This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
The fascinating combination of light-emitting characteristics and electrical amplification identifies organic light-emitting transistors (OLETs) as key enabling devices for a wide variety of applications, ranging from displays to sensors. Pursuing a dual functionality in a single-layer architecture is either the major strength and the major challenge of this technology. Limitations mainly arise from the poor availability of organic semiconductors able to ensure good ambipolar behavior in charge transport together with an efficient light-emission in the solid state. In the present perspective, we report on the new class of thienoimide-ended oligothiophenes as molecular compounds simultaneously endowed with a good field-effect mobility for holes and electrons, good processability, self-assembly capability into nanostructures and remarkable properties of photo- and electroluminescence in solid state.

The versatile chemical tuning of the molecular structure and the fine use of both solution-processed and physical deposition techniques in the realization of nanostructured thin-films are the major tools for controlling the packing of molecules and their intermolecular interactions at the solid state. Indeed, the inherent polymorphism of this class of compounds is directly correlated to their electrical and optoelectronic properties as active materials in multifunctional devices. Considering the field-effect transistor as a benchmark device platform, here we propose the extended family of thienoimide-ended oligothiophenes as a case study in virtue of i) the solid and throughout correlation of the molecular structure and solid-state organization with the figures of merit in transistor-based devices, and ii) the possibility of engineering highly-integrated planar organic optoelectronic devices with multiple functionalities for the investigation of photophysical and charge transport processes in organic compounds and, ultimately, the demonstration of real-setting applications of OLET technology.

1. Introduction

In the last decades, $\pi$-conjugated materials and in particular organic semiconductors (OSCs) have driven the attention of both academia and technological industry. The fascinating combination of soft processability and electronic characteristics opens the way towards the real-setting application of organic materials in highly integrated, flexible and wearable devices.\(^1\) The ease of processing on a wide range of substrates is one of the key factors of the OSC expansion. In addition, the possibility to easily tune the combination of charge-carrier mobility, photonic and electroluminescent characteristics, makes these materials even more appealing.\(^2\) Researchers are therefore constantly looking for new strategies that, by modifying the molecular structure, allow to develop materials with pre-defined advanced and multifunctional features.\(^3\)

The huge impact of OSCs in our daily life is clearly visible from the extensive presence of organic light-emitting diodes (OLEDs) in the display market.\(^4\) Over conventional displays, organic-based ones highlight advantages such as high luminous efficiency, high brightness, fast response time, low power consumption, lightweight, etc.. In general, OLEDs are ultrathin light-emitting devices capable to generate light when an electrical current is passing through it. A thin organic layer, which allows generating excitons, is sandwiched between two electrodes, thus forming a vertical structure a few hundreds of nanometers thick.\(^5,6\) In order to improve the efficiency, the OLED structure has been progressively improved by the insertion of additional functional layers to guarantee a selective injection and transport of charge carriers to the emission layer. Despite that, the generated light needs to pass through at least one electrode to be extracted from the device. As a result, the emission efficiency is closely related to the anode transparency, possible cavity effects and waveguiding processes.\(^7,8\) In view to realize more efficient and multifunctional optoelectronic systems, the scientific community focused the attention on a new device structure, that is the organic light emitting transistor (OLET).\(^9,10\)
OLEDs are planar field-effect devices with three terminals (source, drain and gate electrodes) that, in contrast to the vertical OLED architecture, allow to move the position of the emissive zone far away from any absorbing metal electrodes by the applied gate and drain voltages. In particular, electrons and holes can be injected simultaneously in a single ambipolar semiconducting layer and form hole and electron accumulation near the more positive and more negative electrode, respectively. If the semiconductor is electroluminescent, light emission is generated within the transistor channel where the opposite charge-carrier fronts meet (Figure 1). Given that the recombination of opposite charges is mainly an in-plane diffusion of charges approaching each other, the emission region is extending for about few microns.

This architecture integrates together the logical switching functionality of organic field-effect transistor (OFETs) and the light generation capability of OLEDs. At a first glance, it is easy to understand the reason why the use of OLEDs would drastically reduce the complexity of display pixel circuitry. However, OLEDs offer more substantial advantages that are closely linked to the architecture of the devices. Indeed, the presence of a third electrode (gate) enables a control on two perpendicularly oriented electric fields governed by the bias applied between gate-source electrodes (V_{GS}) and drain-source electrodes (V_{DS}). Hence, under certain conditions of bias, it is therefore possible to horizontally move the emission stripe within the transistor channel, thus reducing exciton quenching processes at the electrodes and increasing the electroluminescence quantum efficiency with respect to the OLEDs. 

Over the years, several advanced geometries have been developed in order to raise the OLED performance, from the use of asymmetric electrodes to alternative structures such as bilayer, trilayer, vertical, OLED-separated, split-gate, overlapping gate, etc. However, the very first step towards the fully exploitation of the OLED technology lies in the development of multifunctional OSC materials which guarantee efficient ambipolar conduction and electroluminescent emission in the solid state. The electrically-induced formation of excitons in a single organic layer is correlated to the nature of the organic compound as well as to the charge transport capability of molecules at the solid state. Since the amount of emitted photons depends on the number of formed excitons, it follows that there is a direct correlation with the electron/hole current flows. The charge transport in OSCs typically occurs via hopping of charges from a molecule to another and it is strongly associated to the chemical structure as well as the molecular packing.

As a result, the fabrication of efficient single-layer OLEDs strongly depends on the availability of OSCs with i) a high charge mobility for both electrons and holes, ii) efficient exciton formation and electroluminescence emission at the solid state and iii) a suitably designed and controlled 3D packing of molecules propaedeutic to the former two points. Furthermore, aiming at full exploiting the functionalities of OLEDs, an accurate balancing of the electron and hole mobility is crucial to guarantee both high external quantum efficiency and throughout spatial tuning of the OLED emission region. In this context, while for p-type small molecules the mobility record is still being reset frequently (43 cm²V⁻¹s⁻¹ for C8-BTBT), much less n-type small molecules have been reported and the absolute mobility values are still lower if compared with the first one (12,6 cm²V⁻¹s⁻¹ for F4-BDOPV) (Figure 2).

The problem behind this gap mainly resides in the intermolecular interaction of molecules. When isolated molecules approach each other, the resulting valence bandwidth remains larger than the conduction bandwidth. This is the basic reason that explains why organic materials typically display higher hole mobilities than electron mobilities.

In the attempt to increase the electron mobility in OSCs, the introduction of strong electron-withdrawing groups such as –CN, –Cl, –F, –CN, –CF₃ and heteroatoms such as N, S was a successful strategy for the design of n-type molecules. However, when an electron is injected into the OSC, the process that occurs is similar to a chemical reduction. Hence, if the lowest unoccupied molecular orbital (LUMO) has high energy, the electron residing in the LUMO is prone to react with O₂ or H₂O. It follows that, over the intrinsic difficulties in obtaining good n-type behavior, molecules might also be not very stable under ambient conditions.

Apart from balanced charge ambipolarity, the other feature that must be provided by good OSC candidate for single-layer OLET is light emission. While charge mobility is typically favored by a strong intermolecular π–π stacking, the luminescence generally decreases due to quenching of singlet excitons.

In recent years, the growing research of novel multifunctional materials for high-integrated systems paved the way to new strategies of molecular engineering. Some of the remarkable approaches that have been recently introduced for tuning the OSCs properties consider: the chemical rigidification of the molecular...
structure by limiting the torsion angle, the increase of the extension of the \(n\)-conjugation, the introduction of substituents with inductive or mesomeric effects, the stabilization of the aromatic or the quinoidal resonance form, the rational conjugation of substituted monomers to induce intermolecular order. Among the others, one of the most successful strategies for the development of multifunctional materials is to synthesize molecules or copolymers with either an electron-donor (D) and an electron-acceptor (A) moiety.\textsuperscript{31,32} While the D-A interaction regulates the strength of intermolecular \(n\)-\(n\) stacking and then the charge mobility efficiency, it is possible to decouple the light emitting function by locating the charge transfer onto the most emissive moiety or by introducing a new moiety devoted to radiative deactivation. Isodindigo,\textsuperscript{33,34} naphthalene diimide\textsuperscript{35,36} (NDI) and diketopyrrolopyrrole (DPP)\textsuperscript{37} are just some among all the electron-acceptor building-blocks used to induce n-type behavior in p-type OSCs. To date, the milestone among emissive ambipolar materials is poly(9,9-di-n-octylfluorene-alt-benzothiadiazole) (F8BT) (Figure 2), a green emitting D-A conjugated polymer with a photoluminescence efficiency of 50-60% in solid film.\textsuperscript{38} Due to the high electron-withdrawing capacity of the benzothiadiazole group (BT), F8BT has a high electron affinity of 3.3 eV and a large ionization potential of 5.9 eV, which allowed its use as electron transporting layer in polymer-blend OLEDs\textsuperscript{39} and photovoltaic cells.\textsuperscript{40}

When implemented in single-layer OLETs, F8BT showed a well-balanced ambipolar charge transport with saturation mobilities of 7-9 \(10^{-4}\) cm\(^2\) V\(^{-1}\) s\(^{-1}\) for both electrons and holes. Due to its polymeric nature, F8BT was spin-coated onto a polymethyl methacrylate (PMMA) dielectric layer and it was evident the influence of the long-range crystalline organization onto charge mobility and EL emission zone within the channel. Zaumseil et al.\textsuperscript{41} further investigated that correlation in amorphous, polycrystalline and nematic liquid crystalline F8BT films. While OLETs including an amorphous film of F8BT showed a featureless and quite narrow emission region (whose width is 2 \(\mu\)m), polycrystalline films led to a much broader (4 \(\mu\)m) emission region with the morphological presence of bright and dark spots.

If amorphous polymers are the preferable systems for optimizing emission properties in OLETs, their (generally) low field-effect charge mobility in amorphous phase pushed the scientific community to look for other materials. Because of the long-range order of molecular packing achievable in thermally evaporated thin films, conjugated oligomers are surely promising structures for realizing high-mobility OLETs.

In this context, major interest has been devoted in the last 10 years to thieno[2,3-c]pyrrole-4,6-diole ended oligothiophenes, better known and herein referred as 2,3-thienoimide (TI) ended oligothiophenes, which showed a great potential as emissive ambipolar compounds endowed with easily tunable structural and optoelectronic properties.\textsuperscript{42} This class of small molecules was inspired by two widely studied analogues, the p-type \(\alpha,\omega\)-dihexylquaterthiophene (DH4T)\textsuperscript{43,44} and the n-type dicabonyl ended quaterthiophene (DHC04T),\textsuperscript{45} i.e. maintaining the oligothiophene size but introducing the end substitution with the Ti group. TI substitution strategy turned out to be a powerful tool to i) obtain electron transport, ii) modulate ambipolarity (major p- or n-type behavior) on the basis of the number of TI groups, iii) tune the highest occupied molecular orbital (HOMO) and the LUMO energy values, iv) influence the solid-state packing.\textsuperscript{46} Furthermore, unexpectedly, TI moieties promoted light emission capability to oligothiophenes. All these features made 2,3-thienoimide oligothiophenes suitable candidates for OLET application. In addition to that, this class of OSCs showed the attractive possibility to tune the optoelectronic and photonic properties also by processing/post-synthesis treatments. Indeed, in many cases, different structural phases (polymorphs) and then different molecular organization were observed.\textsuperscript{47} Hence, through various conventional and non-conventional deposition techniques, it was possible to obtain a specific molecular arrangement characterized by designed features.\textsuperscript{48}

The combination of all these characteristics highlights the great potential of 2,3-thienoimide oligothiophenes for OLET applications. This perspective aims at discussing how synthetic (Section 2) and post-synthetic (Section 3) methods influence the morphological and optoelectronic properties of this class of OSCs in view of their implementation as ambipolar emissive layer of OLETs. In Section 4, their outstanding characteristics are ultimately demonstrated to be suitable both for both fundamental investigations and the development of devices with multifunctional characteristics in advanced technological applications.

2. Molecular tailoring of 2,3-thienoimide oligothiophene derivatives

Organic semiconductors based on oligothiophenes are among the most widely studied compounds for electronic and optoelectronic applications.\textsuperscript{49,50} The polarizability of sulfur atoms in the thiophene rings indeed stabilizes the conjugated backbone thus favoring the charge transport along the oligomeric backbone. In addition, oligothiophenes have unique self-assembly properties in the solid state, which make them attractive candidates for realization of nanostructured systems via non-conventional solution-processed techniques. Among the plethora of advantages, oligothiophenes are also versatile compounds because of the possibility to substitute H atoms of the thiophene rings with suitable functional groups to obtain derivatives endowed with desired physicochemical properties. The chemistry of thiophenes is well known and has been developed over the past years. They are the ideal building blocks for transition metal-catalyzed cross-coupling reactions and hence many possible strategies may be used to modify the molecular structure.\textsuperscript{51,52,53,54}

Oligothiophenes are widely known to be excellent p-type semiconductors. To enhance the electron transport characteristics and hence to obtain compounds having an ambipolar character, electron-withdrawing groups such as cyano groups,\textsuperscript{55} fluorinated aroyls,\textsuperscript{56} etc. have been introduced in the oligomer backbone to modify the frontier orbitals energy and, eventually, to increase the electron mobility. For instance, the development of perfluoroalkyl terminated quaterthiophenes\textsuperscript{57} such as DFH4T (also named as FT4F)
led to OFETs with an electron mobility up to 0.24 cm$^2$V$^{-1}$s$^{-1}$ and an unprecedented solid state optical emission efficiency if compared to the unfluorinated derivative.\textsuperscript{10} The application of DFH4T in advanced multistack OLETs allowed indeed to reach external quantum efficiencies exceeding 5%.\textsuperscript{12}

Despite optical properties and the electron mobility have been effectively increased by using electron-withdrawing perfluoroalkyl moieties in oligothiophenes, either the ambipolar character and the electroluminescent properties resulted to be still limited.

In this context, the insertion of a thienoimide group (Ti or N), which is fully fused to the quaterthiophene core, emerged as an alternative and powerful approach to switch from unipolar thiophene-based materials to ambipolar and electroluminescent ones. As shown in Figure 3, three different oligothiophenes with a single TI moiety were initially developed. While one of them comprised no other functionalization in the molecular backbone (namely T4N), the other two compounds included a hexyl or a perfluorohexyl side chain (respectively named as HT4N and FT4N). In addition, a quaterthiophene derivative endowed with two TIs (namely NT4N or T4DIM) was also synthesized (Figure 3).

Regardless the type of functionalization, the optical properties of all compounds in solution resulted similar, with absorption spectra peaked at around 441-449 nm and unstructured photoluminescence spectra (Table 1). Compared to the benchmark HT4H compound, all functionalized molecules reported a slight reduction of the photoluminescence quantum yield ($\Phi$), which however resulted over 10%, except for T4N (8%). Vacuum-sublimed thin films showed a blue-shift of the optical properties with respect to the correlated solutions, thus suggesting the formation of possible polycrystalline domains in solid state. Interesting differences were obtained in their electrochemical characteristics, especially in the HOMO levels that resulted affected by the presence of TI units. While the presence of a single Ti unit (T4N and HT4N) showed remarkable differences in the energy of the LUMO, which resulted about 1 eV lower with respect to that of HT4H, the introduction of a second Ti unit lowered the energy of HOMO, which resulted -5.73 eV, -5.74 eV and -6.00 eV respectively for HT4N, T4N and NT4N (Table 1).

![Figure 3. Molecular structures of the quaterthiophene derivatives including Ti ended compounds. Reprinted with permission from Chem. Mater. 2013, 25, 5, 668–676. Copyright (2013) American Chemical Society](image-url)
The chemical structure of the reported compounds has a critical long-range effect also in defining the electronic characteristics in the solid state. If comparing NT4N and FT4N as isolated molecules, the HOMO-LUMO positioning and energy gap were almost identical. Nevertheless, their charge mobilities resulted drastically different and NT4N showed the best p- and n-type charge mobilities with respect to all non-symmetric compounds, i.e. 7×10⁻⁵ cm²V⁻¹s⁻¹ and 0.55 cm²V⁻¹s⁻¹ for holes and electrons, respectively. Despite further insight on the field-effect behavior of Ti-ended quaterthiophenes will be discussed in Section 4, it is clear that the best candidate among Ti derivatives towards the achievement of emissive ambipolar devices is represented by NT4N. For a better understanding of the origin of the ambipolar electroluminescent characteristics of NT4N, a deeper analysis on the optical features and solid-state organization is necessary. In particular, from the UV-visible optical characteristics of the molecule, a high molecular planarity and rigidity was suggested because of the similar absorption and emission spectra in both solution and film. Nevertheless, the solvatochromic effect that the solvent can play on the optical properties of the molecule may also contribute to invariant optical spectra. In detail, as shown in Table 1 and Figure 5b, the absorption peak resulted to be located at about 450 nm and 430 nm, respectively for the solution and film. The emission peak was at the energy of 572 nm in solution and 603 nm in the solid state and, similarly to other oligothiophene derivatives (Table 1), the photoluminescent quantum yield of NT4N in thin film was around 1.5 %.

From a crystallographic point of view, the molecular backbone of NT4N resulted to be almost planar as a consequence of the two coplanar inner thiophene rings and the dihedral angle of only 4.4° between the inner thiophenes and the thiophene-imide units (Figure 6a). The crystal packing of NT4N molecules was indeed different from the typical herringbone structure of oligothiophenes and consisted of a slipped \( \pi-\pi \) stacking packing mode with an interplanar distance of about 3.51 Å in which the molecules slide along the long molecular axis of 3.32 Å (Figure 6b).

In details, the intermolecular C-H⋯O H bonds between two oxygen in anti-position and one hydrogen, that is attached to the imide-carbon atom of two different molecules, formed a 1D supramolecular organization constituted by molecules of adjacent \( \pi-\pi \) stacks (Figure 6c). In addition, sulfur atoms of the fused imidothiophene rings had intermolecular interactions with i) the hydrogens of the inner thiophene rings and ii) sulfur atoms of the fused imidothiophene rings, which were not involved in the C-H⋯0 interactions, of neighboring molecules (Figure 6c). By following the process of thin film formation, a layer by layer growth mechanism resulted in a bidimensional surface morphology with an almost perpendicular arrangement of NT4N molecules with respect to the substrate.
As a result of the symmetric and planar structure, the formation of \( \pi \)-stacks of NT4N molecules showed remarkable differences from the herringbone-like crystal packing of FT4N. This may be the enabling factor for the excellent electrical characteristics of NT4N, which strongly differs from the other quaterthiophene derivatives (Table 1). The particular organization of NT4N molecules may also induce a possible reduction of non-radiative exciton paths. Indeed, despite the NT4N photoluminescent quantum yield in thin-film was not as high as that of other compounds, the corresponding single-layer ambipolar OLETs showed an optical power unexpectedly high (hundreds of nW) for this category of conjugated organic semiconductors.

Over the years, major attention has been devoted to the tentative optimization of NT4N and the synthesis of similar chemical structures for the development of efficient ambipolar OLET devices. This approach paved the way to the development of an entire class of TI derivatives, thus allowing to understand the correlation between molecular structure, molecular packing and optoelectronic performance. A schematic representation of the various synthetic strategies to modify the NT4N prototype molecule is reported in Figure 7 and selected examples of each approach are deeply described below.

As a method to perturbate the \( \pi \)-conjugated system of NT4N and ultimately tuning the optoelectronic and packing properties, Zambianchi et al. inserted different unsaturated bridges between the two thiophenes of the inner core. In particular, ethylene, azomethine and ethinyl (or acetylenic) inner bridges were inserted in 2,3-thieno(bis)imide ended oligothiophenes, namely NTE, NTI and NTA respectively (Figure 8a). While ethylene and azomethine bridges were used to enhance the molecular planarity and reduce the optical band gap, the main effect expected from the acetylenic bridge was an increasing of the band gap originating from the mismatch of the sp\(^2\) carbon orbitals with the \( \pi \)-delocalized system. Accordingly, spectroscopic characterizations showed an absorption band strongly red shifted for NTE (465 nm) and NTI (471 nm) while a blue shift was evidenced for NTA (433 nm) if compared to NT4N (451 nm) (Table 1).

Regarding the emission properties, NTE reported a spectrum largely red-shifted with respect to the other compounds. Nevertheless, the photoluminescence quantum efficiency (\( \phi \)) measured in solution resulted to be comparable for NTE (19%) and NTA (20%) and also similar to that of NT4N (13%, Table 1), while a relatively low \( \phi \) was obtained from NTI (2%).

The molecular energy levels investigated via cyclic voltammetry (CV) and computational calculations showed a comparable LUMO energy of NTA and NTE. In comparison, the LUMO energy of NTI was 0.1 eV lower than NTA’s and NTE’s due to the electron withdrawing effect of azomethine. Instead, the HOMO levels decreased in the order NTE > NTI > NTA thus evidencing an optical energy gap of NTA that was significantly larger than that of NTI and NTE (Table 1). To note, while

**Figure 7.** General strategies for the modification of NT4N.

**Figure 8.** (a) Chemical structures of the NT4N-derivatives NTE, NTI and NTA, which respectively include ethylene (blue), azomethine (red) and ethinyl (green) inner bridges between the two thiophene inner cores (b) NTE, NTI and NTA HOMOs plots (c) NTE, NTI and NTA LUMOs plots. Adapted from Ref. [68] with permission from The Royal Society of Chemistry.
the use of ethylene (NTE) mainly enhanced the HOMO level of 0.1 eV with respect to NT4N, the introduction of azomethine (NTI) reduced the LUMO level of 0.1 eV. Hence, both NTE and NTI showed optical energy gaps (about 2.4 eV) that were similarly lower than that of NT4N (2.53 eV).

From a conformational point of view, all molecules were almost planar, with dihedral angles between the inner thiophene and the TI moiety of 160° and between the inner thiophene and the additional inner bridge of 180° and 165° respectively for NTE and NTA. According to what observed for NT4N, the HOMO orbital of NTE and NTA was homogeneously distributed over the inner thiophene cores with extended LUMO orbital distribution to the TI units. Diversely, the lack of a center of symmetry in NTA molecular structure due to the azomethine inner bridge resulted in a high probability of LUMO mainly localized on the thienoimide inner bridge (Figure 8b).

As a further step on the inner core modification of NT4N, Durso et al. reported on the substitution of the bithiophene (TT) π-inner core with bithiazole and thienothiophene fused rings, which are moieties respectively more electron-deficient than TT.46 The new synthesized compounds aimed at improving the ambipolar characteristics of NT4N. Indeed, while thiazole rings are expected to improve the electron transport behavior, the use of thienothiophene is associated to an enhanced hole charge transport as demonstrated in the case of linear oligothiophenes.69 In details, the new compound including the bithiazole core was named as NTzN, while the second one with the thienothiophene was named as NThTN. A further derivative was synthesized by inserting electron rich methyl substituents into the two thiophene inner cores of NT4N (NTMeN) (Figure 9a).

The UV-Vis optical absorption and emission spectra in solutions (Figure 9a). The UV-Vis optical absorption and emission spectra in solutions resulted to be progressively more blue-shifted as the electron-deficiency of the inner-cores increased (Figure 9b). In particular, the presence of the bithiazole core shifted the absorption peak of about 15 nm and 21 nm with respect to NThTN and NTMeN (Table 1). Accordingly, the optical band of NTzN was about 0.1 eV and 0.2 eV lower than that of NThTN and NTMeN, respectively.

Interestingly, the energy of both frontiers orbitals increased in the order NTzN > NThTN > NTMeN, with a different magnitude of variation between the HOMO and the LUMO. Computational analyses confirmed that, while in NTzN both the HOMO and the LUMO were delocalized over the entire molecular backbone, in NThTN and NTMeN the HOMO was localized in the inner core and the LUMO was localized in correspondence of TI moieties.

Electrical characterizations performed on bottom gate-top contacts OFET devices revealed that NTzN had exclusively n-type charge transport with an electron mobility $\mu_e = 0.16 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, while NThTN and NTMeN showed ambipolar behavior. In particular, NThTN showed an excellent electron charge mobility $\mu_e = 0.3 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and hole charge mobility $\mu_h = 6.4 \times 10^{-5} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$. Diversely, the more electron rich core of NTMeN led to a reduction of the electron mobility of about four orders of magnitude with respect to NTzN and NThTN and a relatively low hole mobility $\mu_h = 3.0 \times 10^{-6} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$. It is clear that the modification of the NT4N inner cores generally has a direct impact on the optoelectronic properties. Despite the ambipolar charge transport was not improved with respect to NT4N, important perspectives were provided to improve the electron mobility values through the molecular tailoring of Ti-derivatives.

A further optimization of the NT4N figures-of-merit was pursued with the modification of the end-substituents of the molecular structure. In this regard, by holding the same π-conjugated backbone, length and core type, and by avoiding the perturbation of the backbone electronic characteristics, different alkyl end substituents (Cx) were inserted for a selective modulation of the optoelectronic characteristics due to the different solid state organization.70 In particular, linear (C1-C8), branched (C6br) or cyclic (C6cyc) alkyl end substituents of the TI units were investigated (Figure 10). It is worthy to remind that the NT4N compound is endowed with a C4 alkyl chain and hence it is also labeled as C4-NT4N.

As expected, all compounds showed similar optical characteristics with absorption spectra of thin films mainly located at around 345 nm and 430 nm, and emission spectra peaked at around 603 nm (Table 1).自然而然地，这些分子的吸收和发射光谱在溶液中的结果是渐进地更蓝移的，这与电子缺陷的内核增加有关（图9b）。在具体情况下，对于NThTN和NTMeN，二苯并噻唑环的存在使吸收峰分别向低波长方向移动15 nm和21 nm。因此，NTzN的光学带隙约为0.1 eV和0.2 eV，分别低于NThTN和NTMeN的相应值。

有趣的是，两个前线轨道能量随着内核的变化而增加，在顺序NTzN > NThTN > NTMeN中，不同程度地变化。在HOMO和LUMO之间。计算分析证实，虽然在NTzN中HOMO和LUMO均分布在分子的全部骨架上，NThTN和NTMeN的HOMO仅局限于内核，LUMO则局限于TI基团。

对于电子的传输行为，NTzN具有典型的n型传输，电子移动性$\mu_e = 0.16 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$，而NThTN和NTMeN则显示了双极传输特性。特别是NThTN展示了优秀的电子电荷移动性$\mu_e = 0.3 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$和空穴电荷移动性$\mu_h = 6.4 \times 10^{-5} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$。相反，电子丰富核心NTMeN导致电子移动性的显著降低，约为四量级，而孔移动性$\mu_h = 3.0 \times 10^{-6} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$。很明显，通过改变内核的特性，双极传输性能没有得到改善。

为了进一步优化NT4N的性能，通过保持相同的π-共轭 backbone、长度和核类型，同时避免对骨架电子特性的影响，不同的烷基末端取代物（Cx）被插入用于选择性地调节光学性质。具体来说，线性（C1-C8），分支（C6br）或环状（C6cyc）烷基末端取代物分别用于研究TI单元的电子性质。更重要的是，需要提醒的是，NT4N化合物是带有C4烷基链的，因此它也被称为C4-NT4N。

所有化合物都展示了相似的光学特性，其吸收光谱主要位于345 nm和430 nm，而发射光谱峰值位于603 nm（表1）。

由于TI基团的性质被探索作为一种策略来改变固体状态结构来实现它们在电致发光器件中的有效应用，在电致发光器件中，x射线-衍射(XRD)模式的NT4N-衍生物直接测量在活性层的OLETs设备。作为图11a所示，对优选取向与substrate相呼应的strong preferential orientation，展示了类似方式的特性。在这些情况下，每个分子都表现出高的强度001反射和附加
The investigation of the electrical characteristics revealed low performance in the case of C6cyc-NT4N and ambipolar charge mobility for the linear alkyl tail (C1-C8-NT4N). In the latter case, a slight unbalancing towards the electron conduction was observed as mobility for the linear alkyl tail (C1-C8-NT4N). In the latter case, a slight unbalancing towards the electron conduction was observed as for the benchmark C4-NT4N. In details, the hole mobility (µh) oscillated between 2 and 3.5 orders of magnitude lower than electron mobility (ranging between 0.17 and 0.32 cm²V⁻¹s⁻¹).

Interestingly, C8-NT4N showed the most balanced ambipolar charge transport characteristics. Despite significant variations in thin-film structural arrangement and charge mobility were not observed among NT4N-derivatives, a slightly increase of the electroluminescent intensity was reported on the increasing of the tail length from C3 to C8. In view of OLET applications, a defined role of alkyl end substitution of the TI moiety was evidenced in preserving and increasing the inter-layer order along the direction perpendicular to the flowing-charge plane, as clearly demonstrated by the superior performance of C8-NT4N. A more in-depth discussion of the optoelectronic performance of NT4N-based OLETs can be found in Section 4.

Chemically-driven control of conformational polymorphism

The molecular packing is known to be strongly dependent on the type and the number of interactions occurring among molecules. As shown in the previous Section, the chemical structure of a compound has a critical role in defining the molecular orientation in the solid state. It is therefore clear that the solid state organization and hence the formation of different polymorphs may be induced by playing on the chemistry of the molecule. In this paragraph, the obtainment of different crystal phases via chemical tuning will be discussed by analyzing some of the oligomers already examined in the previous Section. As shown in Figure 7, TI-ended oligothiophenes can be modified at different sites of the oligomer, either in the inner core and in the TI terminations. The insertion of a different saturation degree, specifically ethylene, azomethine and ethinyl (acetylenic) inner bridges, in 2,3-thieno(bis)imide ended oligothiophenes led respectively to NTA, NTE and NTI (Figure 8a and Figure 12). Interestingly, the deposition of the three compounds from a toluene solution onto a flat substrate led to the formation of different large crystals with the presence of concomitant polymorphs for each molecule. More specifically, NTE formed a mixture of rod-like (red emitting, λEM = 640 nm) and platelet-like (orange emitting, λEM = 560 nm and 600 nm) polymorphs as shown in Figure 12a, in which rod-like crystals were up-to-100-µm long while presenting widths ranging from to 5 µm to 10 µm. Diversely, platelet-like crystals showed a regular shape with a long axis ranging from 20 µm to 100 µm. The authors also highlighted the role of the initial solution in the formation of the polymorph: rod-like structures were gradually induced upon increasing the concentration.
NTI deposits showed randomly-distributed crystals with a needle shape which were characterized by a width ranging from 10 µm to 100 µm and an aspect ratio between 1:5 and 1:50. A photoluminescence emission peaked at 660 nm was concomitant to a green signal arising from small aggregates (< 2 µm) decorating the rod-like crystals. Despite polymorphs generated by NTE were clearly different from those of NTI, in all cases single crystals (or iso-oriented domains) were visible under polarized optical microscopy. Diversely, the deposition of NTA gave rise both to fiber-like and rhombohedral polymorphs which were respectively characterized by optical anisotropy and a polycrystalline nature (Figure 12c). Nevertheless, NTA reported photoluminescence quantum yield similar to that of NTE (10% and 6%, respectively). On the contrary, NTI showed a reduced yield of only 4%.

A remarkable impact of the molecular structure on the polymorph formation and correlated optical properties was found out. This pushed the authors to dig deep into the origin of the observed polymorphism. Independent on the molecular structure, computational simulations reported minima of energy upon the rotation of the dihedral angle between the Ti moiety and the inner thiophene. More specifically, ANTI and SYN conformers were confirmed as possible crystallized polymorphs. Furthermore, the crucial role of the chemical structure was even more clear from the analysis of the frontiers orbitals overlap between molecules. With respect to the benchmark NT4N, a reduced orbital overlap was found for both frontier orbitals, with particular impact on the LUMOs. This information is relevant in assessing possible synthetic route for improving optoelectronic performance in Ti-oligothiophene based OLETs.

We have already shown in the previous Section how the optical and charge transport properties of NT4N-derivatives in the solid state depend on Ti substituents. Accordingly, Maini et al. further demonstrated that the conformational polymorphism of this class of compounds can be controlled by modifying the alkyl end symmetry of Ti moieties. In detail, the use of an even number of carbons in the Ti alkyl substituents revealed two possible polymorphic forms with different packing type and molecular conformations. Indeed, while the inner thiophene rings are always arranged in anti conformation, the...
thienoimide moieties can adopt both syn and anti conformation with respect to the inner thiophenes (Figure 13a). As a result, two polymorphs can exist, that are in the conformation anti-anti-anti and syn-anti-syn. The two polymorphs adopt two different molecular packaging, in which the Cx-NT4N molecules are piled in columnar stacks with strong π-π vertical interaction (phase A) or molecules interact in a brick wall arrangement. In the latter, a molecule interacts with four different close molecules and the packing results in a lower degree of interdigitation of the alkyl chains (phase B) (Figure 13b and 13c).

Interestingly, NT4N including odd alkyl substituents in TIs displayed exclusively syn-anti-syn conformation and B-type packaging. Diversely, the use of even alkyl substituents in TIs allowed the conformational polymorphism of NT4N. A more detailed discussion of the crystal structures is reported in Ref. [72]. Despite the chemical structure was proved to enable conformational polymorphism, it is worth mentioning that only the phase B conformation was reported by thermal sublimation of NT4N derivatives. The control on polymorphs in solid-state can be indeed operated by addressing the suitable deposition techniques, as we will highlight in the next paragraph.

Polymorph control by post-synthesis physical methods

Aside from the nature of the chemical compound, a wide variety of post-synthesis factors can further influence the molecular packing in the solid state and hence the formation of possible polymorphs. Processing, crystallization confinement, and post-deposition treatments are some among all possible methodologies which control polymorphism.

For instance, crystal phases of core-modified (NTE, NTA and NTI) and terminal-modified (Cx-NT4N) oligothiophene derivatives showed relevant transitions upon thermal heating. While platelet-like crystals of NTE (Figure 12a) were persistent till the melting point, rod-like crystals showed an irreversible change of the emission from red to orange (corresponding to the emission of platelet-like crystals) without variation of the morphology after the heating cycle “room temperature (RT) → 200°C → RT”. Under the same treatment, NTA fiber-like crystals shifted irreversibly from a yellow to a green emission, while the rhombohedral crystals remained almost unaltered. Diversely, NTI crystals did not show detectable differences in the fluorescence upon the thermal treatment.

The same analysis on C4-NT4N showed an initial preferred formation of phase A at room temperature (Figure 14), which underwent to the transition to phase B upon the thermal treatment. The dependence of photophysical properties on the temperature was initially considered as a drawback for the application of such compounds in OFETs, OLEDs, OLETs, etc.. Nonetheless, the thermal control of polymorphs was then exploited as a tool to record the thermal history of the system. Gentili et al. successfully fabricated a real-time temperature integrator (TTI) device, in which the quantification of the red, green and blue fluorescence components allowed to evaluate the current temperature sensed by the crystal.

In particular, a derivative of NT4N comprising a single thiophene inner core (named as NT3N) exhibited an irreversible change of the solid state photoluminescence, passing from yellow (β polymorph) to green (α polymorph), upon heating to 190°C for 30 seconds (Figure 14a). This time-temperature functionality was combined with information storage capabilities of a logical matrix with micro-meter sized pixels in order to allow time-temperature information to be detected by a conventional optical microscope (Figure 14b).

Post-synthesis methods influencing polymorphism include all processes involved in the solid state formation. Dissolving solvents, kinetic and techniques of deposition, confinement and templating environments, are just some factors that control the formation of polymorphs.

The use of a confined environment during the crystallization process is a method particularly appealing for the proven possibility to be accurately select the desired polymorph. In this regard, Auxiliary Solvent-Based Sublimation-Aided Nanostructuring (ASB-SANS) was recently proposed as a new and simple method which eliminates the issue of separating the polymorph from the matrix. This fascinating approach exploits a material sublimating under ambient conditions to form mesocavities in which the compound of interest precipitates (Figure 15). More specifically, both materials are typically drop casted onto a substrate and, when the solvent shrinks, the sublimating compound first precipitates thus giving rise to 3D cavities. These act as a template for the precipitation of the compound of interest, which occurs under quasi-equilibrium and confinement conditions. In this process, the molecular diffusion is typically limited and the number of nuclei of crystallization are reduced thus favoring the growth of the mean size of the crystalline particles (Figure 15b).
domains. It follows that different polymorphs are selected on the basis of their different critical nuclei sized. The sublimating compound is finally sublimated away. Despite NT3N is known to form α and β polymorphs (Figure 14), the use of ASB-SANS allowed only phase α to appear. Interestingly, the full selectivity of one phase was obtained independently on the dissolving solvent, i.e., chloroform or toluene. However, other deposition techniques influence the process of solid state formation on the basis of the solvent used to dissolve the compound. The selection of the dissolving solvent is therefore crucial for polymorphism control. In addition to that, the deposition process induces itself different kinetics of crystallization. Hence, aiming at fabricating multifunctional devices such as OLEDs with reproducible and outstanding performance, the combination of all elements involved in the solid state formation need to be carefully considered. In this regard, Benvenuti et al. reported on the correlation between type of deposition methods and OFET characteristics, as a result of the diversely induced molecular packing.\(^{44}\) Thermal sublimation and supersonic molecular beam deposition (SuMBD) were used as vacuum-based approaches for preparing thin films compatible with the fabrication of field-effect transistors, while lithographically controlled wetting (LCW) was used as a solution-deposition technique able to manipulate the growth of microstructured films.\(^{76}\) Two different rates of deposition for both thermal sublimation and SuMBD were used for depositing C4-NT4N. Interestingly, the rate of deposition (0.1 Ås\(^{-1}\) and 0.017 Ås\(^{-1}\)) of thermal sublimation did not substantially affect the resulting film, which was composed by phase B. Diversely, the deposition with SuMBD revealed a dependence of the polymorphic phase on the deposition rate, with the consequent obtainment of either phase B and a new phase called C, by respectively using a rate of 0.1 Ås\(^{-1}\) and 0.017 Ås\(^{-1}\) (Table 2).

\(^a\)C4-NT4N films. \(^b\)C6-NT4N films.

The morphologic differences between films deposited by the two techniques had an impact on the ambipolar characteristics of OFETs, in which charge mobilities resulted around 10\(^{-2}\)cm\(^2\)V\(^{-1}\)s\(^{-1}\) (electron) and 10\(^{-4}\)cm\(^2\)V\(^{-1}\)s\(^{-1}\) (hole) in thermal sublimated samples, while 1.2x10\(^{-5}\)cm\(^2\)V\(^{-1}\)s\(^{-1}\) (electron) and 2.2x10\(^{-6}\)cm\(^2\)V\(^{-1}\)s\(^{-1}\) (hole) in the sample deposited by SuMBD at 0.1 Ås\(^{-1}\) (Table 2). To note, the phase C obtained from the SuMBD deposition at lower rate did not show ambipolar OFET behavior, and only an n-type mobility of about 10\(^{-4}\)cm\(^2\)V\(^{-1}\)s\(^{-1}\) was measured.

Concerning LCW deposition, two different C6-NT4N films were deposited using an anisole solution at 80°C and 1,2-dichlorobenzene (1,2-DCB) at room temperature.\(^{48}\) While the presence of phase B was found using anisole, in films deposited from 1,2-DCB the coexistence of both phase A and phase B was reported. As discussed in regard of time temperature sensors, the typical stable phase of C6-NT4N at room temperature is phase A.\(^{74}\) According to that, it is likely that the formation of phase B from anisole was due to the use of 80°C as deposition temperature. In contrast, the coexistence of both phase A and B in C6-NT4N films from 1,2-DCB solution at room temperature was ascribed to the special confinement effect of the LCW technique, which was responsible for the formation of the phase B. Eventually, all films obtained from LCW deposition confirmed the typical ambipolar behavior expected from C6-NT4N, with slightly lower values of charge mobility by using 1,2-DCB as a result of the presence of phase A (electron and hole mobilities were respectively 2.4x10\(^{-5}\)cm\(^2\)V\(^{-1}\)s\(^{-1}\) and 1.0x10\(^{-5}\)cm\(^2\)V\(^{-1}\)s\(^{-1}\) from anisole solution and 4.4x10\(^{-3}\)cm\(^2\)V\(^{-1}\)s\(^{-1}\) and 2.7x10\(^{-5}\)cm\(^2\)V\(^{-1}\)s\(^{-1}\) by using 1,2-DCB) (Table 2).

4. Single layer ambiplolar OLEDs

The possibility to combine high flowing current densities and radiative exciton recombination (occurring far from electrodes) represents a fascinating characteristic which identifies OLEDs as optoelectronic devices endowed with theoretically-high brightness. Obtaining light-emission from an electrical switching and amplifying device is the major strength of the OLET platform. However, pursuing a dual functionality in a single architecture is also the major challenge of this technology. The OLET semiconducting layer indeed needs to ensure similar and high field-effect mobility of holes and electrons (ambipolarity) as well as to allow the radiative recombinations of opposite charge carriers in an efficient way. In 15 years of research, a multitude of materials have been employed as ambipolar emissive semiconductors, ranging from organic to inorganic and hybrid ones.\(^{77}\) In this regard, single crystals played a key role either for their application in the first reported OLET and for their outstanding mobility, which leads to high currents flowing in the device.\(^{78}\) For instance, with the use of p-bis[(p-styryl)styryl]benzene (PSV4), Nakanotani et al. obtained external quantum efficiencies around 0.1% from LETs with a well-balanced charge mobility of electrons and holes.\(^{79}\) Later, Sawaby et al. showed a maximum ambipolar current density of 12.3 kA/cm\(^2\) that opened a realistic route for electrically driven organic lasers.\(^{80}\) Many interesting works have progressively improved single-crystal LET characteristics.\(^{81,82}\) Extensive reviews can be found elsewhere.\(^{83,84}\) Unfortunately, obtaining high electroluminescent yields from this class of highly efficient ambipolar materials still requires a great effort. If, on one side, the charge carrier mobility is favored by increasing the intermolecular overlapping as typically occurs in highly-ordered crystals, on the other side, the electroluminescence efficiency is significantly reduced upon aggregation. It is clear that the optimization of the OLET performance is a trade-off of the two processes. In addition to
that, the anisotropy typical of crystals further reduces the light extraction from the device as a result of waveguiding and cavity effects.

In this regard, the variety of attracting properties shown by molecular materials could represent the effective solution to reach highly-efficient ambipolar OLETs. Tuning the solid-state packing to obtain a mix of polycrystalline phases, or to find the suitable polymorph, can represent the keystone of ambipolar emission without sacrificing either the electrical behavior or the luminescence characteristics of OLETs. As discussed in the previous Sections, oligothiophene derivatives have shown a long list of molecular organizations and structural phases giving rise to different morphological, electrical and optical properties in solid state. Playing on the chemical structure or post-synthesis parameters gives the control of the morphology towards the realization of OLETs with unprecedented characteristics. In the following paragraphs, we will address our attention to NT4N derivative as a prototypical molecule to be used as active material in light-emitting transistor which in turn can be used in single-component device, photonic system and planar platform for electro-optical microscope investigation.

The case of NT4N

The introduction of TI motifs in oligothiophene derivatives has been proven to allow tuning the optoelectronic properties of the semiconductors, thus passing from unipolar and non-electroluminescent molecules to ambipolar and electroluminescent ones. In this paragraph, the characteristics of the reported compounds as active materials of single-layer ambipolar OLETs are discussed. The comparison of all molecules is validated by the similar deposition method which consists in a vacuum sublimation onto a polymethylmethacrylate (PMMA) dielectric layer in order to obtain OLETs with a bottom-gate (Indium Tin Oxide, ITO) top-contact (gold) configuration. Table 3 summarizes the figures-of-merit of OLETs comprising TI-ended oligothiophenes in comparison with those based on the corresponding oligothiophene-based devices. HT4N and FT4N were respectively derived from the most known p-type (HT4H or DH4T) and n-type (FT4F or DFH4T) quaterthiophene semiconductors, which were widely used in multilayer organic devices. The presence of a single TI moiety clearly had an impact on the device characteristics. Both HT4N and FT4N indeed showed ambipolar characteristics and OLET electroluminescence emission in comparison with the unipolarity and non-luminescence of HT4H (or DH4T) and FT4F (or DFH4T). Nevertheless, the mobility of both TI-derivatives resulted quite unbalanced, with a ratio between the electron mobility and the hole mobility around 0.009 and 785.7 respectively for HT4N and FT4N (Table 3). The effect of the electron-withdrawing fluorinated alkyl substituent in FT4N with respect to the alkyl chain of HT4N is visible in the inversion of the field-effect characteristics, passing from a mostly n-type FT4N to a mostly p-type HT4N. However, it can be noted that, while a few nW of electroluminescence were recorded from HT4N, an optical power around 50 nW was observed from OLETs based on FT4N.

Table 3. Summary of the OLET characteristics obtained from the use of oligothiophene derivatives.

$^a$ Film thickness = 30 nm; $^b$ Film thickness = 100 nm; $^c$ A value of 47 nW of OP was measured with a suboptimal film thickness of 100 nm.
In this regard, it is worthy to compare the OLET behavior of FT4N with that of NT4N, as a molecule which includes a second TI moiety in replacement of the fluorinated alkyl chain. Both compounds exhibited a V-shaped saturation transfer curve (i.e. by sweeping the gate voltage at a fixed source-drain voltage in saturation mode) which is typical of the ambipolar FET behavior. However, their charge mobilities resulted drastically different. In particular, NT4N showed an outstanding electron-to-hole mobility ratio of 78.57 and p- and n-type charge mobilities respectively of 7x10^-3 cm^2V^-1s^-1 and 0.55 cm^2V^-1s^-1 (Table 3).

As a result, an intense electroluminescence emission was observed from NT4N-based devices (Figure 16), with an optical power up to 180 nW, that is more than three times higher than that emitted by FT4N (50 nW, Figure 16d). The similarity of the electroluminescence spectrum of the NT4N-based OLET with the photoluminescence of a film of NT4N confirmed that the OLET emission originated from NT4N (Figure 16c). As shown in Figure 16a, the saturation transfer curve at V_DS = 100 V of NT4N-based OLETs reported the electroluminescence signal peaked at about V_GS ≈ ½ V_DS, thus corresponding to the maximum hole-electron balance. In particular, at 50 V, which is a bias at which the emission intensity is still significant, the external quantum efficiency resulted to be maximized (about 0.2%) (Figure 16b). The pronounced ambipolarity shown by NT4N also enabled a fine tuning of the emission stripe position along the channel length of the OLET. Moreover, as shown in Figure 16e, the emission zone could be spatially shifted by tuning the gate voltage. Despite the emissive stripe remained in the proximity of the drain electrode due to the slight unbalance between charge mobilities, it was still well separated from the drain edge, thus preventing exciton quenching by the metal electrode or optical coupling effects of the emitted light with the metal electrodes.

As already introduced in Section 2, tentative improvements of the OLET performance of NT4N were carried out by designing new compounds with modified inner-cores, such as NTzN and NThTN and NTMeN. Nevertheless, devices with mostly unipolar and non-emissive features were obtained in the case of NTzN and NThTN, while a transistor with good ambipolarity but drastically low p- and n-type mobilities was obtained from NTMeN (Table 3).

![Figure 16](image-url)
As a result, slight modifications were introduced in NT4N to further exploit all the advantages of that molecular structure. Despite hexyl or octyl functionalizations led to NT4N-based OLETs emitting light 3 times more intense, the best ambipolar characteristics were still found from the use of the benchmark C4-NT4N (which is commonly named as NT4N). Having good ambipolar characteristics indeed allows the effective spatial tuning of the light stripe in OLETs. The here discussed results highlight also the crucial role that the molecular packing has on the optoelectronic properties of oligothiophene derivatives. Indeed, a mix of phase A and phase B polymorphs with poor optoelectronic properties would be expected from the solution-processed deposition of Cx-NT4N including an even number of alkyl side chains, such as C4-NT4N, C6-NT4N and C8-NT4N. However, the intentionally use of thermal sublimation as film-forming technique generates exclusively the polymorphic phase B, which is the only solid-state organization that guarantees the functionalities reported for NT4N-based OLETs.

In conclusion, the remarkable electroluminescence characteristics in conjunction with the best charge balance shown by C4-NT4N with respect to the other compounds identifies NT4N as the ideal candidate to further develop the OLET technology. Despite the comparative analysis of the OLET emission intensities has been done throughout this Section in terms of optical power, the standard evaluation of the emission intensity from solid-state devices is the measurement of the brightness. As a comparative value for the readers, the brightness reported from C6-NT4N based OLETs was about 20 Cd/m².76

NT4N-based OLET as a device platform for photonic application

OLETs represent a class of devices endowed with properties which are particularly suitable for real-settings applications in photonics. Combining electrical amplification with an efficient emission of light represents a direct route to develop functional pixels for displays at reduced costs and complexity. Furthermore, the possibility to move the light stripe in the horizontal plane of the device and to select the region where the excition recombination occurs is of great interest also for sensing.86

As shown in the previous Sections, the use of semiconducting materials such as the class of NT4N derivatives offers also the benefit of obtaining devices with versatile optoelectronic characteristics. All these features included in such a simple device in-plane geometry pave the way towards the engineering of OLETs to realize highly-integrated organic optoelectronic devices with multiple novel functionalities. To this end, Natali et al. integrated a transparent multilayer photonic crystal (ML PhC) as an optoelectronic gate dielectric to both modulate the light emission output and improve the electrical performance of NT4N-based OLETs.87 The ML-PhC consisted of a stack of nine alternating high-density layers of ZrO2 and Al2O3, and a 30 nm thick buffer layer of PMMA (Figure 17a). The latter polymeric layer provided the surface for the ensuring the molecular packing of NT4N with emissive and ambipolar field-effect behavior. The comparison with standard OLETs showed a 25-fold increased ambipolar source-drain current and, consequently, the optical power of the light stripe in the horizontal plane of the device and to select the region where the excition recombination occurs is of great interest also for sensing.86

By changing the overall thickness of the dielectric structures, the authors prepared two different sets of integrated multilayer stacks with the aim of tuning the photonic bandgap of the photonic crystal and modulating the spatial distribution of the emitted photons. In particular, a dielectric structure, called ML-PhC α, was intentionally designed to locate the maximum of the NT4N EL spectrum in correspondence of the minimum of the ML-PhC transmittance spectrum. The dielectric stack was effectively demonstrated to work as a planar distributed Bragg reflector system, and an almost four-fold increasing of the EL intensity was observed along the optical axis in the top view direction (Figure 17c). In addition, an angular emission profile broader than the typical Lambertian one was recorded from the bottom side of the device.

Despite the great potential of ambipolar OLETs for real-setting applications, this type of device platform provides also the opportunity to investigate a plethora of different phenomena in a single nanometric layer such as hole and electron injection, field-effect conduction, charge recombination, light generation, light extraction. By exploiting the in-plane geometry (thus avoiding possible disturbing metal electrodes) of transistors and the
The possibility of most organics to be photoexcited, the organic active layer in OLETs is accessible by optical scanning probe techniques for the investigation of the major photophysical and charge-correlated processes during device working-conditions.

In this context, the ambipolar emissive features of NT4N-based OLETs were exploited by Koopman et al. to develop a unique approach for the determination of the contact resistance and the channel resistance in a single device. The new method consisted in the local observation of the charge density distribution within the transistor channel. In particular, photoluminescence electro-modulation microscopy was used to optically induce the formation of excitons and then to map their quenching due to the proximity of charges flowing in the organic semiconducting layer during device operation. The spatial localization of the ambipolar recombination region was evidenced by an enhanced fluorescence given by the additional electroluminescence from NT4N (blue region in Figure 18). The ambipolar regime was found to start at $V_{DS}$ around 10 V (in saturation regime of $V_{DS} = 100$ V) and showed its maximum at $V_{DS}$ around 30 V. These values were crucial to understand the difference with respect to threshold voltages extracted from electrical characterizations.

While values extrapolated from the typical electrical curves contained contribution from both contacts and channel resistances, threshold voltages extrapolated by this new approach contained only the voltage drop due to the contact resistance. The authors demonstrated that the contact resistance for the injection of electrons contributed only for the 6% of the total threshold voltage obtained electrically. The reported findings highlighted the possibility i) to study how specific interfaces act during device operation and ii) to identify the device-dependent and material-dependent issues that affect the electrical performance of devices. More importantly, authors showed that functional interfaces are way more complex than an energy mismatch between the metal Fermi level and the transport electronic levels of the semiconductor.

In this context, the same NT4N-based device was lately used to provide further insight on the complex correlation between the nature of the charge-injecting contacts and the electrical characteristics of devices. The authors showed how the presence of thienyl sulfur atoms in NT4N determined the formation of a chemical interaction with gold electrodes, with the consequent formation of small gold nanoclusters during the first stages of contact formation. Multiple analyses repeated at different stages of device fabrication, including also synchrotron X-ray spectroscopy on devices in operando, showed that the electrical performance was the result of the interplay between i) the chemical composition of metal electrodes and the OSC, ii) the type of physicochemical interactions at the metal/OSC interface, iii) the interfacial morphology and iv) the organization of the metal clusters at the OSC interface.

We here provided some examples of the great potential offered by the implementation of TI-ended oligothiophene derivatives in the OLET device platform. The combination of ambipolar field-effect conduction, electroluminescence ability and simple tunability of the optoelectronic characteristics, endorse NT4N as a class of molecules suitable either for fundamental investigations and for the technological development of multifunctional devices.

**Conclusions**

OLETs require the active materials to possess both high in-plane carrier mobility and high luminescence quantum yields to realize the potential applications in active matrix full color display, integrated photonic circuitry, sensing and possibly the long-searched electrically driven organic laser.

However, OSCs (in particular small molecules) presenting high carrier mobility typically suffer from luminescence quenching in the solid state. This simplistic thumb-rule has generally promoted the use of polymers as the proper organic conjugated semiconductors to be used in single-layer single-material ambipolar OLETs given their remarkable emissive properties in the solid state.

Significant effort must be put by the scientific community to synthesize and/or process active materials capable of balancing both high flowing charge-density and efficient rate of formation of emissive excitons.

In this scenario, the present perspective aims at highlighting thienoimide-ended oligothiophenes as a new versatile family of multifunctional conjugated organic compounds which can be considered an ideal test-bed for investigating the relationships between the molecular structure, packing modalities, charge mobility and light emission in thin-films. As we have reported, the insertion of the TI moieties in oligothiophene backbone proved to allow tuning not only of the optoelectronic properties of the semiconductors, thus passing from unipolar and non-electroluminescent molecules to ambipolar and electroluminescent ones, but also of the material processability and self-assembly in nanostructured systems.

The peculiar packing mode of TI-ended oligothiophenes, that typically organize in slipped π-π stacking packing mode differently from most oligothiophenes, are related to planarity, symmetry and alkyl-based end-substitutions in the molecular structure of these compounds. As a remarkable example in the state of the art of ambipolar organic conjugated molecules, NT4N molecule shows an outstanding electron-to-hole mobility ratio of 78.57 and p- and n-type charge mobilities respectively.
of $7 \times 10^{-3}$ cm$^2$V$^{-1}$s$^{-1}$ and 0.55 cm$^2$V$^{-1}$s$^{-1}$ differently from the unsymmetrical fluorinated counterpart. The versatile chemical tuning of the molecular structure of TI-ended oligothiophenes (by both acting on the inner core and the terminations of the molecules) and the fine use of a confined environment during the crystallization process or of the suitable solution-processed or sublimation deposition technique are the major tools for controlling the packing of molecules and their intermolecular interactions at the solid state. Here, we clearly highlight that the analytical investigation of the correlation between polymorphism and optoelectronic performance in nanostructured systems implementing TI-ended oligothiophenes is the driver for designing and realizing multifunctional devices, such as real-time temperature integrator for color-depending sensing and light-emitting transistors for switchable lighting.

By considering the field-effect transistor as a benchmark device platform and the extended family of TI-ended oligothiophenes as a case study in organic electronics, this perspective has assessed the quantification of optoelectronic figures of merit (such as charge mobility, gate threshold voltage, emitted optical power) in OLETS by systematically varying the molecular structures and post-synthesis deposition approaches of the TI derivatives implemented as active material in OLETS.

The field of view has been further broadened in this article by including the report of the use of the NT4N-based OLETS as both scientific and technological viable solutions for optimizing optoelectronic and photonic performance and envisaging real-setting applications in OLETS.

The integration of a transparent multilayer photonic crystal as a dielectric stack in the architecture of a single-layer ambipolar OLET based on NT4N allows the realization of an innovative photonic device capable of probing and managing the direct optical coupling between electrically formed excitons and the planar photonic component in an electrode-free geometry. Moreover, the direct access to the active channel and the remarkable ambipolar charge balance in transparent NT4N-based OLETS enable the use of these devices for optical imaging of the recombination zone location by means of electro-optical scanning probe technique. Consequently, we expect that the same experimental methodology and testbench devices might be used to probe independently how the different functional interfaces in an organic transistor (such as the electrode/organic-semiconductor and the organic-semiconductor/dielectric) affect the charge-carrier injection, transport and recombination properties within the same single device, and in principle to decouple the device-dependent and material-dependent issues that affect the electrical performance in organic field-effect transistors.

If we critically overview all the here reported results, it is evident that an enormous effort has still to be done for understanding the correlation between the compound molecular structure, the solid-state thin film arrangement and the functional properties as a function of the thin-film process parameters. We believe that the development of multiscale computational methods could represent the key to boost the quantum and power efficiency of ambipolar OLETS. Despite a great progress has been progressively done to estimate the optoelectronic characteristics of isolated molecules or small aggregated systems, this know-how must be evolved to include the entire device fabrication. As highlighted in this Perspective, the solid-state organization has a profound influence on the device characteristics. Each deposition technique specifically drives the thin-film formation and controls polymorphism. A comprehensive and predictive view of the entire process of device fabrication, from the synthesis of the single material to its implementation in the device to the design of functional interfaces, would open to a faster selection of materials and processing methods and to dedicated developments for selected purposes.

In this regard, the strategy at the basis of the synthesis of TI-ended oligothiophene compounds contributes to the definition of a throughout multidisciplinary approach combining multiple material-processing techniques with structural, morphological, photophysical and optoelectronic systematic characterization of the nanostructured systems in order to achieve high-performing active materials for single-material single-layer OLETS.

Obtaining light-emission from an electrical switching and amplifying device is the major strength of the OLET platform. However, pursuing a dual functionality in a single architecture is also the major challenge of this technology that has still to be demonstrated in suitable application-driven paradigm in organic optoelectronics. In the next future, the major driver in the progress towards real-setting applications of OLET technology is the achievement of standards of performance in relation to high internal quantum efficiency values, outperforming device outcoupling efficiency (allowing for a significant light fraction to be extracted outside the device) and lowering of the device operating voltages in order to minimize the device energy footprint.

We believe that TI-ended oligothiophene family is a remarkable example of the introduction of new paradigms in designing organic semiconductors and in engineering organic field-effect thin-film devices, which in turn may play a key-role in the demonstration of real-setting applications in electronics and photonics for organic compounds.
