Photoredox-mediated remote C(sp³)–H heteroarylation of free alcohols†

Guo-Xing Li, a Xiafei Hu, a Gang He,*a and Gong Chen†ab

We report an efficient and economical method for remote δ C(sp³)–H heteroarylation of free aliphatic alcohols using a hypervalent iodine PFBI-OH oxidant under photoredox catalysis. The reaction sequence involves in situ alcoholysis of PFBI-OH with alcohol, generation of an alkoxy radical intermediate by SET reduction, 1,5-HAT, and Minisci-type C–C bond formation. This method uses a slight excess of alcohols, can facilitate reaction at δ methyl and methylene positions, and has been successfully applied to modification of complex drug molecules.

Introduction

Selective C(sp³)–H functionalization of easily accessible aliphatic alcohols could streamline the synthesis of alcohols of complex structures. Radical-mediated reactions based on the 1,5-hydrogen atom transfer (1,5-HAT) of an alkoxyl radical intermediate have been widely used to functionalize the remote δ C(sp³)–H bond of alcohol derivatives even in complex molecular settings. While great success has been achieved using various pre-activated derivatives of alcohols, the corresponding reactions of free alcohols are more desirable but pose a significant challenge due to the strong O–H bond (∼105 kcal mol⁻¹). A few exciting advances featuring new catalysis strategies have emerged recently (Scheme 1A). Notably, Zuo demonstrated δ C–H amination of primary alcohols with azodicarbonyl using a cerium photocatalyst. Jiao reported a δ C–C bond forming reaction with sulfonyl oxime ether using a Ag(I) catalyst and K₂S₂O₈ oxidant. Zhu reported a δ C–H Minisci-type heteroarylation of alcohols using a PhI(OTFA)₂ (PIFA) oxidant and LED light irradiation. In Zhu’s report, 5 equiv. of alcohols are typically required and the δ C–H bonds of alcohols are limited to unactivated secondary and tertiary C–H. Herein, we report an efficient and economical protocol for δ C(sp³)–H heteroarylation of free aliphatic alcohols with various N-heteroarenes using a perfluorinated hydroxybenziodoxole (PFBI-OH) oxidant under photoredox catalysis (Scheme 1C).

Results and discussion

The Minisci reaction via radical pathways offers a convenient strategy to access complex heteroarenes from simple precursors. In our previous studies, we discovered that benziodoxole...
reagent BI-OAc 1, a cyclic hypervalent iodine(III), can promote C–H alkylation of various electron-deficient N-heteroarenes with alkyl boronic acid and alkyl carboxylic acid under photoredox catalysis (Scheme 1B). Interestingly, these two reactions proceed through different mechanisms.

The I-OAc bond of BI-OAc 1 can be activated by single electron transfer (SET) reduction by photoexcited Ru(II)* to form an acetate anion and BI radical (see fluorinated analog 35 in Scheme 4E), which reacts with boronic acid (RB(OH)2) to generate an alkyl radical intermediate following deboronation. In contrast, carboxylic acid (RCO2H) can undergo ester exchange with BI-OAc to form BI-O2CR, which can be activated by SET reduction to generate a BI anion and carboxyl radical, which provides an R radical following decarboxylation.

Encouraged by the BI-OAc-mediated activation of carboxylic acid and a recent study by Chen on BI-mediated β-C–C scission reactions of cycloalkyl alcohols under photoredox catalysis, we began to test whether common aliphatic alcohols can react with a suitable BI reagent to generate an alkoxyl radical, which can be trapped with N-heteroarenes to give useful products. As shown in Table 1, we were pleased to find that the reaction of pentanol (1.5 equiv.) with 4-chloroquinoline 4 (1 equiv.) gave alkylation product 4a with an exclusive δ regioselectivity in 80% isolated yield using 1.35 equiv. of PFBI-OH 2 and 0.5 mol% of Ru(bpy)3Cl2 in hexafluoroisopropanol (HFIP) solvent at 30 °C under irradiation with a 23 W compact fluorescent lamp (CFL). In comparison, the use of BI-OAc 1, BI-OH 5, and other benziodoxoles bearing different aromatic substituents gave considerably lower yield (entries 2–4). Reaction with acyclic I(III) reagents including PhI(OTFA)2 or PhI(OAc)2 also proceeded in low yield under our optimized conditions (entries 5 and 7). Other important observations regarding the reaction optimization include the following: (1) no α-heteroarylation product 4aα was obtained. Little butyl-substituted product 4aα (<2%) via the β-scission pathway of a pentoxy radical intermediate was obtained. (2) HFIP solvent is critical for obtaining high yield (entries 12 and 13). (3) While the use of 1 equiv. of alcohol 3 gave 42% yield of 4a, increasing the amount of 3 from 1.5 to 2 equiv. only slightly improved the yield (entries 15 and 16). (4) The reaction yield is sensitive to the amount of 2 used (entries 17 and 18). (5) A reaction conducted under a CFL in the absence of Ru(bpy)3Cl2 gave no product (entry 11). (6) Pre-stirring of 3 and 2 is unnecessary.

α NMR yield. β Isolated yield on a 0.4 mmol scale.
We next examined the scope of alcohols and N-heteroarenes under optimized conditions (Schemes 2 and 3). In general, reaction of primary and secondary alcohols proceeded in good to excellent yield with exclusive $\delta$ selectivity. Alcohols bearing relatively weak benzylic (4f), allylic (4h), $\alpha$ C–H of ether (4j), and tertiary (4e) C(sp$^3$)–H bonds also worked well. A wide range of functional groups including terminal alkene and alkyne (4h and 4g), Cbz (4k), azido (4i), ester (4l), aldehyde and ketone (13 and 10), halo (4l), and even pinacol boronate (15 and 26) groups were tolerated. Alcohols without any $\beta$-substituent usually gave little $\beta$-scission/alkylation side product. As shown in 4p, a small amount of 4-heptyl substituted byproduct (16%) was formed with 2-propylpentanol. While the radical functionalization of $\delta$ methylene C–H bonds of alcohols and their derivatives has been widely demonstrated in previous studies, we were pleased to find that our reaction at the more challenging $\delta$ methyl group also proceeded in good yield (see 4t, 4u, 23–25, 28 and 29) under slightly more forced conditions with 3 equiv. of alcohols and 2 equiv. of PFBI-OH. In comparison, N-heteroarylation at the methide position gave little product (see 4v) probably due to oxidation of the 3$^\circ$/C14 radical to a 3$^+$ cation.$^{19}$ As shown by 4s, tertiary alcohols gave little $\delta$ functionalization product.$^{20}$

As shown in Scheme 3, electron deficient N-heteroarenes showed good to excellent reactivity with various alcohols under the standard conditions. Chemoselectivity typical of Minisci reactions was observed for heteroarenes such as quinolines (8–11), isoquinolines (12–15), phenanthridine (16), phthalazine (17), quinoxaline (18), azaindole (19), and benzothiazole (20). Reaction of symmetric phthalazine (17) and pyridines (21 and 25) mainly gave mono-alkylation products. Reaction of complex N-heteroarene-containing drug molecules also worked well. For instance, reaction of famciclovir with 7-octyn-1-ol gave 27 in 53% yield. Reaction of quinoxyfen with 9-borylnonanol gave 26 in 67% yield. Reaction of tarocin A1 and camptothecin with 1-butanol gave 28 and 29 bearing a simple alkyl alcohol handle in good yield.

**Scheme 2** Scope of alcohols. Isolated yields on a 0.4 mmol scale. *3 equiv. of 1-alcohol and 2 equiv. of PFBI-OH were used, 36 h. *16% of 4-heptyl substituted side product was obtained.

**Scheme 3** Scope of N-heteroarenes. Isolated yield on a 0.4 mmol scale. *3 equiv. of alcohol and 2 equiv. of PFBI-OH were used, 36 h.
Preliminary experiments were carried out to probe the reaction mechanism (Scheme 4). Similar to the ester exchange reaction of BI-OAc 1 with carboxylic acids, PFBI-OH 2 can readily undergo alcoholysis with 1-butanol in HFIP at rt to give PFBI-OBu 30 (Scheme 4A). Reaction of 4-chloroquinoline 4 with 30 under similar photoredox conditions gave product 34 in comparable yield as with using PFBI-OH 2 and BuOH (63%) in Scheme 2. Stern–Volmer (SV) fluorescence quenching experiments of Ru(bpy)_3Cl_2 showed that the Ru(II)* excited state is quenched by PFBI-OBu 30, but not by 4-chloroquinoline 4 (Scheme 4C). In comparison, quenching of Ru(II)* by PFBI-OH 2 also occurs but with a much smaller SV quenching constant (K_{SV}) than when using 30 (83 vs. 382), indicating a weaker oxidative quenching ability of 2.

As shown in Scheme 4D, reaction of 4 with isobutanol 31, bearing a β substituent but lacking δ C–H bonds, gave product 32 in high yield. This indicated that the corresponding isobutoxy radical is generated and then undergoes β-scission to form an isopropyl radical. Based on these pieces of evidence, we propose that the reaction of alcohol 33 starts with alcoholysis with PFBI-OH 2 to form 34 (Scheme 4E). 34 can be activated by SET reduction by Ru(II)* to give Bz0 anion 36 and alkoxyl radical 37.

The fluoro substitution on benziodoxole probably makes the iodo center of PFBI-OH 2 more electrophilic for alcoholysis and makes 34 more easily reducible by SET. The 1,5-HAT reaction of 37 gives C-radical 38, which reacts with N-heteroarenes to give 41. SET oxidation of 41 by Ru(III) gives the alkylated product 42 and regenerates Ru(II). Alternatively, 41 could be oxidized by 34 to form 42 and 37, propagating a radical chain reaction. In principle, alkoxyl radical 37 can also undergo β-scission to give 39 and shortened alkyl radical 40. In our system, we found that this competing pathway was negligible for alcohols bearing no β substituent (see 40, R'' = H).

Conclusions

In summary, we have developed an efficient and economical method for remote C(sp^3)–H heteroarylation of free aliphatic alcohols under mild conditions using photoredox catalysis. The reaction sequence involves facile in situ alcoholysis of PFBI-OH with alcohol, generation of an alkoxyl radical intermediate by SET reduction, 1,5-HAT, and Minisci-type C–C bond formation. The reaction shows broad substrate scope for both alcohols and N-heteroarenes. Importantly, this method uses a slight excess of alcohols, can facilitate reaction at the δ methyl and methylene positions, and has been successfully applied to modification of complex drug molecules. The high electrophilicity of PFBI-OH is critical to achieving high efficiency without the use of a large excess of alcohols. Remote C–H functionalization reactions of other types of substrate using a similar strategy are currently under investigation.

Notes and references

7 During the preparation of this manuscript, the following work by Zhu was published online. X. Wu, H. Zhang, N. Tang, Z. Wu, D. Wang, M. Ji, Y. Xu, M. Wang and C. Zhu, Nat. Commun., 2018, 9, 3343.

16 For the original report of PFBI-OH 2, see: R. D. Richardson, J. M. Zayed, S. Altermann, D. Smith and T. Wirth, Angew. Chem., Int. Ed., 2007, 46, 6529. PFBI-OH can be readily prepared on the gram scale in 2 steps from a cheap precursor (2,3,4,5-tetrafluorobenzoic acid, <$250 per kg).

Alcoholysis of PFBI-OH 2 with tertiary alcohol is probably hampered by steric effects.

20 HFIP is a weak acid. We suspect that proton-coupled electron transfer may be involved in SET reduction of 34, forming BzOH and 37. In comparison, formation of PFBI radical 35 via SET reduction of 34 is possibly less favoured due to the weaker basicity of the alkoxyl O on 34. PFBI-OH
2 could also be activated by SET reduction to generate PFBI radical 35. The use of slightly more alcohol than PFBI-OH 2 (1.5 vs. 1.35 equiv.) might help suppress the formation of 35.  
22 Our previous study showed that PFBI radical 35 is more electrophilic for H-abstraction than the corresponding plain BI radical (ref. 19).

23 Even reactions with butanol gave little propyl-substituted side products (see 41). As seen with isobutanol 31, some β-substituted alcohols can readily undergo β-scission to form more stabilized C-radical 40, which can be effectively engaged in the subsequent Minisci reaction. Detailed study of this transformation will be reported in a future paper.
