We report an efficient protocol for tandem Pd-catalyzed intramolecular addition of active methylene compounds to alkynes, followed by subsequent cross-coupling with (hetero)aryl bromides and chlorides. The reaction proceeds under mild conditions, providing excellent functional group tolerance, including unprotected OH, NH₂ groups, enolizable ketones, or a variety of heterocycles. Mechanistic studies point towards a catalytic cycle involving oxidative addition, intramolecular nucleophilic addition to the Pd(II)-activated alkyne, and reductive elimination, with 5-*exo-dig* cyclization being the rate limiting step.

Introduction

Palladium complexes emerge as some of the most versatile homogenous catalysts with a myriad of applications in both academic and industrial research. The most prominent area of palladium catalysis, awarded with the 2010 Nobel Prize to R. Heck, A. Suzuki, and E. Negishi,¹ covers cross-couplings of (hetero)aryl or vinyl(pseudo)halides with nucleophilic or organometallic partners. High efficiency of these and many other processes (*e.g.* Wacker oxidation) arises from the facile interconversion of palladium oxidation states through two-electron redox chemistry. Besides the most widespread Pd(0)/Pd(II) cycle, palladium is also able to enter radical processes or to serve as a carbophilic Lewis acid in redox-neutral transformations. The ability to mediate mechanistically distinct transformations makes palladium the catalyst of choice for the design of tandem reactions in which a single metal complex catalyzes a sequence of transformations.² In our research, we are focused on the development of tandem processes combining the nucleophilic addition to alkynes and subsequent cross-coupling, which give the access to a wide set of carbo- and heterocyclic systems.³ In contrast to cross-coupling reactions, these transformations are highly underdeveloped and suffer from harsh reaction conditions (*e.g.* the use of strong bases), narrow substrate scope (usually limited to active aryl iodides), and poor functional group tolerance, as well as insufficient mechanistic understanding.

In the late 1980s, Gore disclosed seminal works on a novel Pd-catalyzed dicarbofunctionalization of unsaturated C–C systems through arylation with iodobenzene and intramolecular nucleophilic additions of malonates to alkylidene-cyclopropanes or alkenes.⁴ In subsequent accounts, the authors reported a sequential 5-*exo-dig* cyclization of malonates and β-ketoesters tethered to the alkyne moiety, followed by coupling with aryl iodides.⁵ The scope of the methodology was further extended to the use of haloalkynes,⁶ allyl halides and acetates⁷ as coupling partners. Recently, we have developed a protocol enabling the effective reaction of much less active aryl bromides with acetylenic β-ketoesters.⁸ A similar strategy, utilizing a 5-*endo-dig* cyclization has also been applied to the synthesis of cyclopentenes⁹ and indenenes.¹⁰ Propargylmalonates led to substituted cyclopropanes *via* analogous cyclization/coupling protocol.¹¹ On the other hand, propargyl-β-ketoesters underwent 5-*exo-dig* oxocyclization/coupling, leading to the formation of substituted furan systems due to ambident nature of enolates of β-ketoesters.¹² Interestingly, the analogous transformation involving homopropargyl-β-ketoesters possessing an internal or terminal alkyne motif clearly led to either cyclopentenes⁹ or dihydropyranes,¹³ respectively.

The vast majority of the known methodologies utilizing sequential Pd-catalyzed nucleophilic cyclization and cross coupling are limited to aryl iodides. Moreover, the functional group compatibility appeared very narrow, which could possibly arise from the use of a strong base. Recently, we have addressed these challenges in a transformation involving acetylenic β-ketoesters which readily undergo cyclization. Extension of the scope with respect to activated methylene compounds still awaits investigation. Although there are examples of such transformations involving derivatives of ketoesters and malonates (with active aryl iodides), to the best of our knowledge, cyclization/coupling of haloarenes with acetylenic derivatives of

Here, we report an efficient protocol for tandem Pd-catalyzed intramolecular addition of active methylene compounds to alkynes and subsequent cross-coupling with (hetero)aryl bromides and chlorides. The methodology features excellent tolerance for functionalities present in either reaction partner.

Results and discussion

The reaction of dimethyl pent-4-yn-1-ylmalonate **1** with bromobenzene was chosen as a model transformation for the development of the reaction conditions. First, a range of Pd-complexes of mono- and diphosphine ligands were examined using 3rd-generation Buchwald-type palladacyclic system as a platform in order to identify an active catalyst system. Optimization revealed XPhos Pd G3 as the pre-catalyst of choice. Then, the benchmark reaction was evaluated against various reaction conditions, including base, solvent, catalyst loading, temperature, and time, among others (Table 1).¹⁴ A polar aprotic solvent appeared to be crucial for the efficiency of the cyclization. Reactions carried out in moderately polar, or nonpolar solvents (*e.g.* dioxane, THF, toluene) failed to proceed at all, or competitive Sonogashira coupling was observed. The best results were achieved for the reaction run for 24 h at 50 °C in DMF with potassium phosphate as the base. 2 mol% of palladium complex was necessary to achieve a high yield of desired product **2**.

With satisfactory conditions developed for the model substrate, we proceeded to investigate the scope of the reaction. First, we examined the performance of various aryl and heteroaryl bromides in the reaction with malonate **1** (Table 2).

Table 2 Substrate scope: aryl bromides^a

^a Reaction conditions: dimethyl pent-4-yn-1-ylmalonate **1** (0.400 mmol), aryl bromide (0.500 mmol), K₃PO₄ (0.600 mmol), XPhos Pd G3 (8.0 μmol, 2 mol%), DMF (1 ml), 50 °C, 24 h. ^b Run for 4 h.

Both electron-rich and electron-poor bromoarenes smoothly underwent the reaction, affording the expected products with good to excellent yields and complete stereoselectivity on the olefinic bond. A range of functional groups including, *inter alia*, unprotected amines (**4**), alcohols (**12**), aldehydes (**21**), nitriles (**20**), nitro (**25**), carbamates (**22**), or enolizable ketones (**7**) were well tolerated. Furthermore, sterically hindered *o*-substituted bromo(hetero)arenes also proved to be complementary reaction partners (**8**, **17**, **24**). The use of various heteroaryl bromides enabled the introduction of the heterocyclic moiety to the product (**10–11**, **14–16**, **18–19**, **23**), including pharmaceutically relevant *N*-heterocyclic motifs (**10–11**, **14–16**, **18–19**).

Next, we proceeded to examine the scope and limitations with respect to various acetylenic active methylene compounds (Table 3). Selected derivatives of malonates, cyanoacetates, cyanomalonates, β -ketoesters, and 1,3-diketones were subjected to the reaction with both electron-poor and electron-rich bromoarenes – bromobenzene, *p*-bromoanisole, and *p*-bromobenzonitrile. Transformations with more sterically hindered *i*-propyl and *t*-butyl malonates delivered the expected products (**26–31**), although with diminished yields, compared to the less sterically demanding methyl malonate **1**.

^a Reaction conditions: acetylenic active methylene compound (0.400 mmol), aryl bromide (0.500 mmol), K₃PO₄ (0.600 mmol), XPhos Pd G3 (8.0 μ mol, 2 mol%), DMF (1 ml), 50 °C, 24 h. ^b Run for 4 h. ^c Run at 80 °C for 24 h. ^d Run at 50 °C for 2 h.

The considerably more C–H acidic cyanoacetates, cyanomalonates, and β -ketoesters appeared to be the more reactive substrates, usually providing the appropriate products (**32–43**) with very good yields (70–96%). The only exception was a reaction of electron-deficient bromoarenes with cyanomalonate and *t*-butyl cyanoacetate, which afforded products (**34** and **40**) with moderate yields (33–40%). Notably, reactions involving electron-deficient bromoarenes and all of the above-mentioned acetylenic substrates proceeded with high, but not complete diastereoselectivity (*E/Z* selectivity). All reactions involving electronically neutral, or electron-rich bromoarenes provided complete selectivity.

Next, we investigated various phosphorus-substituted acetylenes as potential reaction partners. We were pleased to find that esters, ketones, and nitriles bearing phosphoryl or phosphinoyl functions entered the reaction with bromobenzene, affording the target cyclopentanes (**49–54**) with moderate to good yields and complete diastereoselectivity. Compound **49** was isolated with a low yield due to difficulties in the isolation and purification.

Finally, we were pleased to find that the developed protocol is also applicable to the remarkably less active aryl chlorides (Table 4). Both electron-rich and electron-deficient chloroarenes, as well as heteroaryl chlorides (2-chloropyridine) entered the reaction, yielding the expected products in moderate to good yields (39–69%). Interestingly, electron-deficient chloroarenes gave products with low diastereoselectivity, in contrast to their corresponding aryl bromides which provided the products as single isomers (except 4-nitrobromobenzene).

The postulated mechanism, based on the observations of the reaction outcome, several control experiments, and literature data, is depicted in Scheme 1. First, the bromoarene undergoes fast oxidative addition to Pd(0) complex **57** (formed upon the activation of the precatalyst with a base)¹⁵ leading to the

formation of aryl-Pd(II) species **58** which coordinates to the alkyne moiety. Then, intramolecular nucleophilic addition to the activated unsaturated system occurs, providing vinyl-Pd(II) species **60** which undergoes facile reductive elimination affording the expected product **61** and reconstituting the Pd(0) complex **57**. Although the above mechanism seems viable for the majority of the investigated reactions, for some specific combinations of substrates, alternative scenarios should also be considered. For instance, the formation of chelate **62** (possibly being in equilibrium with **59**), in which palladium is bound by both alkyne and active methylene moieties, could facilitate the insertion of the Pd-arene to the alkyne (*syn*-carbometallation), and thus rationalize the formation of some amount of another diastereoisomer of the product with altered configuration at the exocyclic double bond (**64**).

Oxidative addition to Pd(0) ligated to a single electron-rich monophosphine is fast. In fact, oxidative addition of bromoarene to XPhos-Pd(0) complex proceeds within minutes at room temperature, as observed by ^{31}P NMR spectroscopy. Reductive elimination from Pd complexes of sterically demanding ligands is also facile. In particular, we have recently shown that the reductive elimination is not a rate-limiting step in the XPhos-Pd-catalyzed tandem cyclization/coupling of ϵ -acetylenic β -ketoesters with aryl bromides (Scheme 2a).⁸ The tandem reaction of ketoester **65** with bromobenzene is much slower than Negishi coupling of compound **66** with diphenylzinc, both proceeding through reductive elimination from a common intermediate **67**. This points towards the conclusion that the cyclization step is a bottleneck of the transformation. In order to shed more light on the influence of the structure of reagents on the reaction outcome, we compared the rate of

reactions of bromobenzene with three acetylenic substrates – derivatives of malonate **1**, β -ketoester **65**, and β -diketone **68** (Scheme 2b). As expected, malonate **1** reacted significantly slower than ketoester **65**, providing the corresponding product in only 21% yield after 1 h, compared to 90% for **65**. This is due to considerably lower C–H acidity of the malonate. Surprisingly, under identical conditions, the more C–H acidic β -diketone **68** delivered the product with only 14% yield. Competition experiments, involving pairs of acetylenic substrates (1 equiv. of each) and bromobenzene (1 equiv.) were also conducted (Scheme 2c). A reaction involving ketoester **65** and malonate **1** delivered only the product of the cyclization/coupling of **65**, demonstrating the huge difference in their reactivity. Despite diketone **68** reacting slower than malonate in a parallel experiment (see: Scheme 2b), in the competition experiment it provided higher yield of the corresponding product (60% and 31%, respectively). Similarly, the cyclization of ketoester and diketone occurred at comparable rates under the competition conditions (42% and 27%, respectively), in contrast to the parallel experiment (90% vs. 14%). The remarkably slow reaction of diketone **68** could be attributed either to the lower nucleophilicity of its enolate due to extended resonance stabilization, or the capability for the formation of stable complexes with palladium.¹⁶ The relatively stable palladium complex with diketone (or its anion) could possibly be in tautomeric equilibrium with Pd-alkyne complex suitable for intramolecular nucleophilic addition leading to **61**. Thus, the involvement of arylpalladium **58** in complexation with diketone **68** could make it less available for the catalytic transformation of the more reactive ketoester **65** in the competition experiment.

Competition experiments of malonate **1** with pairs of electronically divergent bromoarenes revealed the preference for the reaction with the more electron-deficient substrate (Scheme 2e). This stays in contrast with the outcome of the parallel experiments of **1** with each of the above bromoarenes showing comparable rates (Scheme 2d). Apparently, oxidative addition is not a rate limiting step, although in control experiments it determines the ratio of aryl-Pd(II) intermediates, which in turn dictates the final product distribution.

Another factor used for better understanding the reaction mechanism is the stereochemical outcome of the transformation. All of the reactions with malonates proceeded with complete diastereoselectivity, arising from *anti*-carbopalladation of the alkyne moiety. Similarly, other acetylenic active methylene compounds delivered the corresponding products as single isomers, unless electron-deficient bromoarenes (*e.g.* *p*-bromobenzonitrile) were used as coupling partners. In this case, the isomer with the alternate configuration on the double bond was formed to some extent, suggesting an alternative pathway for these sets of substrates (Scheme 1, dashed lines).

General procedure A for Pd-catalyzed carbocyclization-coupling of aryl bromides with acetylenic active methylene compounds

In a drybox, a 4 ml screw-cap vial was charged with XPhos Pd G3 (6.8 mg, 8 μmol), aryl halide (0.5 mmol), K₃PO₄ (127.2 mg, 0.6 mmol), DMF (1 ml), and a magnetic stirring bar. Then, acetylenic active methylene compound (e.g. dimethyl pent-4-yn-1-ylmalonate **1**) was added (0.4 mmol), the vial was tightly sealed and removed from drybox. The reaction mixture was stirred for 24 h at 50 °C in a heating block, then cooled to room temperature, quenched with 20 ml of an NH₄Cl solution, added to 10 ml of water, and extracted with MTBE (3 × 10 ml). The combined organic phases were dried with Na₂SO₄, filtered, and concentrated. The crude product was purified by column chromatography on silica gel.

Conclusions

In summary, we developed an efficient protocol for tandem Pd-catalyzed intramolecular addition of active methylene compounds to alkynes, followed by subsequent cross-coupling with (hetero)aryl bromides and chlorides. The methodology features exceptional tolerance to functional groups (including unprotected OH, NH_2 , or enolizable ketones), broad applicability of aryl and heteroaryl bromides of different electronic properties, as well as a range of active methylene partners,

including acetylenic derivatives of malonates, cyanomalones, β -ketoesters, β -diketones, cyanoacetates, and organophosphorus compounds. Mechanistic studies revealed a plausible mechanism comprising oxidative addition of haloarene, nucleophilic addition to alkyne activated by coordination to aryl-Pd(II), and reductive elimination. However, for the transformations of less C–H acidic substrates (e.g. β -ketoesters, β -diketones) and electron-deficient haloarenes, an alternative path involving *syn*-carbometallation may operate in parallel.
