N* with 1 M KOH at 60 °C exhibited slight degradation; especially, CAPSF-100 maintained 85% IEC and 84% ion conductivity and showed good alkali stability. In ED tests, the preferred CAPSF-100 membrane exhibits excellent desalination performance and low energy consumption with proper water uptake, low area resistance and high migration rate; its

performance was better than that of commercial Neosepta AMX in the same test conditions. These results suggest that the CAPSF-100 membrane has potential to be applied in ED and meets the needs of alkaline environmental applications.
