A reactive coordinatively saturated Mo(III) complex: exploiting the hemi-lability of tris(tert-butoxy)silanolate ligands†

Margherita Pucino, Florian Allouche, Christopher P. Gordon, Michael Wörle, Victor Mougell and Christophe Copéret

Coordinatively unsaturated Mo(III) complexes have been identified as highly reactive species able to activate dinitrogen without the need for a sacrificial reducing agent. Here, we report a coordinatively saturated octahedral Mo(III) complex stabilized by $\kappa^2$-tris(tert-butoxy)silanolate ligands, which is yet highly reactive towards dinitrogen and small molecules. The combined high stability and activity are ascribed to the dual binding mode of the tris(tert-butoxy)silanolate ligands that allow unlocking a coordination site in the presence of reactive small molecules to promote their activation at low temperatures.

Results and discussion

Mo(OSi(OtBu)_3)_3, 1, is prepared by reaction of [Mo(N(R)Ar)_3] with ($\text{tBuO}_2$)Si=O-H (TBOS-H) in a slurry of diethyl ether at $-80 \degree C$; it is isolated as dark brown crystals in 36% yield after evacuation of the solvent and aniline byproduct under high vacuum at low temperature, followed by crystallization from pentane. NMR studies indicate a quantitative reaction, but the tedious isolation of this compound, which is required to separate the highly soluble compound 1 from the residual amine, diminishes the overall isolated yield for the pure crystalline form significantly. Compound 1 is, however, stable for months when in the solid state under an argon atmosphere at $-35 \degree C$ and is rather stable in apolar solvents such as benzene, allowing investigation of its reactivity with small molecules in solution (Scheme 1).

Single-crystal X-ray diffraction† shows that complex 1 adopts a distorted octahedral geometry with three $\kappa^2$-TBOS ligands, where the Mo–O distance of the silanolate is $ca. 0.3 \text{ Å}$ shorter than that of the tert-butoxy moiety($2.020(4) \text{ Å}$ vs. $2.302(4) \text{ Å}$) (Fig. 1). The $^1$H NMR spectrum of 1 shows a single very broad

Introduction

The presence of a Mo center in the active site of the FeMo cofactor of nitrogenase enzymes has stimulated numerous studies on the synthesis of low valent Mo complexes and their reactivity towards small molecules. Trivalent Cr or Ga, while terminal $k^1$ modes are found for larger metal ions such as trivalent Cr or Ga, while terminal $k^2$ modes are found for larger metal ions such as trivalent Sc, Yb, Lu or Dy. Mo(III) possesses a distorted octahedral geometry with three $k^2$-$\text{TBOS}$ ligands. Coordination of the $\text{TBOS}$ ligand in a bidentate $k^2$-fashion prevents dimerization and allows isolating a mononuclear Mo(III) complex, while the flexibility of its binding mode provides high reactivity as evidenced by the activation at low temperature of small molecules like $\text{N}_2$, $\text{N}_2\text{O}$ and $\text{CO}_2$, among others.
The fluxionality of the ligand prompted us to further investigate the reactivity of 1 towards small molecules, namely N₂, N₂O and CO₂. Exposing 1 to a N₂ atmosphere at room temperature led to an immediate color change from amber to dark blue within seconds. This blue color fades away after 2 h at room temperature, leaving a colorless solution.

Removal of all volatiles followed by extraction in pentane and crystallization at −35 °C affords the Mo(VI) nitride complex [Mo(N)(TBOS)₃]₂, in 40% yield. The relatively low isolated yield reflects the high solubility of the material, despite the quantitative reaction yield according to NMR. Single crystal X-ray analysis of 2 (Fig. 2a) shows a tetrahedral terminal nitride complex of Mo(VI) with three κ₁-TBOS ligands (Scheme 3); the limited quality of the collected data however precludes an accurate discussion of bond distances. The presence of a nitride ligand was confirmed by FTIR, as evidenced by a band at 1011 cm⁻¹ associated to ν(Mo≡N). To unequivocally verify the signal, we carried out the reaction with ^15N₂. The infrared spectrum of ^15N≡Mo(TBOS)₃ shows a band at 997 cm⁻¹ that is red shifted compared to its ^14N analogue, consistent with their attribution to Mo≡N vibration. ¹H NMR of 2 shows a single and sharp peak at 1.49 ppm, in agreement with a Mo(VI) diamagnetic species. The blue resonance at 3.82 ppm (J = 164 Hz, RT), suggesting a fluxional coordination of the tert-butoxy moieties in solution. At −80 °C, the ¹H NMR spectrum displays three peaks at 22.6, 4.9 and −1.36 ppm, in agreement with the three inequivalent tert-butoxy groups (see the ESI for details). However, complex 1 still displays broad peaks at this temperature, suggesting fast dynamics of the methyl groups. The magnetic susceptibility (μ_eff = 3.74 μ_B) measured by the Evans method at 298 K is close to the expected value for a d³ complex with three unpaired electrons (3.75 μ_B).

We first explored the reaction of complex 1 with alkenes (ethylene and isobutene) as well as alkynes (2-butyne). By condensing the gas at a low temperature (−196 °C) in the solution and then warming to room temperature, the corresponding π-complexes were obtained in quantitative yields (Scheme 2, see the ESI† for details). The alkene and alkyne adducts [Mo(C₂H₄)(OSi(OtBu)₃)₃], 1-(ethylene), [Mo(C₄H₈)(OSi(OtBu)₃)₃], 1-(isobutene), and [Mo(C₄H₆)(OSi(OtBu)₃)₃], crystallize in a tetrahedral geometry, while 1-(but-2-yne) still displays broad peaks at this temperature, suggesting fast dynamics of the methyl groups.

Fig. 2 Thermal ellipsoid plot at 50% probability of (a) 2 and (b) 3. Hydrogen atoms, siloxide methyl groups and disorder have been omitted for clarity.
intermediate observed upon N₂ addition can be isolated by rapid cooling of the reaction mixture (−196 °C) followed by fast solvent-exchange at 5 °C (from benzene-d₆ to pentane) and crystallization at −35 °C. A dimeric Mo dinitrogen complex, (μ⁻N₂)[Mo(TBOS)₃]₂, 3, is isolated as dark blue crystals. Single crystal X-ray analysis of 3 (Fig. 2b) displays two Mo ions in a distorted TBP (Trigonal BiPyramidal) geometry with two κ¹ and one κ² TBOS ligands along with the end-on bound dinitrogen molecule sandwiched between the two Mo centers (Mo1–N1–N2 and N1–N2–Mo2 angles of 172.5(3)° and 169.0(3)°, respectively). The N1–N2 distance is notably elongated with respect to the free N₂ molecule (1.209(5) Å vs. 1.0976(2) Å (ref. 11)) indicating a significant degree of activation. When 3 is warmed to room temperature the subsequent step of the overall 6 e⁻ reduction of N₂ occurs, leading to the formation of two equivalents of 2 (Scheme 3). While this mechanism is similar to the one observed with coordinatively unsaturated tris-amido complexes, the complete process is much faster with 1 (2 h for the quantitative reaction at room temperature vs. less than 5% conversion after 12 h at 28 °C for Mo(NtBuAr)₃). It is worth noting that the corresponding complex bearing three very large siloxy ligands – Mo(OSiBu₃)₃ – does not activate dinitrogen. This high reactivity towards N₂ reduction is unusual for an octahedral Mo(III) complex, and highlights the particularity of the TBOS ligand, which can adopt mono- or bidentate binding modes while being relatively small compared to larger siloxy (e.g. (Bu₅SiO)₉ or N(tBu)(3,5-Me₂C₆H₃) ligands.⁷⁵

To corroborate our data, we performed DFT calculations in order to better understand the reactivity difference between these three systems. Due to the very large size of the investigated systems, we calculated the entire potential free energy surface with simplified models and calculated all reaction intermediates with the full ligand set (Scheme 4). The DFT calculations show that if electronic effects were the dominant factor (small models), one would predict the tris-amido system to be the most effective for N₂ cleavage (TS energy of 17.2 kcal mol⁻¹ above separated reactants), while the siloxy derivatives should have significantly lower reactivity (with TS energies of 27.4 and 30.9 kcal mol⁻¹ for 1 and the model siloxy derivatives) in contrast with the observed trend, i.e. 1 reacts much faster with N₂ than the Cummins Mo(III), while the Wolczanski analog is unreactive towards N₂ (Scheme 4).
Once steric contributions are taken into consideration, it is notable how 1 yields more energetically accessible reaction intermediates and a significantly more stable nitrido complex: dinitrogen coordination costs only 6 kcal mol\(^{-1}\) for 1 vs. 13–15 kcal mol\(^{-1}\) for the two others, and the formation of the dimeric species prior to \(\text{N}_2\) activation costs only 13 kcal mol\(^{-1}\) for 1 vs. 27 and 33 kcal mol\(^{-1}\) for the Cummins and Wolczanski systems, respectively, in line with their relative difference of reactivity. Overall, the DFT calculations show that the TBOS ligand favors \(\text{N}_2\) activation because of its hemilability while protecting Mo(III) thanks to the possible \(\kappa^2\)-configuration.

We then further explored the reactivity of 1 towards other small molecules. Upon exposure to \(\text{N}_2\)\(_2\), a solution of 1 undergoes fast color change from amber to bright yellow upon warming up from liquid nitrogen temperature to room temperature (Scheme 4). Analysis of the reaction mixture by \(^1\)H NMR shows the presence of two peaks at 1.51 and 1.50 ppm. FTIR analysis of this reaction mixture after removal of the solvent \textit{in vacuo} reveals the presence of an intense band at 1678 cm\(^{-1}\) which is attributed to Mo nitrosyl.\(^{16,21}\) Two species are obtained as crystals, and X-ray crystallography analyses revealed species 2 and [Mo(NO)(TBOS)]\(_3\), 1-NO (Scheme 5). The nitrosyl compound 1-NO crystallizes in a distorted TBP geometry, with a linear NO ligand ([Mo–N–O = 178.6(2)\(\text{Å}\)]) in the apical position and a \(\kappa^2\)-TBOS ligand. The Mo–NO bond distance of 1.715(3) \(\text{Å}\) is consistent with the literature value for linear nitrosyl complexes of Cummins and Zubiesta, two molybdenum thiolate species with metal–nitrogen distances of 1.769(13) and 1.766(6) \(\text{Å}\), respectively.\(^{21a,22}\) It is slightly shorter, consistent with the weaker trans influence of the siloxy ligand. Despite a high kinetic barrier to reduction, the activation of \(\text{N}_2\)\(_2\) has been observed with numerous low valent metal complexes.\(^{23}\) However, the majority of metal-mediated activation of \(\text{N}_2\)\(_2\) generally involves the scission of the N–O bond, as the N–N bond is significantly stronger (\(~481\) \text{kcal mol}\(^{-1}\) and \(~167\) \text{kcal mol}\(^{-1}\) for \(\text{N}_2\)\(_2\) and \(\text{N}_2\)–N, respectively) with a few examples of N–N bond activation,\(^{6c,21e-24}\) highlighting the high azophlicity of the Mo complex 1. The extremely challenging purification\(^{21a}\) of the reaction mixture did not allow any further characterization of 1-NO and of the impurities which appear to be paramagnetic.

Compound 1 when in contact with \(\text{CO}_2\) also results in a rapid color change from amber to red upon warming from the liquid nitrogen temperature to room temperature, to yield a 1 : 1 ratio of two compounds according to NMR spectroscopy. Crystallization of the reaction mixture from pentane at \(-35\ \text{°C}\) affords two sets of red crystals, assigned to [Mo(O)(TBOS)]\(_3\), 4, and [Mo(CO)(TBOS)]\(_3\), 1-CO (Fig. 3) according to X-ray single-crystal diffraction studies. The X-ray diffraction analysis of the monocarbonyl complex 1-CO shows that the CO-adduct adopts a distorted TBP geometry with a \(\kappa^2\)-TBOS ligand. The CO ligand occupies an axial position and is almost linear with a Mo–C–O angle of 175.2(3)\(\text{°}\). The Mo–C and C–O distances of 1.931(3) \(\text{Å}\) and 1.156(3) \(\text{Å}\), respectively, are in between those of Mo(CO)\(_6\) (Mo–C 2.059(3) \(\text{Å}\) and C–O 1.125(5) \(\text{Å}\))\(^{25}\) and [Mo(CO)(Ph\(_2\)-PCH\(_2\)-CH\(_2\)-PPh\(_2\))\(_2\)] (Mo–C 1.90(1) \(\text{Å}\) and C–O 1.19(1) \(\text{Å}\))\(^{24}\) indicating a \(\pi\)-back-donation on the carbonyl, comparable to that of cis-(diethylentriamine)molybdenum tricarbonyl.\(^{27}\) This is consistent with the red shift of the \(e(C=O)\) band at 1869 cm\(^{-1}\) observed in the FTIR spectrum, which can be attributed to the weak \(\sigma\)-donor ability of the TBOS ligand.\(^{28}\) Complex 1-CO can also be synthesized upon exposing 1 to an excess of carbon monoxide, see the ESI† for details. The structure of 4 presents a Mo(v) complex in a distorted TBP geometry with an equatorial oxo moiety with no trans ligand. The Mo=O bond length is 1.665(2) \(\text{Å}\), which lies in the usual range for terminal Mo(v) oxo complexes.\(^{29}\)

Scheme 5 Reaction of 1 with \(\text{N}_2\)\(_2\) and \(\text{CO}_2\).
Conclusions

In conclusion, we have shown that the TBOS ligand can bind Mo(III) in a bidentate $\kappa^2$-fashion, providing an isolable – yet highly reactive – mononuclear octahedral Mo(III) complex. This complex thus activates a large variety of small – often rather inert – molecules, cleaving N–N and C–O bonds at low temperatures. An example is the 6-electron reduction of $N_2$, which occurs faster than with other tri-coordinated Mo(III) complexes. The high reactivity of this coordinatively saturated complex illustrates the high adaptability of the TBOS ligand, which occurs faster than with other tri-coordinated Mo(III) activation at Mo centers.
