Advances and challenges in electrochemical CO$_2$ reduction processes: an engineering and design perspective looking beyond new catalyst materials

Sahil Garg,$^{a}$ Mengran Li,*$^{a}$ Adam Z. Weber,$^{b}$ Lei Ge,$^{b}$ Liye Li,$^{d}$ Victor Rudolph,$^{a}$ Guoxiong Wang$^{a}$ and Thomas E. Rufford$^{a,*}$

Electrochemical CO$_2$ reduction (CO$_2$R) is one of several promising strategies to mitigate CO$_2$ emissions. Electrochemical processes operate at mild conditions, can be tuned to selective products, allow modular design, and provide opportunities to integrate renewable electricity with CO$_2$ reduction in carbon-intensive manufacturing industries such as iron and steel making. In recent years, significant advances have been achieved in the development of highly efficient and selective electrocatalysts for CO$_2$R. However, to realize fully the potential benefits of new electrocatalysts in low cost, large scale CO$_2$R electrolyzers requires advances in design and engineering of the CO$_2$R process. In this review, we examine the state-of-the-art in electrochemical CO$_2$R technologies, and highlight how the efficiency of CO$_2$R processes can be improved through (i) electrolyzer configuration, (ii) electrode structure, (iii) electrolyte selection, (iv) pH control, and (v) the electrolyzer’s operating pressure and temperature. Although a comprehensive review of catalytic materials is beyond this review’s scope, we illustrate how other engineering and design decisions may also influence CO$_2$R reaction pathways because of effects on mass transfer rates, the electrode surface chemistry, interactions with intermediate reaction species, and rates of charge transfer.

1 Introduction

Utilization of CO$_2$ from industrial waste gases is considered a complementary route to other CO$_2$ emission reduction strategies such as renewable energy sources, CO$_2$ capture and storage (CCS), and other low carbon emission technologies.$^1$ The main pathways to utilize CO$_2$ include reuse of CO$_2$ without
conversion (e.g. enhanced oil recovery, supercritical CO₂) or to convert the CO₂ to a valuable fuel, energy storage vector, or chemical feedstock. Among CO₂ conversion technologies such as biochemical, photosynthetic, thermo-catalytic, and photocatalytic processes, electrochemical CO₂ reduction (CO₂R) is one of the most promising CO₂ utilization strategies because of the mild electrolyzer operating conditions, opportunities to tune the process towards desired products, the potential to use industrial or municipal wastewaters as electrolytes, and modular reactor designs. In addition, CO₂R technologies could be integrated with renewable electricity generation from solar or wind (as shown in Fig. 1) to reduce carbon footprints in carbon intensive manufacturing industries such as ammonia production or iron and steel production through CO recycling, for example.

Table 1 shows several organisations report electrochemical CO₂R technologies to operate at pilot-scale with current densities in the range j = 100–200 mA cm⁻². These technologies could lead to commercially viable processes to convert CO₂ to CO, light hydrocarbons including CH₄ and C₂H₄, alcohols, and chemical feedstocks like formic acid (HCOOH). However, most of these technologies are currently too costly for practical applications and market penetration. The first challenge to low cost CO₂R is the high energy requirement to break bonds in the CO₂ molecule. The second challenge is to achieve a high selectivity of CO₂ to desired products to minimize costs and complexity of product separation processes. Achieving high selectivity is difficult because a large number of CO₂R reactions and the competing hydrogen evolution reaction (HER) all have standard potentials (E°) in a narrow range (−0.25 V to 0.17 V vs. standard hydrogen electrode (SHE)) as shown in Fig. 2. The

Adam Z. Weber is a staff scientist and Group Leader of the Energy Conversion Group at Lawrence Berkeley National Laboratory, USA. Adam holds B.S. and M.S. degrees from Tufts University, and a Ph.D. in chemical engineering from the University of California, Berkeley. He has authored over 100 peer-reviewed articles and 10 book chapters on fuel cells, flow batteries, and related electrochemical devices. Adam’s work has been recognized by a number of awards including a 2012 Presidential Early Career Award for Scientists and Engineers (PECASE), the 2014 Charles W. Tobias Young Investigator Award of the Electrochemical Society, and the 2016 Sir William Grove Award of the International Association for Hydrogen Energy.

Guoxiong (Geoff) Wang is a Professor in Chemical Engineering at the University of Queensland, Australia. Geoff received his BEng in 1983, MEng in 1986, and PhD in 1990 from Northeastern University, China and specialized in process metallurgy focusing on iron- and steel-making. He joined the University of Queensland in 1996 and leads research on modeling and simulation of the Chemical and Metallurgical Engineering processes, coalbed methane (CBM) extraction and carbon dioxide geo-sequestration with enhanced coalbed methane (CO₂-ECBM) recovery. His research activity and interests are directed towards developing energy and environmental technologies.

Lei Ge is a research fellow in the Centre for Future Materials at the University of Southern Queensland, and an adjunct fellow in the School of Chemical Engineering at the University of Queensland, Australia. He completed his PhD in 2013 at the University of Queensland and ME in 2008 at the Nanjing University of Technology, China. His research interests include materials for membrane separation and selective gas adsorption, metal organic frameworks related materials for electrolysis, and energy devices (e.g. fuel cells). Thomas (Tom) Rufford is an Associate Professor in the School of Chemical Engineering at the University of Queensland, Australia. Tom completed his Bachelor and PhD degrees in Chemical Engineering at the University of Queensland in 2000 and 2009, respectively, with four years engineering practice in the oil industry between these degrees. His research interests include electrode materials for supercapacitors and electrocatalysts for CO₂ reduction, industrial gas separation and purification technologies, and fluid-solid interactions in coal bed methane production systems. Tom has published more than 65 journal articles, 2 book chapters, and an edited book on carbon materials.
that a catalyst reviews with a critical analysis of engineering factors the scope of this article. Instead, we complement existing carbon materials. Further review of electrocatalysts is beyond energy can convert the captured CO2 into chemicals or fuels for direct usage or energy storage.

third challenge is to ensure the overall rate of reaction is not limited by rates of CO2 mass transfer from the gas phase to electrolyte and to active sites on the cathode catalyst. The fourth practical challenge is to maintain stable electrocatalyst performance over extended operating periods because the catalyst can be poisoned by impurities in the electrolytes or CO2 feed gas (e.g. sulphur compounds), or by products stemming from corrosion of the electrolyzer components.

To circumvent these challenges, a significant amount of research effort aims to develop highly efficient, stable, and selective CO2R electrocatalysts. Many comprehensive reviews on CO2R catalysts are available, and these reviews cover advances in transition metals, alloys, metal–organic complexes, metal chalcogenides, metal–nitrogen–carbon materials, and carbon materials. Further review of electrocatalysts is beyond the scope of this article. Instead, we complement existing catalyst reviews with a critical analysis of engineering factors that affect the performance of CO2R electrolyzers. These factors include the reactor configuration, electrode structures, electrolyte selection, and the choice of reaction conditions such as pH, pressure, and temperature. These engineering factors not only predetermine the CO2R mass-transport characteristics but can also have significant impacts on the catalytic reaction pathways. The review concludes with a discussion of the priorities for future research to understand better the fundamental mechanisms of CO2R and improve CO2R performance.

2. Working principles of electrochemical CO2 reduction

A typical CO2 electrolyzer (see for example Fig. 3a showing a H-cell type reactor used in research laboratories) consists of a cathode to reduce CO2 to products such as CO or HCOOH/ HCOO− and produce hydroxyl ions (OH−); an anode to oxidize water via the oxygen evolution reaction (OER) that consumes OH− or generates protons (H+) and electrons (e−); an electrolyte to conduct ions and to dissolve and transport CO2 to the cathode active sites; an ion-exchange membrane or porous diaphragm to separate the cathode and anode electrodes; and a voltage source with sufficient potential (E) to transfer electrons from anode to cathode. In such a system, there are several key steps involved in a CO2R process, including (1) mass transfer of CO2 from the gas phase to the bulk electrolyte, (2) transport of dissolved CO2 from the bulk electrolyte to cathode/electrolyte interface, (3) absorption of CO2 at the cathode surface, (4) dissociation of adsorbed CO2 species into adsorbed intermediates such as *COOH, *CO, CHO, and COH, (5) electron transfer from the cathode catalyst to intermediates, (6) desorption of products from the electrode, and (7) migration of products away from the cathode/electrolyte interface to the bulk gas or liquid phases.

We start our discussion at the electron transfer step (5) to examine the minimum theoretical energy requirement for CO2R. The minimum potential required for a CO2R reaction is the half-cell standard potential described by $E' = -\Delta G^\circ/nF$, where $\Delta G^\circ$ is the Gibbs free energy at 1 atm and 298 K, $n$ is the number of moles of electrons transferred in the half-cell reaction, and $F$ is Faraday constant (96 485 C mol$^{-1}$). For example, the half-cell reaction $\text{CO}_2(g) + 2\text{H}^+(aq.) + 2\text{e}^- \rightarrow \text{CO}(g) + \text{H}_2\text{O}(l)$ with $\Delta G^\circ = 20.09 \text{ kJ mol}^{-1}$ has $E' = -0.104 \text{ V vs. SHE}$. Other half-cell standard potentials at 1 atm and 298 K are shown in Fig. 2. To drive a sufficient CO2R rate, an excess voltage or overpotential to $E'$ must be applied to overcome the sum ($R_{\text{total}}$) of several energy barriers or resistances as described in eqn (1):

$$R_{\text{total}} = R_{\text{cathode}} + R_{\text{anode}} + R_{\text{ions}} + R_{\text{membrane}} + R_{\text{bubble,cathode}} + R_{\text{bubble,anode}} + R$$

The resistances include (1) the activation barriers or activation overpotentials ($\eta_a$) for CO2R at cathode ($R_{\text{cathode}}$) and OER at the anode ($R_{\text{anode}}$); (2) ohmic losses from conduction of ions ($R_{\text{ions}}$) in the bulk electrolytes, ion transport across the membrane ($R_{\text{membrane}}$); (3) loss of active electrode area from the bubbles formation at the electrodes (e.g. $R_{\text{bubble,cathode}}$ for CO and $R_{\text{bubble,anode}}$ for O2 at the anode); and (4) the sum ($R$) of electrical resistances in other cell components and contact resistances between components.

Because the CO2R reaction depletes CO2 concentrations at the electrode surface, at high current densities the overall reaction rate can be limited by the rates of CO2 mass-transfer to the electrode surface. In addition according to the Nernst equation, the change in concentration affects the equilibrium potential and this effect can be approximated by the concentration overpotential. In large scale industrial electrolyzers operating at high temperature concentration overpotential becomes important because at higher temperatures the activation overpotential is lower and the improved electrolyte conductivity leads to smaller ohmic losses. Therefore, now that we have established the minimum energy requirements for

$^a$ The information presented in above table is mostly collected from relevant papers or websites. Some companies have not publicly disclosed any data on CO$_2$ electrolysis amid high competition.
CO₂R, we will look next at the steps involved in transferring CO₂ from the gas phase to the electrode surface.

In most CO₂R electrolyzers, gaseous CO₂ is first dissolved in the liquid electrolyte, then transferred through the liquid to the cathode–electrolyte interface. This process is driven by CO₂ concentration gradients as illustrated in Fig. 4a, and the rate of CO₂ transfer depends on the interfacial contact area, film and overall mass transfer coefficients, and the overall concentration driving force. The concentration gradients in the system are dependent on the solubility of CO₂ in the electrolyte and the selected operating pressures and temperature of the electrolyzer.

However, prediction of these gradients is complex during CO₂R because acid/base reactions (for example CO₂ consumption by OH⁻) in the electrolyte can lead to non-linear deviation of the concentration away from Fick’s law behavior, which reduces the concentrations of CO₂ available to react at the electrode’s surface. This effect can be partially controlled with buffering electrolytes such as potassium carbonate (KHCO₃) to maintain pH at the cathode. The interfacial contact area can be maximized by reducing the size of gas bubbles injected to the electrolyte or using a 3D-structured electrode such as a gas diffusion electrode (GDE). The magnitudes of CO₂ and CO₂ product mass transfer coefficients generally increase with temperature, pressure, and the velocities of gas and liquid in the electrolyzer, but also are affected by electrolyte density, viscosity and solubility relationships.

Next we examine the cathode–electrolyte interface where CO₂R occurs in a typical aqueous electrolyzer. Cations in the electrolyte migrate towards the negatively charged cathode surface to form an electrochemical double layer (DL), as shown in Fig. 4b. This DL is formed by the outer Helmholtz layer (OHL) of fully-solvated cations, and the inner Helmholtz layer (IHL) of less-solvated halide ions or CO₂-related adsorbed species directly adsorbed at the electrode surface. The presence of this DL can affect CO₂R through several mechanisms. For example, the local electrical field between the negatively charged cathode and the positively-charged adsorbed cations has been reported to stabilize CO₂-related intermediates such as ∗CO₂ and ∗COOH. On the other hand, in the OHL solvated cations like Li⁺, Na⁺, and K⁺ act as a source of protons for the HER and disrupt the local pH within the DL. Another effect relates to interactions between anions and the electrode surface, which have been reported in some cases like I⁻ and a Cu surface to be strong enough to allow anion absorption within the IHL. In most cases, anions with a pKₐ close to the local pH may help buffer the pH and adsorbed ions may be directly involved in CO₂R pathways by affecting the binding strength or adsorption geometry of CO₂R intermediates such as ∗COOH. Fig. 4c illustrates that the concentrations and rates of consumption of protons, CO₂, and other species in the DL are directly proportional to the current density and product selectivity during a CO₂R reaction and these changes in the local reaction environment could occur even at low currents, and thus limit the

overall reaction rate before all available CO$_2$ becomes depleted at the electrode surface.$^{52,67}$

This background discussion of the principles of CO$_2$R highlights that even though the electrocatalyst determines the underlying reaction kinetics, other factors such as reactor configuration, electrode structure, and conditions including the type of electrolyte, pH, pressure, and temperature can affect the overall rate of CO$_2$R reactions.

2.1 Figures of merit to describe electrochemical CO$_2$R

We briefly describe here the figures of merit commonly used to evaluate and compare electrochemical CO$_2$R processes. These are Faradaic efficiency, current density, and energy efficiency.

- Faradaic efficiency (FE) is the ratio of the amount of charge used to form a product species (e.g. CO) calculated from Faraday’s law to the total charge ($Q$) supplied.$^{68}$

$$\text{FE}_{\text{product}} = \frac{\text{mol of product}}{\text{Q}}$$

where $y$ is the number of moles of the product species formed, $n$ is the moles of electrons transferred in the half-cell reaction per mole of product, and $F$ is Faraday’s constant.

- Current density ($j$ or CD) is the total current ($I$, in Amps) per unit area of the cathode ($A$, m$^2$ or commonly cm$^2$) calculated by eqn (3), and describes the total rate of reaction so is an important input to estimate electrolyzer size and capital cost for a CO$_2$R process.$^{69}$

$$j = \frac{I}{A}$$

Partial current density ($j_{\text{product}}$) for a specific product can be obtained by:

$$j_{\text{product}} = \text{FE}_{\text{product}} \times j$$

- Energy efficiency (EE) is a measure of net energy consumption toward a specific product expressed in eqn (5) as a ratio of amount of energy used to produce the specific product to the net electrical energy supplied to the system.

$$\text{EE}_{\text{product}} = \frac{E^0 \times \text{FE}_{\text{product}}}{E^0 + \eta}$$

where $E^0$ is the equilibrium cell potential for the desired product ($E^\text{cathode} - E^\text{anode}$), and $\eta$ is the sum of overpotentials on the cathode and anode.

3 Electrolyzer configurations

The background discussion in Section 2 highlights how, in addition to catalyst materials, the configuration of the electrolyzer impacts the overall efficiency of a CO$_2$R process by effecting the limiting rates of CO$_2$ mass transfer to the catalyst, controlling resistances of cell components, and determining the reaction distribution across electrodes. The two general categories of electrochemical reactors are (i) batch or semi-batch cell and (ii) continuous flow-cell configurations. Batch and semi-batch electrolyzers like the H-cell in Fig. 3a are commonly used in laboratory CO$_2$R studies with electrodes simply immersed in liquid electrolytes with CO$_2$ gas bubbled to saturate the catholyte.$^{78}$ This configuration is simple, low cost, and allows rapid screening of novel electrocatalysts and electrolytes, but is not practical for treatment of large volumes of CO$_2$ gases$^{40,71}$ because rates of CO$_2$ mass transfer to the electrode surface (even if the catholyte is vigorously stirred) are too slow and limit CDs to less than 100 mA cm$^{-2}$. In addition, in a semi-batch cell any cations (e.g. K$^+$) that pass through the separator accumulate in the catholyte, and this accumulation can degrade the electrode kinetics and CO$_2$R selectivity over extended cell operation or result in high ohmic losses due to electrodialysis.$^{72,73}$

Industrial-scale CO$_2$R processes require continuous processes to achieve sufficient reaction rates and be economically viable. Table 1 presented examples of continuous flow-cell electrolyzers reported for pilot-plant and scale-up studies, and most of these follow scale-up and engineering strategies that were developed for polymer electrolyte (PE) electrolyzers. In this section we will discuss the separator, which is a critical component in all batch cells and continuous flow-cells, and then describe the liquid-fed, vapor-fed, and microfluidic electrolyzers illustrated in Fig. 5. Our review does not cover flow-field patterns (e.g. straight, parallel, serpentine) that can be manufactured on current collectors to optimize CO$_2$ and electrolyte contact with the catalyst, and to minimize pressure drop, and to manage heat transfer in the cell.$^{74}$ We refer readers interested on flow-field patterns to reviews of PE electrolyzers.$^{74-76}$

3.1 Separator considerations

In a CO$_2$R electrolyzer the separator between cathode and anode chambers, just like separators in water splitting electrolyzers,$^{73,77}$ is critical to safe and efficient operation of the cell. An effective separator (1) minimizes the risk of a short circuit between electrodes; (2) prevents exchange of reactants and CO$_2$R products between cell chambers to reduce the risk of forming unsafe gas mixtures (e.g. H$_2$ and O$_2$) and prevent oxidation of products at the anode; (3) maintains desired local conditions in the anode and cathode reactions, (4) provides mechanical support to withstand any pressure differences between chambers, and (5) must have a good conductivity for certain ions. The two classes of materials that can provide the required selective ion transport and low permeability to other species are porous separators and ion exchange membranes (IEM). Porous separators include plastic mesh (e.g. polyolefin or Netlon) with large pores (0.5–12 mm widths) and microporous diaphragms with pore sizes 0.1–50 µm (e.g. glass fibres, polytetrafluoroethylene (PTFE)).$^{77}$

Semi-permeable ion exchange membranes selectively transport certain dissolved ions but are not permeable to other ions or non-charged species. Most CO$_2$R electrolyzers use monopolar IEMs that are either cation exchange membranes (CEM) such as Nafion® or anion exchange membranes (AEM) such as Sustainion®. Bipolar membranes (BPM) with electrocatalyst
sandwiched between CEM and AEM layers are also available,\textsuperscript{78} and are reported to achieve more stable pH levels between two electrodes at steady state.\textsuperscript{79,80} A further advantage of the BPM is that this design may allow lower, cost abundant metals to be used as catalysts instead of precious and noble metals.\textsuperscript{81,82} Further detailed descriptions of IEM working principles and recent advances in IEMs are provided in reviews by Kusoglu and Weber,\textsuperscript{83} Kaczur et al.,\textsuperscript{84} Luo and Wessling,\textsuperscript{85} and Kimberly et al.\textsuperscript{86}

The selection of a cation exchange, anion exchange, or bipolar membrane must be considered together with catalyst selection, electrolyte selection, and the targeted CO\textsubscript{2}R products. For example, a CEM is commonly used for CO\textsubscript{2}R to formate because this IEM blocks formate anions from crossing over to the anode chamber. If the CEM is also proton exchange membrane like Na\textsuperscript{+} on then an acidic anolyte must also be selected to manage proton concentrations,\textsuperscript{88} and these decisions limit the choice of OER anode catalysts to expensive precious noble metals such as Ru and Ir. Another consideration for proton exchange membranes is that excess protons will promote HER at the cathode.\textsuperscript{89}

Anion exchange membranes can transport anions such as HCO\textsubscript{3}\textsuperscript{−}, OH\textsuperscript{−} and CO\textsubscript{3}\textsuperscript{2−} ions from alkaline catholytes to the anode chamber.\textsuperscript{90} Hori et al.\textsuperscript{91} reported a FE\textsubscript{CO2} up to 92% at 20 mA cm\textsuperscript{−2} which shows the improved performance of AEM-based reactor over CEM. However, there are some important considerations in the use of AEM. For example, CO\textsubscript{3}\textsuperscript{2−} and HCO\textsubscript{3}\textsuperscript{−} transported to the anode chamber are expected to produce CO\textsubscript{2}, and this reduces the overall efficiency of the CO\textsubscript{2}R process. Further, the extended exposure of AEM to alkaline catholytes can lead to blockage of the membrane with less mobile HCO\textsubscript{3}\textsuperscript{−} and CO\textsubscript{3}\textsuperscript{2−} anions, which degrades the AEM’s ionic conductivity and increases the membrane’s ohmic resistance.\textsuperscript{87,92–94} In addition, AEM may be susceptible to degradation by excessive OH\textsuperscript{−}, especially if the membrane is insufficiently hydrated. A recent report by Sun et al. revealed CO\textsubscript{2}R to methanol and ethanol can also accelerate such degradation.\textsuperscript{95}

3.2 Continuous liquid-fed electrolyzers

Fig. 5a depicts a two-chamber liquid-fed electrolyzer in which a CO\textsubscript{2}-saturated catholyte and an anolyte are pumped through the separate cell chambers. In this configuration, the catholyte is saturated with CO\textsubscript{2} outside the electrolyzer which requires additional CO\textsubscript{2} capture process units. A more recent integrated design for a liquid-fed electrolyzer is the three chamber cell shown in Fig. 5b that uses a gas diffusion electrode to enhance transfer of CO\textsubscript{2} from the gas phase to the electrolyte–cathode interface. We provide further discussion of GDEs in Section 4.

Fig. 5 Schematic of CO\textsubscript{2} electrolyzer in flow-cell configurations (a and b) liquid-fed electrolyzer, (c) vapor-fed electrolyzer and (d) microfluidic reactor. The main cell components are labelled as (1) cathode, (2) anode, (3) separator or ion-exchange membrane which could be a cation exchange membrane, anion exchange membrane, or a bipolar membrane, (4) anolyte, and (5) catholyte.
Obviously, one control on the overall mass transfer rates and thus reaction rate in liquid-fed electrolyzers is the flow-rate of the catholyte because it directly affects superficial liquid velocities in the cell. For example, Alvarez-Guerra et al. reported that at low current density \( (\text{CD}) \approx 2.5 \text{ mA cm}^{-2} \) the overall rate of \( \text{CO}_2 \)R to formate over a lead-based cathode was insensitive to catholyte flow rates. However, they reported that at higher current densities \( (12.25 – 22 \text{ mA cm}^{-2}) \) increasing the catholyte flow-rate from 0.57 mL min\(^{-1}\) cm\(^{-2}\) to 1.44 mL min\(^{-1}\) cm\(^{-2}\) enhanced formate production because of an improved supply of dissolved \( \text{CO}_2 \) at the electrode interface for \( \text{CO}_2 \)R.

Both liquid-fed configurations provide larger active electrode area to electrolyte volume ratios than semi-batch cells, and thus can achieve higher overall reaction rates and lower ohmic losses than batch operation. An additional advantage of the high electrode area to electrolyte volume ratio in liquid-fed electrolysers in laboratory studies is that this allows detection of low concentration products and accurate voltage measurement. For example, Kuhl et al. used a liquid-fed flow-cell electrolyzer like that in Fig. 5a to detect the first time acetone, glycolaldehyde, ethylene glycol, glyoxal, and hydroxyacetone as \( \text{CO}_2 \)R products at low concentrations. The expected \( \text{H}_2 \), \( \text{CH}_4 \), \( \text{CO} \), \( \text{HCOOH} \), and \( \text{C}_2\text{H}_4 \) were also reported by Kuhl et al. Other groups report also sandwich type compression flow-cells for detection of low concentration products in \( \text{CO}_2 \)R reactions.

Fig. 6a shows an example of a liquid-fed electrolyzer with a BPM separator that due to the better control of pH imparted by the BPM achieved a more stable cell voltage during a 12 hour \( \text{CO}_2 \)R experiment than an electrolyzer with a CEM (Fig. 6b and c). However, a potential issue with BPs in liquid-fed electrolysers is ensuring the rate of water dissociation to prevent dry-out of the membrane because it directly affects superficial liquid velocities in the cell. For example, Haas et al. operated a liquid-fed electrolyzer at 150 mA cm\(^{-2}\) with a CO FE close to 60% for more than 200 h over a 100 cm\(^2\) electrode area. A potential adverse effect of operating with a high gas overpressure across the GDE in a liquid-fed electrolyzer is that the higher partial pressure of \( \text{CO}_2 \) leads to precipitation from the bicarbonate/carbonates catholyte which can reduce electrolyte conductivity, block GDE pores or modulate pH. All such effect increase the overall ohmic losses in the cell.

### 3.3 Vapor-fed electrolyzers

Fig. 5c shows a vapor-fed flow-cell electrolyzer with an IEM coated on one-side with a cathode catalyst and on the other side with an anode catalyst to create a zero-gap cell. In this configuration, the catholyte is supplied via humidified \( \text{CO}_2 \)-containing gas to maintain membrane hydration during \( \text{CO}_2 \)R. Compared to liquid-fed electrolysers, the key advantages of vapor-fed electrolysers are lower ohmic losses and reduced risk of catalyst poisoning from impurities in the catholyte. In addition because the vapor-fed cell does not require pumps to feed the electrolyzer the equipment and operating costs may be lower than a liquid-fed cell; however, this comparison depends on the cost of the processes required to vaporize catholyte into...
the CO₂ feed gas. One potential drawback of vapor-fed electrolyzers is liquid CO₂R products like alcohols can flood back into GDE pores and thereby hinder CO₂ access to the active sites.

Most vapor-fed electrolyzers reported in the literature use a CEM to transport protons from the anode chamber to the cathode for CO₂R. For example, Lee et al.\textsuperscript{112} reported more stable formate production over a tin nanoparticle cathode catalyst in a vapor-fed electrolyzer than a liquid-fed electrolyzer, and they attributed the improved performance to a shorter CO₂ diffusion pathway to the catalyst. However extended CO₂R operation in CEM vapor-fed electrolyzers is reported to lead to acidification at the cathode, which promotes unwanted HER.\textsuperscript{113} In an alternative design, Kutz et al. used AEM like a methylimidazolium-based styrene polymer in a vapor-fed electrolyzers with Ag-based catalyst and reported stable operation for 6 months at CD = 50 mA cm\textsuperscript{-2} with a FEO = 90%.\textsuperscript{41} Mallouk’s laboratory\textsuperscript{73} reported a vapor-fed electrolyzer with a BPM separator and liquid catholyte that achieved CDs two times larger than a liquid-fed cell and relatively stable cell voltage close to 3 V during operation at 80 mA cm\textsuperscript{-2} for 14 h. However, they did report that the FEO began to degrade after 1 h, which may have been due to de-wetting of the liquid IL from the surface of the catalyst.\textsuperscript{71} Salvatore et al.\textsuperscript{114} enhanced the stability of this vapor-fed with BPM configuration using a solid support layer of aqueous NaHCO\textsubscript{3} between the Ag-decorated GDE and the BPM, and demonstrated a steady FEO = 65% at 100 mA cm\textsuperscript{-2} and 3.4 V for 24 h.\textsuperscript{114}

3.4 Microfluidic electrolyzer

A microfluidic electrolyzer (Fig. 5d), such as the cells described by Kenis and co-workers,\textsuperscript{115,116} does not use a membrane separator but instead uses a thin (less than 1 mm) electrolyte flowfield channel to separate electrodes. In this configuration gaseous CO₂ diffuses to the electrode-electrolyte interface through a gas diffusion layer (GDL), and crossover of reactants and products is controlled at laminar flow conditions because diffusion of the products is slow. Due to its compact design and high surface area to volume ratio, a microfluidic electrolyzer design could allow fast rates of CO₂ mass transfer to the cathode surface and thus high CDs for CO₂R.\textsuperscript{115,116} Additionally, microfluidic electrolyzers may provide new opportunities for fundamental studies into the effects of temperature, pH, catalyst deposition methods, electrolyte composition, GDL composition, and channel length on CO₂R processes and thus help provide new insights for technology improvement.\textsuperscript{115,117}

3.5 Separation of CO₂R products downstream of the electrolyzer

Efforts towards improving the selectivity of CO₂R through catalyst innovations and optimization the electrolysis process are aimed partly at increasing the concentration of products in the electrolyzer effluents so as to the cost of product separation processes.\textsuperscript{118-119} Greenblatt et al.\textsuperscript{118} showed just how energy intensive separation of liquid products from a photoelectrochemical CO₂R could be, with 4.7 to 45 MJ kg\textsuperscript{-1} of product required using distillation to recovery products from 10 wt% to 1 wt% in the catholyte stream from the electrolyzer.\textsuperscript{120} Greenblatt et al. reported more energy efficient technologies such as membranes and solvent extraction could potentially reduce the energy requirements to 0.1–8.3 MJ kg\textsuperscript{-1} product, but these technologies cannot always compete with distillation in terms of higher throughput and desired purity.\textsuperscript{120}

One strategy to avoid separation costs could be direct use of effluent streams from the CO₂R reactor. For example, potential opportunities could include tuning the CO₂R performance tuned to produce CO + H\textsubscript{2} mixtures to feed a Fischer–Tropsch process, CH\textsubscript{4} + C\textsubscript{2}H\textsubscript{4} mixtures for synthesis of C\textsubscript{3}H\textsubscript{6},\textsuperscript{121} or alcohol and/or hydrocarbon mixtures for liquid fuels.\textsuperscript{122,123} However, that strategy is likely only viable in a small number of circumstances where the CO₂ source and the potential use of CO₂R products are closely located and integrated. Therefore, consideration must be made for separation of CO₂R product streams. One of the challenges with CO₂R processes compared to many other industrial conversion processes is that the concentration of products, especially liquid products, leaving the electrolyzer are low. For example, in the conventional formic acid route of hydrolysis of methyl formate produces formic acid + methanol mixtures with more than 10% formic acid that are relatively easy to separate by distillation or liquid/liquid extraction.\textsuperscript{124,125} However, the concentration of formic acid leaving a CO₂R electrolyzer is typically less than 1% in a mixture of water and the electrolyte salts. Recovery of the formic acid from this CO₂R effluent stream requires an acidification process then azeotropic separation to obtain a pure formic acid product. Furthermore, formic acid separation processes are sensitive to pH like acidification and potential inorganic salts separation (e.g. crystallization) so conditions in the electrolyzer may affect downstream process.\textsuperscript{126}

Control of the engineering factors described in the article (e.g. reactor design, electrode structure, electrolyte, pH, pressure, and temperature) may ultimately help to design efficient downstream separation processes. For example, the choices of conducting salts, solvents, IEMs, and flow rates can all effect the concentration and types of liquid CO₂R products that must be recovered from the electrolyte. Yang et al.\textsuperscript{127} provide a clear demonstration of the relationships between reactor design and product distribution in their report of electrolyzer with a Sustain™ AEM to obtain streams with up to 20 wt% formic acid from the reactor. In summary, the overall reactor design is a key factor that governs the properties of the CO₂R product streams.

4 Electrode structure

The cathode in a CO₂R electrolyzer must provide active catalyst sites, facilitate sufficient contact between CO₂, electrolyte and catalysts, and conduct electrons. Fig. 7 depicts the three types of cathode architectures: (a) planar electrodes (e.g. a metal foil or glassy carbon plate),\textsuperscript{128-131} (b) simple porous electrodes (e.g. carbon paper or mesh),\textsuperscript{134-138} and (c) gas-diffusion electrodes (GDEs).\textsuperscript{139-144} Most CO₂R electrocatalyst screening and fundamental catalysis studies\textsuperscript{103,107,132-144} use planar electrodes or simple porous electrodes because these types are relatively simple to construct and immerse in a CO₂ saturated electrolyte.
Overall, the ultimate goal of developing 3D-structured electrode is to minimise the various cell resistances due to electron and ion transport, multiphase flow (e.g. bubble), transport-related, and electrochemical reaction. The ohmic resistance of 3D-structured electrode is mainly influenced by both the 3D-skeleton and the interfacial conductivity. The 3D-electrode structure is a composite made of conductive matrix (carbon or metals) and less-conductive binders (e.g. PTFE or ionomers) and/or pores containing electrolyte or gas, thus requiring multiple percolations pathways for reactant molecules, ions and electrons.150-152 Simply put, increasing porosity decreases the overall conductivity of the matrix and therefore increases the overall ohmic resistance. The interfacial conductivity, governed by the interfacial contacts and heterogeneous phases, contributes more to the ohmic resistance. This is valid especially for a pure metal matrix as prepared through sintering, where sintering temperature, interfacial contact and sizes of metal particles and pore formers are important factors to consider.153 3D-structured electrodes decorated with heterogeneous catalyst materials also have extensive interfaces between the conductive backbone and less conductive catalysts, thus facing an increase of ohmic resistance. Therefore, the size and shapes of the catalysts and pore structures of the matrix also matter for the overall electrical conductivity of the structure.153 Compared with the ohmic resistance, the resistance related to transport is more critical, particularly for mass-transport-controlled CO₂R electrolysis.111 In a 3D-porous electrode, transport of liquid and/or gas reactants and products is dominated by either molecular or Knudsen diffusion, depending on the pore size and electrode structures. Similarly, wettability and pore size dominate the intrinsic saturation/capillary-pressure relationship that is critical for optimal multiphase performance.146

The electrochemical reaction resistance is related to the electrode kinetics. In addition to the catalyst materials (where compositions, surface orientations, morphology, and sizes are important factors) that directly affect the kinetics, catalyst support, multiphase flows within the electrode and local environments are all crucial for CO₂R surface reaction rate and selectivity. For the effects of catalyst support, one could refer to a recent review published by Li, MacFarlane, and Zhang,30 as well as herein. However, there are still gaps remaining, especially regarding the exact interfacial structure of the catalysts (especially with ionomer),146 and how these structures affect the electrode kinetics. Answering these questions is essential to guide where and how to deposit catalysts in the electrode structure. It is also important to note that an optimal balance has to be achieved among these resistances. For example, oxide-derived catalysts are active for CO₂R154,155 but may not be very electrically conductive, leading to a decrease of electrode kinetic resistance but an increase of ohmic resistance. In the case where liquid products are targeted products, a high reaction rate consumes quickly the CO₂ gas and lowers the local gas pressure, which may lead to local flooding that blocks gas transport and in turn degrades CO₂R selectivity. Such a balance appears more crucial in the GDEs that include the transport of gases in the electrode structure. Because recent works have

(for example, in a electrochemical cell like that shown in Fig. 3a).

The planar electrode is useful to screen catalyst materials in a laboratory scale because of its relatively simple geometry that rules out impacts induced by complex factors such as structures of the electrodes. In addition, placement of a reference electrode is straightforward, thereby enabling single electrode overpotential measurements. However, the CO₂R half-cell reaction rates achieved with a planar electrode or porous electrode are often limited by the rate of CO₂ transfer across the hydrodynamic layer from the bulk electrolyte to the electrode surface especially at a high CD.38 In such systems, mass-transfer rates could be improved by operating the electrolyzer at high pressure, low temperature, or selecting organic electrolytes to increase the solubility of CO₂ in the electrolyte. But those options add costs and complexity to the CO₂R process.

For high CD electrolyzers, one prefers the application of the last three electrode types (Fig. 7b–d) that are 3D-structured catalytically-active materials or electron conducting material with coverage of catalysts. A 3D-structure increases the active electrode area and decreases the transport resistance of gaseous and liquid reactants and products. Increasing the active electrode area reduces overall cell voltage and increase the rate of charge and mass-transport. Fast charge and reactant transport also accelerate the electrode kinetics. However, challenge arises in understanding the property-performance relationship and optimisation of the 3D-structure for efficient CO₂R conversion. This results from the complexity of the 3D-structured electrodes that involves multiphase flow in the pores, interactions at interfaces and multiscale kinetics at the catalysts. Though this area still remains underexplored in CO₂R application, a lot can be drawn from the studies in other electrochemical conversion applications such as PEM fuel cells and redox flow batteries. Recently, Shojaeefard _et al._145 Weber _et al._,146 and Fadzillah _et al._147 reviewed the electrode microstructure restructuring and pore-scale simulations. Moreover, Lai _et al._148 and Walsh _et al._149 reviewed the design and fabrication of general 3D-structured electrodes, including the 3D-electrode architecture and decoration of catalysts.
demonstrated a superior CO₂R performance of GDEs compared to planar and simple porous electrodes, in the following subsections we mainly focus the review of recent GDE development for CO₂R.

4.1 Gas diffusion electrodes

GDEs offer an alternative approach to improve mass-transfer and overall CO₂R rates.¹⁵⁶,¹⁵⁷ The key difference between a GDE and a simple porous electrode is that in a GDE, the CO₂ gas diffuses through a gas-diffusion layer (GDL) to the electrode–electrolyte interface inside the catalyst layer (CL). This type of GDE electrolysis has been reported to achieve reaction rates up to an order of magnitude faster than porous electrodes that require CO₂ transfer from the bulk electrolyte to the electrode surface.⁵⁸ A typical GDE, as shown in Fig. 8, consists of a GDL, a CL, and a current collector as shown in the two examples in Fig. 7c and d. The porous metal mesh or foam current collector serves to distribute current and maybe engineered with gas flow channels.¹⁶²,¹⁶³ The porous GDL should enable fast transport of gaseous CO₂ to the CL, where the electrochemical reactions occur. A critical property of the GDL is that this layer must be hydrophobic (or more generally, the GDL must be gas wet relative to the wetting with electrolyte) to prevent liquid electrolyte from seeping to the gas flow channel. The GDL can be designed with a single-layer of porous materials (Fig. 7c) or dual-layers with different porosities and wettabilities (Fig. 7d). In a single-layer GDL, the hydrophobic macroporous layer might be a metal mesh or metal foam, or a hydrophobically-treated porous carbon such as polytetrafluoroethylene (PTFE) treated carbon paper. A dual layer GDL (Fig. 7d) includes a macroporous layer and a microporous layer (MPL).¹⁶⁴ The MPL is normally a hydrophobic layer with small pores that is composed of carbon powder and PTFE.¹⁶⁵ The catalyst layer (CL) is commonly prepared by depositing the catalytically active phase, including catalysts and an ionic binder on the GDL or membrane.

In a recent publication, Weng, Bell and Weber predicted with a mathematical model that a Ag-based GDE could potentially achieve a partial CD (PCD) for CO one order of magnitude higher than that achieved with a planar Ag electrode.⁵⁸ That study concluded that good GDE performance is achieved by (1) a high density of active sites per geometric electrode area, and (2) a low mass-transfer resistance in the GDE, especially at more negative potentials. The predictions of the Weng, Bell and Weber modelling study are consistent with various experimental studies.⁵⁸ For example, Castillo et al. reported that a Sn-based GDE with 1.5 mg Sn cm⁻² achieved a maximum FE of ~70% in producing formate at a current density of 40 mA cm⁻², which was more efficient than the planar Sn electrode with a maximum formate FE of 67% at 12 mA cm⁻².¹⁶¹ In another example, Hass et al.¹⁷ demonstrated a commercial Ag-based GDE, which was developed by Covestro as an oxygen depolarized electrode (ODE) for chlor-alkali applications, as a cathode in a CO₂ flow cell electrolyzer with stable operation at a CD of 300 mA cm⁻² and CO FE close to 70% for over 1200 h. A brief summary of other recent reports of GDEs as cathode for CO₂R is provided in Table 2.

Although only a relative small number of studies report use of GDEs for CO₂R,¹⁴¹,¹⁵⁷,¹⁵⁸,¹⁵⁹,¹⁶¹ GDEs have been extensively developed and optimized for fuel-cell applications.¹⁶¹,¹⁷²,¹⁷³ The knowledge from this field can be leveraged to develop more efficient GDEs for CO₂R, but the requirements for CO₂-electrolyte contacts in a CO₂R electrolyzer are more challenging than in a fuel cell. We describe in the following sections recent advances to optimize GDEs for use as the cathode in a CO₂R electrolyzer.

4.2 Engineering the gas diffusion layer

4.2.1 Macroporous layer. As one of the key components of GDE, the GDL normally (1) serves as a mechanical support for the CL, (2) allows an easy diffusion of the gaseous CO₂ and release of gas products such as CO and CH₄ through its pores at the reaction sites, (3) enables electron conduction from the current collector to the CL, and (4) prevents the electrolyte from seeping to the gas channel. The macroporous layer of the GDE can be fabricated by (1) mixing the carbon materials (e.g. acetylene black¹⁶²,¹⁶₄,¹⁷₄ and carbon fiber) with PTFE¹⁶₄ or Teflon,¹⁷₄ (2) hydraulic pressing or rolling⁷⁰ the mixture with or without current collector to form the film, and (3) sintering the film at 340 to 380 °C. The sintering temperature is slightly above the melting temperature of the hydrophobic agents, so that the agent can bind strongly with the carbon materials. In most cases, however, commercially available carbon papers (e.g. Toray or SGL carbon papers) have been used as the macroporous layer of the studied GDEs.

The thickness and hydrophobicity of the macroporous layer predetermine the mass-transfer resistance of CO₂ in the GDEs, and thus have an impact on the CO₂R reaction rate. For example, Kim et al. compared the CO₂ gas permeability and CO₂R performance over Ag-based GDEs with carbon-fiber substrates (i.e. macroporous layer) in different thicknesses ranging from 170 to 380 µm.¹⁶₂ With the reduction of substrate thickness from 370 to 190 µm, they found that the CO₂ gas permeability increases from 69.25 ± 0.69 to 72.42 ± 0.72 mL min⁻¹ m⁻², and that the PCD of CO also improves from ~180 to ~220 mA cm⁻² at −2.05 V vs. Ag/AgCl. The enhanced PCD of CO₂R for thinner substrates is attributed to the improved CO₂
gas permeability. However, a too thin substrate (Toray Carbon Paper 30 with a thickness of 110 μm) leads to electrolyte flooding (i.e. the electrolyte fully occupies the pores) in the GDE during the CO₂R operation, in essence turning into a simple electrode case. Therefore, an optimal thickness of the microporous layer is essential to ensure a balanced gas permeability and effective electrolyte management in the GDE.

Another key factor is the wettability of the microporous layer: too high a hydrophobicity may cause poor electronic conduction due to the high amount of non-conductive hydrophobic agents, while too high of a hydrophilicity may limit the conduction due to the high amount of non-conductive hydrophilic treatments (such as plasma treatments, addition of hydrophilic treatments). The wettability can be adjusted by controlling the content of hydrophobic agents [e.g. PTFE], hydrophobic treatments (such as plasma treatments, addition of inorganic oxides or carbon black, etc.), and hydrophilic treatments (such as plasma treatments, addition of inorganic oxides or carbon black, etc.).

### 4.2.2 Microporous layer
As compared with the macroporous layer, the MPL is normally a thinner porous layer with smaller pore sizes and volumes, and is sandwiched in between the macroporous layer and CL. A comparison of scanning electron micrographs of GDE with or without MPL is shown in Fig. 10b and d, respectively. The fabrication procedure of MPLs is similar to the processes to make the macroporous layer. The mixtures of carbon black and hydrophobic agents are casted onto one side of the macroporous layer, followed by sintering treatment to ensure sufficient bonding. One should note that the carbon-based materials normally contains metal residues such as Fe, Co and Ni. As the MPL is in direct contact with the catalyst layer, these metal impurities in the carbon materials may promote unwanted HER during the cell operation. Therefore, cleaning the MPL or the whole GDL in highly concentrated acid is highly recommended to minimize the content of metal impurities before deposition of catalyst layer. As shown in the Table 2, not all of the GDE-based cathodes for CO₂R contain MPLs. Research in polymer electrolyte fuel cells have demonstrated that the MPL layer not only plays a key part in maintaining separation between liquid and gas, but also evidenced by the observed lower charge-transfer resistance from the electrochemical impedance spectra (Fig. 9b). In the studied PTFE range (10 to 50 wt%), additionally, the authors observed negligible effects of the PTFE content in the macroporous layer on the CO₂ gas permeability and durability of the GDEs.

provides the electrode with improved interlayer contact, lower electrode ohmic resistance, higher CL temperatures, and better structural integrity.\textsuperscript{161,184} For the application of CO\textsubscript{2}R, Kenis et al. found that the MPL in the GDE could provide a support for the CL and prevent potential flooding in the macroporous layer.\textsuperscript{162} The MPL can also prevent the exposure of the carbon fiber to the electrolyte (Fig. 10a–d) and thereby suppressing the undesired HER catalyzed by the exposed carbon fibers. As a result, the presence of MPL in the GDE-based cathode contributes to a significantly improved CD as high as ~220 mA cm\textsuperscript{-2}, ten-fold higher than the one without MPL at ~2.2 V vs. Ag/AgCl\textsuperscript{162} (Fig. 10e).

Additionally, in the same work, the authors also studied the effects of PTFE content of the MPLs on CO\textsubscript{2}R reaction rate. As shown in Fig. 11a, the CO PCD increases with PTFE at low PTFE contents \textleq{20 wt\%}, but decreases with PTFE at contents >20 wt\%.\textsuperscript{162} Too little PTFE content (i.e. 4.5–10 wt\%) in the MPL is insufficient to prevent flooding of the layer by electrolyte and does not provide strong binding between the carbon and catalysts in the CLs, which resulted in the higher HER level and poorer cathode durability. A higher content of PTFE (>20 wt\%) in the MPL degrades the electronic conductivity of the GDE (Fig. 11b) and also reduces the MPL porosity.\textsuperscript{185} Correspondingly, both the resistances of GDE for electron transfer and CO\textsubscript{2} mass transfer become higher, thus leading to a degraded CO\textsubscript{2}R performance.

### 4.2.3 CO\textsubscript{2} adsorption layer

A CO\textsubscript{2} adsorption layer can also be incorporated at the GDL surface facing the CO\textsubscript{2} to further promote the CO\textsubscript{2}R. For example, by covering a substituted imidazolate-based metal–organic framework (SIM-1) on a macroporous layer, Marepally et al. significantly improved the performance over a Pt/carbon nanotube (CNT)-based GDE, with an increased rate of CO\textsubscript{2}R products, including methanol, ethanol, acetone, and isopropanol, by 1.5 times as compared with the counterpart without the adsorption layer.\textsuperscript{166} Such remarkable >C1 production improvement, as brought by deliberately concentrating the surface CO\textsubscript{2} through the adsorption layer, highlights the essential roles of electrode design, in addition to the effects from electrocatalysts, in controlling the CO\textsubscript{2}R pathways.

4.3 Optimization of the catalyst layer

The CL is mainly a layer of the electroactive cathode materials normally immobilized on one side of the GDL (typically on the MPL) facing the electrolyte or membrane through various deposition methods (e.g. electrodeposition,

\textsuperscript{45a} drop casting,

\textsuperscript{45} thermal evaporation,

\textsuperscript{45} ionic displacement, or pressing\textsuperscript{159}), though the position of the CL can be also extended inside the GDL structure to further increase the electroactive interface boundaries.\textsuperscript{188} There are several factors that could contribute to the activity and product distribution of the CO\textsubscript{2}R electrolysis, such as the catalyst materials, catalysts loading (i.e. the mass of catalyst per electrode geometric area), ionic binders, and CL deposition methodology.

Immensely research efforts have been and continue to be devoted to the study and development of catalyst materials suitable for CO\textsubscript{2}R, and the recent advances in the catalyst development have been extensively reviewed recently.\textsuperscript{28,30,31,107,148} Most of these studies mainly focused on catalysts supported by a planar electrode or simple porous electrode, but not by a GDE, where the CL must deal with complex transport and reaction processes simultaneously and there is an inherent need for porosity.

The processes taking place at the CLs of GDE cathodes are even more complex than those in the GDL, since all of those processes occur as well as the electrochemical reactions and ionic transport. Weng et al. recently discussed in detail regarding the processes involved in the CL of an Ag-based GDE.\textsuperscript{38,149} In addition to local environment change close to the electrode surface in the electrolyte during CO\textsubscript{2}R operation, as discussed in the electrolyte selection and pH effects sections, the CL of the GDE also needs to manage the transport of gas and ions to achieve an optimal cathode performance. Too dry of a CL results in catalytically active sites becoming inactive due to the absence of supporting electrolyte or ionic pathways, but flooded pores increase the mass-transfer resistance of gaseous CO\textsubscript{2}. An ideal CL should facilitate a sufficient contact of liquid electrolyte and gas with the catalysts. Furthermore, the reaction kinetics are intimately connected with the transport phenomena. What also matters is the pore size in the CL. Small hydrophilic pores will be flooded when the liquid/gas pressure difference is low. When the pressure difference between gas and electrolyte increases, the susceptibility to electrolyte flooding of the pores in CL follows the trend: large hydrophilic pores > large hydrophobic pores > small hydrophobic pores.\textsuperscript{58}

The amount of catalysts loading in the CL also alters the CD and product distributions. For example, through varying the Sn catalysts loading content ranging from 0 to 15 mg cm\textsuperscript{-2}, Kopljar and co-workers found that a higher content of Sn increases the CO\textsubscript{2}R activity as evidenced by the observed higher CD and lower Tafel slope, especially at the higher potential range as shown in Fig. 12a.\textsuperscript{159} Such enhancement could be a result of the increased concentration of catalytically active sites as imparted by the higher Sn loading. Moreover, the product distribution was also found to be dependent on the catalyst loading: a Sn loading of less than 5 mg cm\textsuperscript{-2} could lead to ~90% of FE for HCOO\textsuperscript{-} formation, <10% for CO and 3% for H\textsubscript{2}, and further increase of the loading decreases the selectivity of the HCOO\textsuperscript{-} production but promotes CO and H\textsubscript{2} evolution (see Fig. 12b). The authors considered the effects of catalyst loading on product distribution analogous to the effects of cathodic potentials, where a low cathode potential leads to the promotion of CO and H\textsubscript{2}. Alternatively, we explain such phenomena by two possible reasons. First, a higher Sn loading may hamper the diffusion of CO\textsubscript{2} to the active regions and therefore lead to the promotion of HER. Second, similar to the effects of interparticle interactions on Cu nano-particles for CO\textsubscript{2}R catalysis,\textsuperscript{199} a higher catalyst loading could increase the availability of neighboring active sites and therefore promote re-adsorption of HCOO\textsuperscript{-} for further reduction to become CO as the final product.

Sargent et al. recently used Cu-based GDEs with a very thin Cu CL (i.e. 10 or 25 nm thick) as the CO\textsubscript{2}R cathode to achieve a higher CD and higher FE for C\textsubscript{2}H\textsubscript{4} formation than the ones with thicker Cu CLs (i.e. 1000 nm thick and ~1000 µm cm\textsuperscript{-2} CL) at a higher cathodic potential (i.e. ~0.54 V vs. RHE).\textsuperscript{45} At lower cathodic potential (~0.4 V vs. RHE), in contrast, the GDEs with
thick CLs exhibited higher CDs than the thin CLs. They explained the higher FE for GDE with the thin Cu CLs by the catalyst-mediated abrupt interface as imparted by the thin layer of Cu, which could accelerate the rate-determining CO dimerization step for C₂H₄ formation. It could be thought that the thin layers and high flowrates of electrolyte also did not provide sufficient time for the homogenous acid/base reactions of CO₂ to occur, thus resulting in higher CO₂ local concentrations compared to the thicker CLs, where the CO₂ and electrolyte residence time was higher. The multi-physics model of Ag-GDE developed recently for CO₂R showed that a thinner CL could enhance the mass transfer of the CO₂ in the GDE, which normally dominates the overall reaction rate at high cathodic potential. Consequently, the negative effect on CD due to

the low density of active sites of thin CL could be less significant at high cathodic potential. This mechanism could also partially explain the higher CD of Cu-based GDEs with thin CLs at higher cathodic potentials, as experimentally observed by Sargent et al.145

In addition to the catalyst loading, the ionic binder also influences the cathode performance. Taking Nafion ionomer for example,144 it not only forms a continuous matrix in the CL that promotes cation conduction, but also has an impact on the microstructure of the CL that governs CO2 diffusion. For efficient CO2 electrocatalysis, therefore, an optimal balance needs to be achieved among the pores for CO2 diffusion, catalyst particles for electron conduction and catalysis, and ionomer for ion conduction.179 Through constraining the Sn loading, Zhou and co-workers found that the electrode performance is dependent on the content of the Nafion ionomer, and reported an optimal Nafion loading of 20 wt% in terms of CD and FE.179 Moreover, the ionomer in the CL can also serve as a co-catalyst promoting the CO2R reaction. An example is the incorporation of the imidazole-based ionomers to an Sn-based CL could stabilize the *CO2/C0 intermediates and therefore enable the electroreduction of CO2 to HCOOH.127,191,192

The dispersion of the catalysts in the CL is another crucial factor for the electrode performance towards CO2R. Kenis’s and

³⁵ GDE means gas diffusion electrodes.
coworkers studied the effects of catalyst dispersion by comparing the performance of Ag-based GDEs prepared using hand painting and air-brushing CL deposition methods. They found that the automated air-brushing technique renders a more uniform catalyst distribution and reduced particle agglomeration in the CL, as shown in Fig. 13a–c, thereby suppressing the HER and promoting the evolution of CO₂, though the overall CD was not significantly affected by the microstructural difference. They considered such product yield difference to be a result of exposed carbon from MPL that promotes HER, which is evidenced by the observed high HER PCD for bare GDL (Fig. 13d and e); a uniformly dispersed CL could reduce such carbon exposure and therefore suppress the unwanted HER.

5 Electrolyte selection

The primary function of the electrolyte in a CO₂R electrolyzer is to conduct ionic charge between electrodes. An electrolyte generally consists of three components: an inert electrolyte or salt, the solvent (e.g. water), and the electroactive species. A good solvent should have (1) a high solubility for the reactant (CO₂) and desired electrolyte to provide conduction; (2) electrochemically stable; (3) be chemically compatible with the electrode materials including the active catalysts; (4) low viscosity if liquid at the cell operating temperature to ensure good rates of CO₂ mass transfer from the bulk electrolyte solution to the electrode surfaces and (5) easy to handle, storage, and safe. Water is the most common solvent for CO₂R electrolytes because water satisfies the properties listed above, and can act as both a proton donor and proton acceptor to facilitate production of different electroactive species.

A key requirement of inert electrolytes commonly used in CO₂R processes is that the electrolyte easily dissociates into cations and anions so as to provide a high ionic conductivity. However, the effect of the electrolyte ions on CO₂R is far more complex than a simple charge carrier relationship. Even if the ions of inert electrolytes do not participate directly in redox reactions, an inert electrolyte can affect CO₂R, for example, through interactions of electrolyte ions with radicals and ions produced in the CO₂R reaction as described by Setterfield-Price and Dryfe.

An operational issue common for all types of electrolytes is that impurities in the electrolyte can poison cathode catalysts. For example, trace metal impurities electrodeposited at the cathode during the CO₂R process can lead to loss of CO₂R selectivity with increased relative rates of the HER. Therefore, usually high purity inert electrolytes or electrolyte purification by pre-electrolysis is required. Alternatively, chelating agent such as ethylenediaminetetraacetic acid (EDTA) or a solid-supported iminodiacetate resin (Chelex) could be used to mitigate effects of impurities on CO₂R.

5.1 Aqueous solutions of inorganic salts

The most commonly reported electrolytes for CO₂R are simple aqueous, inorganic salt solutions such as potassium bicarbonate (KHCO₃), and some common examples are summarized in Table 3. Although CO₂ solubility in aqueous salt solutions may be low as compared to other CO₂ capture solvents such as aqueous amine solutions; aqueous salt solutions are widely available at large scale and low cost; are relatively easy to prepare, handle, and store safely; and exhibit stable ionic conductivity. Since the 1950s the natural gas and ammonia industries have captured CO₂ using the Benfield Process with hot solutions (100–116 °C) of potassium carbonate (K₂CO₃) to capture CO₂ to form KHCO₃. It’s not surprising that given this long industrial history, KHCO₃ solutions have become the most commonly reported aqueous electrolytes for CO₂R. Carbonates are also chemically compatible with most electrode materials (relative to other conducting salts such as sulfides, sulphates, and halides). Importantly, bicarbonate solutions provide capacity to buffer the local pH at the electrode surface during CO₂R. The KHCO₃ cases described here highlight the complexity of the effects of electrolyte choice in a CO₂ electrolyzer, and to understand these effects more clearly, we discuss separately the roles of cations and anions in aqueous salt electrolytes.

5.1.1 Cationic effects. Many studies report that alkali cations effect CD and product distribution of CO₂R in aqueous electrolytes. Several theories have been proposed to explain these observations, including the specific adsorption of cations or DL blocking by cations, the degree of cation hydration, and stabilization of the negatively charged intermediate (*CO₃⁻) and related electronic field effects by the cation. For example, as shown in Fig. 14, Akira and Hori observed a higher selectivity for C₂H₄ and alcohols over CH₄ and H₂ in electrolytes with larger cations using a series of electrolytes with ionic size increasing from Li⁺ < Na⁺ < K⁺ < Cs⁺. Hori et al. proposed that such cationic effects arise from the tendency of the cations to specifically adsorbed on the electrode surface, which is predominated by the reaction energetics and the hydration capacity of the cation. The hydration capacity is stronger for smaller alkali cations, and therefore a Li⁺ ion binds more strongly with water molecules than a Cs⁺ ion, and...
the Li$^+$ is less likely to adsorb at the cathode surface than Cs$^+$. Larger cations such as Cs$^+$ are more readily adsorbed at the electrode surface due to their weaker hydration capacity,\textsuperscript{223} which will shift the CO$_2$ reduction potential towards the positive direction at the outer Helmholtz layer (OHL). This decreased reduction potential will result in a lower proton concentration at the OHL,\textsuperscript{223} as suggested by Frumkin as early as 1959.\textsuperscript{231} Also, the repulsion between the adsorbed cations and H$^+$ can further reduce proton concentrations at the electrode surface, therefore contributing to a reduced selectivity towards CH$_4$ and H$_2$ as observed by Hori et al. (Fig. 14).

Thorson et al.\textsuperscript{224} proposed that adsorbed cations at the electrode surface could stabilize the intermediate *CO$_2$* and thus promote the CO$_2$R. This theory could explain the observed enhancement in total CO$_2$R efficiencies with cation size from Li$^+$ to K$^+$ (Fig. 14). Recently, Kim et al.\textsuperscript{232} provided further evidence to support this proposed mechanism by observing an efficient CO production over a Au electrode in K$^+$-based electrolyte (K$^+$ is prone to adsorb at the Au electrode) than in a Na$^+$-based one. Further DFT calculations reported by Liu et al.\textsuperscript{233} revealed that higher electron-density of adsorbed K$^+$ close to the carbon atom could facilitate in the stabilization of intermediates such as *COOH and *CO.$^\diamond$

However, there remains some debate around the conclusions of Thorson et al. For example, Mills et al.\textsuperscript{244} and Strmcnik et al.\textsuperscript{245} argued that the specific adsorption of cations seems impossible under the operating conditions for CO$_2$R (usually for potentials larger than $-1.4$ V vs. a normal hydrogen electrode (NHE, potential defined at 1 M H$^+$ concentration and 1 atm pressure)). Bell and co-workers proposed that the observed cationic effect originates from the hydrolysis of the solvated cations close to the cathode surface.\textsuperscript{62} At the cathode surface,
pK_a of hydrolysis decreases significantly due to an increasing electrostatic force between the water molecules in the hydration sphere of cation and negatively charged cathode. These interactions can further polarize O–H bonds of water molecules, and consequently facilitate water dissociation to increase the local proton concentration as illustrated in Fig. 15a. This effect decreases the local pH, which permits an increase of dissolved CO_2 concentration locally that can approach the CO_2 concentration in the bulk electrolyte (Fig. 15b and c). The net effect reported by Singh et al.\textsuperscript{66} was that switching from Li\textsuperscript+ to Cs\textsuperscript+ in an aqueous electrolyte suppressed HER and significantly promoted CO\textsubscript{2}R over Ag cathodes (Fig. 15d) or Cu cathodes (Fig. 15e).

Note that these interpretations of the effects of cation hydrolysis only explain experimental observations at potentials less than −1.1 V vs. RHE. The phenomenon of hydrolysis of solvated cations is only applicable when (1) the pH of the electrolyte is close to 7; and (2) the pH of the electrolyte is close to local pH at the electrode; and (3) the reactant concentration is pH dependent.\textsuperscript{62} The hydrolysis of the solvated cations close to the cathode surface does not adequately explain the same cationic effects in CO reduction,\textsuperscript{231} because the CO concentration is not pH dependent. Koper et al.\textsuperscript{236} used density functional theory (DFT) calculations to predict the effect of cations on CO reduction to C_2H_4 at pH close to 13, and found that cations could stabilize intermediates, especially dimers of OCCO and OCCOH, via interactions of oxygen atoms in these intermediates.\textsuperscript{236} Moreover, the shift in average reaction energies (for Li\textsuperscript+, Na\textsuperscript+, and Cs\textsuperscript+) of CO to C\textsubscript{2} products is close to that reported by Nørskov and co-workers,\textsuperscript{60,61} who showed that the cation-induced local electric effect could alter the free-energy landscape of CO\textsubscript{2}R to CO by stabilizing the key reaction intermediates.\textsuperscript{236}

Bell along with other JCAP researchers\textsuperscript{63} conducted experimental measurements and DFT calculations at low cell potentials, and reported electrostatic interactions between the hydrated cations located at the OHL and the adsorbed reaction intermediates that have high dipole moments (such as CO\textsubscript{2}, CO\textsubscript{3}, and OCCO) at the cathode surface. Such electrostatic interactions lower the energy required for CO\textsubscript{2} adsorption (an intermediate for HCOO\textsuperscript{−}) and for C–C dimerization to form OCCOH or OCCO (which are the key intermediates for C_2H_4 and C_2H_5OH, respectively).\textsuperscript{64} As a consequence, the PCD for H_2 and CH_4 formation are uninfluenced by the cation size, while the PCD for HCOO\textsuperscript{−}, C_2H_4, and C_2H_5OH enhanced with cation size.

In future research, the investigation of monovalent cations for CO\textsubscript{2}R should be expanded to multivalent cations. Schizodimou and Kyriacou\textsuperscript{237} showed that rates of CO\textsubscript{2}R can be accelerated by increasing the size of cations and the surface charge of cations. They demonstrated that the CO\textsubscript{2}R rate is almost two-fold higher in electrolyte containing La\textsuperscript{3+} than in electrolytes containing Na\textsuperscript{+} at similar operating conditions.

5.1.2 Anionic effects. Two principle explanations are described to explain the impact of anions in an electrolyte on CO\textsubscript{2}R:\textsuperscript{229,238–241} pH and buffering effects, and specific adsorption of anions at the cathode surface.\textsuperscript{229} Hori et al.\textsuperscript{238–241} studied the effects of pH and reported that the production ratio of C_2H_4/CH_4 varies significantly for different anions in electrolyte: the C_2H_4/CH_4 ratio is higher for K_2SO\textsubscript{4} (4.16) and KCl (3.74) than for KHCO\textsubscript{3} (1.02) and K_2HPO\textsubscript{4} (0.11) (Fig. 16). This result was attributed to the inadequate neutralization capacity of the non-buffering K_2SO\textsubscript{4} and KCl, which leads to an increase in local pH, promotes higher hydrocarbons and suppresses CH_4.\textsuperscript{238,241} Another interesting feature is the promotion of the HER upon increasing the concentration of the K_2HPO\textsubscript{4} from 0.1 to 0.5 M. This result was attributed to the low pH value at the electrode/electrolyte interface as the concentration of the buffer increases.\textsuperscript{229,238} Through varying the anion types of the electrolyte with or without buffering (e.g. perchlorate, sulfate, bicarbonate, borate and phosphate), Bell and co-workers\textsuperscript{240} found that all the studied anions have negligible effects on evolving pH-independent products, such as CO, HCOO\textsuperscript{−}, C_2H_4 and C_2H_5OH,\textsuperscript{238,241} but significantly influence the CDs of H_2 and CH_4, which are highly dependent on pH. In comparison with buffering electrolytes (i.e. HPO\textsubscript{4}\textsuperscript{2−} and HCO\textsubscript{3}−), the non-buffering electrolytes with ClO\textsubscript{4}− and SO\textsubscript{4}\textsuperscript{2−} as anions demonstrated a higher local pH and significantly lower CDs in producing pH-dependent H_2 and CH_4.\textsuperscript{240} We discuss the effects of pH on CO\textsubscript{2}R in more detail in Section 6 of this review.

The specific adsorption of anions on cathode can also alter the CO\textsubscript{2}R activity and selectivity.\textsuperscript{190,225,245,246} In particular, the adsorption of halide ions on the electrode surface can alter the electronic structure of the catalysts, and thereby influence the interactions between the electrode surface and intermediates.\textsuperscript{190} For example, Varela et al. showed that Br\textsuperscript{−} and Cl\textsuperscript{−} enhanced CO formation, but I\textsuperscript{−} facilitated formation of CH_4 instead of CO.\textsuperscript{246} Moreover, specifically adsorbed halide anions can suppress proton adsorption and thus prefer CO\textsubscript{2}R to HER for a Cu-metal electrode.\textsuperscript{246} This can be attributed to the presence of covalent interaction between the halides and Cu electrodes, which facilitates the transfer of electrons from Cu-surface to CO\textsubscript{2}.\textsuperscript{246} In addition, several studies have reported the changes of morphology of a catalyst's surface in the presence of halide anions, especially via oxidation–reduction cycles to promote C_2 products over copper catalysts.\textsuperscript{190,225,247–249} However, it still remains unclear which anion factor influences CO\textsubscript{2}R reaction the most.

**Fig. 16** Effect of anionic species (different 0.1 M bicarbonate solutions) on FEs of various products at a Cu electrode and at 5 mA cm\textsuperscript{−2}; E° values are vs. SHE, *refer to 0.5 M, reproduced from the data in Hori et al.\textsuperscript{238} (1989).
5.2 Organic solvent electrolytes

Some typical examples of organic solvent electrolytes used for CO$_2$R are shown in Table 4 with dimethyl sulfoxide (DMSO), dimethylformamide (DMF), propylene carbonate (PC), and acetonitrile (ACN)\textsuperscript{250,251} the most commonly reported organic solvents used in CO$_2$R. The solubility of CO$_2$ in organic solvents could be much higher than in water (as presented in Fig. 17). As a result of their higher CO$_2$ solubility and absence of proton, organic solvents can achieve higher CD and better product distribution for CO$_2$R than in aqueous electrolytes.\textsuperscript{257,197,198,229} Vassilev \textit{et al.}\textsuperscript{232} reported that DMSO, DMF, PC, and ACN assist in dimerization of *CO$_2$* with adsorbed CO$_2$ molecules to form oxalate ($\text{C}_2\text{O}_4^{2-}$) over Pb, In, Sn, and Hg cathodes, which tend to produce HCOO$^-$/HCOOH in aqueous electrolytes.\textsuperscript{229} Moreover, the overpotential required to convert CO$_2$ into products is lower than that in aqueous solution, making the process energy-efficient.\textsuperscript{253} Mixed electrolytes containing both organic solvents and water are reported, which allows tuning of proton concentrations.\textsuperscript{254} Hori \textit{et al.}\textsuperscript{254} found that upon increasing the concentration of water in ACN, CO$_2$R favors the formation of formic acid rather than oxalic acid.

Although organic solvents offer higher CO$_2$ solubility than aqueous electrolytes, some critical disadvantages of organic solvent electrolytes are their high cost, their volatility and flammability, and possible toxicity. As the organic solvents are not typically consumed in the CO$_2$R reaction it could be possible to recycle solvents to reduce the operational costs of CO$_2$R.\textsuperscript{298} However, recycling of organic solvents from the electrolyzer liquid product may be complicated and costly due to the volatility and toxicity of the solvent and potential miscibility with the desired products.\textsuperscript{260}

5.3 Ionic liquids

Ionic liquids (IL) have been proposed as alternatives to aqueous amines for CO$_2$ capture process\textsuperscript{264} because ILs exhibit high CO$_2$ solubility\textsuperscript{266} and high selectivity for CO$_2$ over other gases such as N$_2$, O$_2$, and CH$_4$.\textsuperscript{266} Ionic liquids also exhibit other desirable properties for CO$_2$R electrolytes such as excellent thermal stability,\textsuperscript{267,268} stability across a wide electrochemical potential window,\textsuperscript{268,269} high ionic conductivity,\textsuperscript{268} and low vapor pressure.\textsuperscript{268,270} In addition, some ILs can form a complex with the intermediates during CO$_2$R and thus lower the energy barrier of the reaction.\textsuperscript{191} Table 5 provides a summary of some ILs reported as CO$_2$R electrolytes. The most extensively studied ILs for use in CO$_2$R electrolyzers are two commercially available ILs: 1-ethyl-3-methylimidazolium tetrafluoroborate ([EMIM] [BF$_4$]), and 1-butyl-3-methylimidazolium tetrafluoroborate ([BMIM] [BF$_4$]).\textsuperscript{191,271,272}

In 2011, Rosen \textit{et al.}\textsuperscript{191} first reported the catalytic effect of an 18 mol% aqueous solution of [EMIM][BF$_4$] in the CO$_2$R to CO over an Ag electrode at low overpotentials to achieve FE$_{CO}$ of over 96%. Fig. 18 illustrates Rosen \textit{et al.’s}\textsuperscript{191} hypothesis that an IL cation can stabilize the *CO$_2$* intermediate, and therefore substantially lower the energy barrier for the formation of *CO$_2$* and its subsequent reduction to CO.\textsuperscript{191,273,274} Subsequently, the Rosen’s team investigated the effect of water on CO$_2$R in [EMIM][BF$_4$] solutions and found that addition of water in the IL enhanced the CO selectivity, with an optimal CO selectivity.

close to 100% in a solution of 10.5 mol% IL in water. Such performance enhancement was attributed to a synergistic effect of mass-transfer improvement due to lower the electrolyte’s viscosity by dilution with water and an optimal pH (pH around 3.2 at 89.5% water).274

Following Rosen et al.’s work,191 others have attempted to understand the catalytic effect of the ILs in CO₂R, and although there is still more to understand about the reaction mechanism most reports suggest that the cation is primarily responsible for the observed catalytic effects.271,275 For example, Rosenthal and co-workers proposed that ILs serve as a proton source by deprotonation from the C₂ position (refer to Fig. 19) of the [EMIM]+ or [BMIM]+ cation; this would result in the conversion of CO₂ to CO via the 2e⁻ / 2H⁺ reduction pathway, which has a lower energy barrier.279,281,282

Despite the many promising properties of ILs for CO₂R electrolytes, the high viscosity of ILs can severely limit the rates of CO₂ diffusion, and thus ILs achieve very low CDs272 and, as shown in Table 5, most CO₂R studies dilute ILs in aqueous solutions or organic solvents such as AN, DMF, or CH₃OH to reduce the electrolyte’s viscosity.191,271,275,277 Progress in development and application of ILs has progressed rapidly in the last 30 years to provide a large amount of fundamental scientific data and knowledge on the use of ILs in CO₂R research.

understanding of IL properties and physicochemical data, and to lower IL production costs significantly. Thus, ILs are becoming more available and could soon be viable options for use in CO₂R electrolyzers.

6 pH effects

The pH of the electrolyte affects the phase stability of CO₂ in aqueous solutions as illustrated by the Pourbaix diagram in Fig. 20.²²⁹ The Pourbaix diagram highlights the acid/base homogeneous interactions of CO₂ into different forms, such as carbonic acid (H₂CO₃), bicarbonate (HCO₃⁻), carbonate (CO₃²⁻) and methanol (CH₃OH) in water as a function of pH and potential. Reaction (6) shows that the introduction of CO₂ into an aqueous solution entails a complex series of reversible reactions between CO₂, water, carboxylic acid, and its deprotonated species. In solutions with a pH up to about 6, CO₂ is in the form of a weak carboxylic acid; at pH between 6 and 10.3, HCO₃⁻ anions are formed; and at pH above 10.3 HCO₃⁻ deprotonates further to CO₃²⁻ (reaction (7)). Due to the various reactions and the feed CO₂, most aqueous solutions are normally in the HCO₃⁻ form and around pH 9 unless specific measures are used to counteract them (e.g., high flow rates).⁴⁵

Note that the local pH near the cathode surface is usually different to that in the bulk electrolyte due to the catalytic reactions generating OH⁻ or consuming H⁺, and diffusion limitations.²⁸⁷ Despite the significance of local pH on CO₂R as discussed in Hori’s works,²²⁸,²³⁸,²⁳⁹ only recently has the influence of local pH been re-re-examined.²⁵,²⁸⁷–²⁹² Additionally, some electrolytes, such as bicarbonates provide pH buffering effects (see Section 5.1.2 for more details).²⁴⁰

As the major competing side reaction, HER needs to be minimized for an optimal CO₂R reaction. Therefore, pH is crucial in determining the HER activity, as it characterizes the availability of the protons. Although CO₂R produces OH⁻, its equilibrium potential is not much influenced by the pH in comparison to HER.²⁹³ A rise in pH moves the equilibrium potential of HER to a more negative value, thus significantly slowing down HER.²⁹³ As shown in Fig. 21, the equilibrium potential denoted by \(E_{\text{rev}}\) reflects the potential of the HER derived from the Nernst equation. Moreover, the mechanism of HER switches from protons-to-H₂ in acidic media to water-to-H₂ in alkaline media, where the kinetics of latter is significantly slower and does not have a pH dependence, although the concentration is typically much greater.²⁹⁴–²⁹⁷

The pH is also an essential factor in determining the products of CO₂R. TakingCu as an example, an increase of pH shifts the product selectivity from H₂ and CH₄ to higher carbon products such as C₂H₄.²⁴⁵,²³⁸,²⁴⁰,²⁹⁸,²⁹⁹ The HER suppression at higher pH can be easily described by the reduced availability of H⁺/H₂ during. However, how pH affects CO₂R products (i.e. CH₄ preferred at low pH and C₂H₄ at higher pH) is very complex, and is likely related to the multiple proton-coupled-electron steps involved in their various reaction pathways, and the rate-determining steps in those various microkinetics.²⁹³,²⁹⁸,¹⁰⁰–¹⁰²

The different onset potentials\textsuperscript{218,299,303} and Tafel slopes\textsuperscript{314–316} for CH\textsubscript{4} and C\textsubscript{2}H\textsubscript{4} evolution suggest that they follow different reaction pathways. Hori and co-workers proposed that C\textsubscript{2}H\textsubscript{4} evolution is pH independent, while the pathway for CH\textsubscript{4} evolution is pH-dependent, during or prior to the rate-determining step (RDS).\textsuperscript{306} By using online electrochemical mass spectrometry (OLEMS), however, Schouten’s group found that the onset potential for forming CH\textsubscript{4} and C\textsubscript{2}H\textsubscript{4} are both pH-dependent particularly over Cu (111) electrode.\textsuperscript{307,308} Schouten and co-workers proposed two possible reaction pathways for the formation of C\textsubscript{2}H\textsubscript{4} as illustrated in Fig. 22a. One pathway is pH-independent, involving the formation of CO dimer where proton transfer is not the RDS, and preferentially takes place at Cu (100) facets. This pathway has also been theoretically confirmed by Calle-Vallejo and Koper.\textsuperscript{309} Another pathway is pH dependent, sharing the same *CHO intermediate, which is also critical in evolving CH\textsubscript{4}, and takes place both at Cu (100) and (111) facets. More interestingly, the overpotential for both CH\textsubscript{4} and H\textsubscript{2} evolution is lowered at a very high pH (e.g. pH = 13, see Fig. 22b).\textsuperscript{308,310} The reduced overpotential of HER at higher pH could be a result of the possible reaction pathway shift from pH dependent (due to proton availability) to pH independent (due to water discharge).\textsuperscript{291,311} Likewise, it could be understood that a similar shift likely takes place during the formation of the CH\textsubscript{4} at higher pH. Based on this understanding, electrolytes with higher pH can favor the formation of higher hydrocarbon products (especially over copper catalysts). Recently, Sargent and co-workers\textsuperscript{312} showed that strong alkaline media (7 M KOH) accelerates the kinetics of CO\textsubscript{2}R by lowering the C–C coupling energy barrier over Cu catalyst and could achieve a C\textsubscript{2}H\textsubscript{4} FE of ~70% at ~0.55 V vs. RHE over 150 h of continuous CO\textsubscript{2}R operation. Therefore, more researchers are investigating KOH as electrolyte to further enhance the efficiency and selectivity of >C\textsubscript{2} products.\textsuperscript{45,312}

Additionally, it could be understood that a rise in the local pH could be beneficial for >C\textsubscript{2} products; however, with a rise in local pH, the equilibrium of CO\textsubscript{2} and water neutralization reaction shifts more towards bicarbonate formation, which eventually depletes the local CO\textsubscript{2} concentration and thus reduces the CO\textsubscript{2}R selectivity by promoting HER.\textsuperscript{52,290} This conflicting statement really begs a question on whether a high local pH is really desirable or deleterious for the CO\textsubscript{2}R reaction. At higher pH, CO\textsubscript{2} may still exist in low quantity (if ample CO\textsubscript{2} is transported into the solution) due to its limited hydration kinetics.\textsuperscript{312,313} Therefore, an optimal pH may exist for an efficient reaction and sufficient CO\textsubscript{2} supply. Recent modeling studies found a relationship between pH and selectivity of CO\textsubscript{2}R with a maximum CO\textsubscript{2} selectivity over an optimal local pH range of 9 to 10 (especially for C\textsubscript{2} products).\textsuperscript{304,314} Interestingly, at a higher pH, the selectivity and activity of >C\textsubscript{2} products reach a maximum and finally start decreasing, whereas, CH\textsubscript{4} evolution starts increasing.\textsuperscript{61} A possible reason for this behavior could be the increased coverage of H* caused by the depletion of CO* in the limited mass-transport regime. Such adsorbed protons promote CH\textsubscript{4} evolution (by CO hydrogenation) and reduce the chances of CO* coupling to make >C\textsubscript{2} products.\textsuperscript{315,316}

Furthermore, in a relatively alkaline environment, the Cannizzaro reaction (Fig. 23a) could take place during CO\textsubscript{2} electrolysis. In a Cannizzaro reaction, an aldehyde can disproportionate to the corresponding carboxylic acid and alcohol.\textsuperscript{317} Through investigating the reduction of formaldehyde in various electrolytes, such as perchloric acid (HClO\textsubscript{4}), sodium perchlorate (NaClO\textsubscript{4}), and phosphate buffers, Koper and co-workers observed that the disproportionation reactions are strongly influenced by the electrolyte pH and buffering strength.\textsuperscript{317} As OH\textsuperscript{-} ions are essential for the Cannizzaro reaction, HCOOH is easier to form in the HClO\textsubscript{4}-based electrolyte (pH = 3) than the one with pH = 1 (see Fig. 23b). In phosphate electrolyte with a high buffering capacity and thereby a relatively low local pH, Cannizzaro reaction was significantly hindered, leading to a negligible formation of HCOOH.\textsuperscript{317} Therefore, researchers should be careful in distinguishing the products such as acids and alcohols formed from the disproportionation reactions and those formed by direct CO\textsubscript{2}R, especially for the liquid products such as methanol and ethanol, where the corresponding aldehyde is often proposed as a reaction intermediate.\textsuperscript{318} This is especially true since interrogation of the just produced products is hard to measure compared to

![Figure 22](image-url)

the ones that further react and transport and are detected in the bulk solution or gas flows.

Enhanced mass transport makes the value of local pH closer to the bulk pH, thus influencing the activity and selectivity of cathodic reactions. Through rotating a Cu cylinder electrode to enhance the mass transfer, Marshall and co-workers found that the CO$_2$R activity decreased with the increasing rotation speed, along with a change in product preference from CH$_4$ to CO, while HER was promoted. Such degradation of CO$_2$R is attributed to the formation of graphitic carbon on electrode surface due to low local pH at higher rotation speed, resulting in the deactivation of the active sites for CO$_2$R. This evidence is also supported by Mul and co-workers, who presented a pH-dependent pathway for the deactivation of Cu electrode due to carbon formation. In addition, the change in product selectivity from CH$_4$ to CO at higher rotation speed could be due to lower coverage of adsorbed *CO, which is a precursor for CH$_4$ formation.

7 Pressure and temperature effects

7.1 Pressure

The partial pressure of CO$_2$ in the gas fed to the electrolyzer directly impacts the rate of CO$_2$ mass transfer to the electrode surface due CO$_2$-solvent solubility relationship. For example, at a given temperature CO$_2$ solubility in aqueous electrolytes and physical organic solvents typically increases linearly with pressure according to Henry’s law. Other solvent-electrolytes like amines and ILs exhibit non-linear CO$_2$ solubility relationships that may reach a plateau at a critical pressure (e.g. around 10 MPa for imidazolium-based ionic liquids and ~1 MPa for amines) beyond which further increase of pressure does not improve solubility. Raising the operating pressure increases complexity and cost of electrolyzer construction and operation, so optimization of the pressure must consider costs and the effect of pressure on CO$_2$R selectivity.

A large number of studies report the effects of pressure on product selectivity and FE of CO$_2$R processes. Hara et al. reported that on a Cu wire (0.16 cm$^2$) in 0.1 M KHCO$_3$ the CO$_2$R products shifted from H$_2$ at 1 atm to hydrocarbons then to CO and/or HCOOH as the pressure was increased to 30 atm, with PCD$_{CO}$ up to 523 mA cm$^{-2}$ observed. Table 6 summarizes a typical example reported by Hori et al. of the effect of CO$_2$ pressure on product selectivity over different metal electrodes. Hori et al. observed that over group B catalysts, which include Fischer–Tropsch catalysts like Ni, Co and Fe, product selectivity shifted from H$_2$ at ambient pressures to HCOOH and CO at high pressure. Kudo et al. reported similar shifts from H$_2$ at low pressures to CO, HCOOH, and hydrocarbons at 60 atm over Ni catalysts as shown in Fig. 24a. They observed that the hydrocarbons from CO$_2$R over Ni followed a Schulz–Flory probability distribution like that obtained by the Fischer–Tropsch reaction, and proposed that like the conventional Fischer–Tropsch process electrochemical CO$_2$R at high pressures may involve hydrogenation of metal

carbonyl intermediates to facilitate production of carbene groups (–CH2–) that polymerize to longer-chain hydrocarbons. In addition, high CO2 pressure increases the surface coverage of CO2R intermediates on the electrode surface, which promotes CO2R and suppresses HER as illustrated in Fig. 24b and c.210,331

For group C catalysts like Ag and Sn, Hara et al.310 did not report a major shift in the type of CO2R products at higher pressure but the FE towards CO and HCOOH did increase (relative to H2), and this was attributed to increased CO2 solubility at higher pressures. Over Cu catalysts (group D), Hara et al.310 reported a shift from hydrocarbon production at 1 atm to CO and HCOOH at 30 atm. Jesús-Cardona et al.326 proposed that at concentrations of CO2 in the electrolyte at elevated pressure, CO2 molecules displace may displace at the electrode’s surface some of the CO∗ that are a key intermediate in the CO2R to hydrocarbon pathway.

High-pressure CO2R requires balancing the pressure in the anode and cathode chambers to prevent damage to the separator.98,212,262 Ramdin et al.98 compared the effects of BPM and CEM on CO2R to formic acid/formate at high CO2 pressure, and after the experiment observed delamination of BPM layers. Note that even in electrolyzer operating at near ambient pressures there can be a pressure imbalance across the separator, especially in CO2R processes where the anode produces O2 and the cathode reduces CO2 to liquid products. This pressure imbalance can deform the separator, so to improve mechanical strength thicker membranes, fabric-reinforced membranes, or additional porous substrates may be required. These approaches may improve strength and durability, but also increase the resistances across the separator.332

7.2 Temperature
Temperature effects CO2R electrolyzer performance because of both CO2 solubility (i.e. the Van’t Hoff equation)233,334 and minimum half-cell potentials are temperature dependent, and temperature influences CO2R kinetics because of its effect on mass transfer rates, reaction pathways, viscosity and conductivity of electrolytes, and the conductivity of IEM separators. The stability of cell components like membranes, electrodes, and gaskets may also be affected by temperature extremes or by temperature cycles. The range of temperatures reported for electrochemical CO2R processes is commonly between 20–40 °C, although a few studies have explored CO2R at temperatures as low as 0 °C (ref. 209) and up to 125 °C.34 Within this operating range the temperature dependency of electrical conductivity of cell components like current collectors is unlikely to have a significant effect on CO2R electrolyzer performance.

The main CO2R reactions and the HER have a positive entropy change so that lower overall thermodynamic cell voltages are required for reactions at higher temperatures. Additionally, lower activation overpotential are required at higher temperatures than lower temperatures to drive a sufficient overall CO2R rate, which can be quantitatively determined through the Butler–Volmer equation.335 The effect of temperature on overpotential appears to be more significant than the effect on thermodynamic potentials. For example, Dufek et al. reported a significant reduction of cathode potentials from −2.19 V to −1.87 V to achieve 70 mA cm−2 over an Ag-based GDEs when operating temperature was elevated from 18 to 70 °C, while less than 0.1 V decrement in thermodynamic voltage was observed when the temperature was increased from 25 to 125 °C.34 Ryu et al.336 reported a similar trend for CO2R over Hg electrodes.

Temperature has a significant effect on hydrodynamic properties (viscosity and density) and concentration gradients (due to solubility relationships) that control rates of CO2 mass transfer. For example, faster CO2 mass transfer coefficients from the gas to electrolyte is observed at higher temperatures because diffusivity of CO2 in gas and liquid phases increases, and the viscosity of the catholyte decreases.337,338 But, a reduced solubility at higher temperatures lowers the overall driving force for the mass-transport across the gas/liquid interface. The relative changes in solubility with temperature for CO2 compared to CO2R products such as CH4 and C2H4 that are

Fig. 24 Electrochemical reduction of CO2 on Ni electrodes, (a) effect of pressure on the FE of various products; reaction mechanism (b) at high pressure (60 atm), and (c) at atmospheric pressure. Adapted with permission from Kudo et al. Copyright 1993, The Electrochemical Society.

Temperature effects CO2R electrolyzer performance because of both CO2 solubility (i.e. the Van’t Hoff equation)233,334 and minimum half-cell potentials are temperature dependent, and temperature influences CO2R kinetics because of its effect on mass transfer rates, reaction pathways, viscosity and conductivity of electrolytes, and the conductivity of IEM separators. The stability of cell components like membranes, electrodes, and gaskets may also be affected by temperature extremes or by temperature cycles. The range of temperatures reported for electrochemical CO2R processes is commonly between 20–40 °C, although a few studies have explored CO2R at temperatures as low as 0 °C (ref. 209) and up to 125 °C.34 Within this operating range the temperature dependency of electrical conductivity of cell components like current collectors is unlikely to have a significant effect on CO2R electrolyzer performance.

The main CO2R reactions and the HER have a positive entropy change so that lower overall thermodynamic cell voltages are required for reactions at higher temperatures. Additionally, lower activation overpotential are required at higher temperatures than lower temperatures to drive a sufficient overall CO2R rate, which can be quantitatively determined through the Butler–Volmer equation.335 The effect of temperature on overpotential appears to be more significant than the effect on thermodynamic potentials. For example, Dufek et al. reported a significant reduction of cathode potentials from −2.19 V to −1.87 V to achieve 70 mA cm−2 over an Ag-based GDEs when operating temperature was elevated from 18 to 70 °C, while less than 0.1 V decrement in thermodynamic voltage was observed when the temperature was increased from 25 to 125 °C.34 Ryu et al.336 reported a similar trend for CO2R over Hg electrodes.

Temperature has a significant effect on hydrodynamic properties (viscosity and density) and concentration gradients (due to solubility relationships) that control rates of CO2 mass transfer. For example, faster CO2 mass transfer coefficients from the gas to electrolyte is observed at higher temperatures because diffusivity of CO2 in gas and liquid phases increases, and the viscosity of the catholyte decreases.337,338 But, a reduced solubility at higher temperatures lowers the overall driving force for the mass-transport across the gas/liquid interface. The relative changes in solubility with temperature for CO2 compared to CO2R products such as CH4 and C2H4 that are
sparsely soluble in the catholyte,\textsuperscript{139,140} could be advantageous to promote quick desorption of products from the electrode surface. However, proton transfer rates may also increase at high temperatures and so increasing temperature can potentially promote HER at the cathode.

The enhanced diffusivity and thinner static laminar layer at the electrode exhibited at higher temperatures reduces ohmic resistances in the electrolyte. In GDEs, temperature can also change the phase-change induced flow and result in dryers CLs.\textsuperscript{189} However, increased temperature means higher water entering into the electrolyzer at same relative humidity and so that can help get to higher CDs, especially if the system is water limited.\textsuperscript{189}

Temperature is known to affect the product distribution of the CO\textsubscript{2}R reaction over different catalysts.\textsuperscript{341–344} for example, Hori et al.\textsuperscript{399} reported a decrease of FeCH\textsubscript{4} and increase of FeC\textsubscript{2}H\textsubscript{4} over Cu foil at 5 mA cm\textsuperscript{-2} when the temperature was raised from 0 to 40 °C. Ahn et al.\textsuperscript{343} reported a similar trend when increasing the temperature from 2 to 22 °C. A close proximity of *CO intermediates is important for the formation of C–C bond, meaning that a high *CO coverage should make it easier for the C\textsubscript{2}H\textsubscript{4} evolution. However, the reported suppression of C\textsubscript{2}H\textsubscript{4} at high temperature, where the coverage of *CO is low, suggests that *CO coverage may not play a dominating role at least within the studied range. Alternatively, several recent theoretical studies proposed that *COH and *CHO intermediates are crucial to determine whether the product is CH\textsubscript{4} or C\textsubscript{2}H\textsubscript{4}, respectively with a Cu electrode.\textsuperscript{318,345,346} According to the work reported by Luo et al.,\textsuperscript{446} the availability of absorbed protons is essential to form *CHO, while the absorbed H\textsubscript{2}O is important to serve as a shuttle (H\textsubscript{3}O\textsuperscript{+}) to transfer the proton to the *CO intermediate to form *COH. Therefore, one possible explanation of the reported temperature effect is that low temperature can stabilize the formation of (H\textsubscript{3}O\textsuperscript{+}) proton shuttle, making it easier to form *COH intermediate, thus facilitating the production of CH\textsubscript{4}. On the other hand, higher temperatures increase the availability of adsorbed protons at the electrode surface, resulting in an easier formation of *CHO intermediates that promote C\textsubscript{2}H\textsubscript{4}. Moreover, the adsorbed protons could also partially contribute towards promoting HER. When temperature further increased from 22 °C, a degraded FE(C\textsubscript{2}H\textsubscript{4}) over Cu electrode was observed by Ahn et al.\textsuperscript{343} This suggests that the aforementioned coverage of *CO starts to dominate instead of the coverage of adsorbed protons.\textsuperscript{443} Interestingly, potential vs. RHE showed an opposite trend when comparing the temperature-effect results reported by Hori et al. and Ahn et al. Nevertheless, both studies report similar observations towards FE of CH\textsubscript{4} and C\textsubscript{2}H\textsubscript{4}, suggesting that the potential effect as imparted by the temperature change on the product distribution could be negligible in the studied temperature range.

Considering the effects of the potential on the reactivity and selectivity as mentioned, we recommend the design of experiment to keep the potential versus RHE constant when investigating temperature effects, as this potential is corrected by both temperature and pH. Overall, the temperature has significant impacts on the surface coverage of CO\textsubscript{2}R-related species (*COOH and *CO) through affecting their mass-transfer characteristics (e.g. solubility), as well as the coverage of proton-related adsorbates (e.g. H\textsuperscript{*} and H\textsubscript{2}O\textsuperscript{+}) that also are important for the formation of key intermediates (e.g. *CHO and *COH). Such effects likely contribute the observed temperature-dependent CO\textsubscript{2}R selectivity.

A small increase in temperature can lower the ohmic resistance of the separator.\textsuperscript{441,447} However, too high of a temperature degrades the ionic conductivity and mechanical structure of the membranes. Taking perfluorosulfonic acid (PFSA) polymer-based membrane as an example, its clusters of the hydrophilic sulfonic-acid group uptake sufficient water and allow protons to move easily in the membrane. In a fuel-cell configuration, a too high temperature (>90 °C) lowers the water content in the membrane, leading to a decreased ionic conductivity.\textsuperscript{448} Common AEMs, such as quaternary ammonia polysulphone, limit the operation to a much lower temperature than CEMs due to chemical stability concerns.\textsuperscript{449} The Sustainion® membrane, developed by Dioxide Materials, has an improved ionic conductivity (~140 mS cm\textsuperscript{-1} in 1 M KOH aqueous solution at 80 °C) and can stably be operated at temperature up to 80 °C.\textsuperscript{347} Ceramic based separators such as ZrO\textsubscript{2} diaphragm can withstand higher operating temperature, but again they also pose other key risks such as product crossover that lose conversion efficiency of the cells.

8 Summary and outlook

We have examined in this review the impact of design and operating decision related to electrolyzer configurations, electrode structure, electrolyte selection, pH, pressure, and temperature affect the reaction conditions at catalyst sites in a CO\textsubscript{2}R electrolyzer, and thus impact on the overall efficiency of the process. The key challenges for low cost CO\textsubscript{2}R that can be addressed by these factors together with catalyst materials are reducing the required cell voltages, improving selectivity, and lowering product separation costs.

The most promising CO\textsubscript{2}R electrolyzers under development are based on designs and understanding translated from polymer electrolyte fuel-cells. Of the types of continuous CO\textsubscript{2}R electrolyzers under development, vapor-fed electrolyzers may be the most promising for the large-scale CO\textsubscript{2}R processes because this configuration provides opportunity to feed wet CO\textsubscript{2}-rich flue gas directly to the electrolyzer without CO\textsubscript{2} capture process units.\textsuperscript{350} This technology if coupled with renewable electricity generation could also provide opportunities for passive CO\textsubscript{2} capture from the atmosphere.\textsuperscript{351} Vapor-fed electrolyzers may also reduce risks of catalyst poisoning from trace impurities in liquid electrolytes. For large-area electrodes in industrial scale electrolyzers, achieving uniform current and voltage distribution throughout the electrode surface and managing pressure gradients at the gas–electrolyte interface are critical, thus further work is required to optimize the electrode and flow-field design. In this regard, advanced manufacturing technologies like 3D printing\textsuperscript{352} combined with computational modelling may help to optimize electrode and electrolyzer geometries.

There are fundamental aspects of electrolyte interactions in CO\textsubscript{2}R processes that are not fully understood. For example, although the charge carrying capacity of electrolytes is the

primary function, researchers have discovered that electrolyte cations contribute in other ways to effect to the availability of protons and to stabilize CO2R intermediates. Likewise, electrolyte anions can provide local pH buffering effects due to specific adsorption of anions at the cathode surface. Low CO2 solubility and competitive HER remain major challenges in inorganic salts-based aqueous electrolytes. Other new solvent-electrolytes such as ionic liquids and deep eutectic solvents may become more attractive if their cost reduces in the future, but to be effective CO2R electrolytes the viscosity of these solvents will also need to be managed, for example by mixing with a co-solvent such as water.

While our review has focused on electrochemical CO2R at the cathode, we acknowledge that the anode catalyst is also critical and especially because the state-of-the-art Ru and Ir based anode materials are a major contributor to the cost of electrochemical CO2R. Therefore, any advances in anode technologies achieved in other applications such as the oxygen evolution reaction in water splitting should help inform development of electrochemical CO2R processes. Water purification from treating wastewater through anodic oxidation of organic pollutants could be another approach to be considered for coupling with CO2R. Moreover, since the oxidation potential of chloride is similar to that of water, producing chlorine at anode [54,55] (similar to chlor-alkali cells) without the expense of extra energy could be beneficial for optimizing the overall process.

A final consideration in research needs for CO2R relates to experimental methods used to test novel catalysts and electrolytes. Most laboratory studies still use H-type batch setups [49] in which the solubility of CO2 in electrolyte and gas-liquid mass transfer limits can control the overall rate of CO2R reactions, plus the transport of ions across separators in H-type cells can limit applicability of long term stability tests. Lab scale continuous flow-cell electrolysers offer opportunities to detect minor CO2R products [56] and to better control reaction conditions than in H-cells. The cost of flow-cell apparatus is no longer significantly higher than a batch cells, so we expect the trend in reporting continuous CO2R measurements in catalyst studies may become more common. Clark et al. [57] have also highlighted the urgent need for standardized protocols, such as those developed for battery testing and fuel cell performance, to benchmark performance of catalyst and electrolyzers for electrochemical CO2.
