A near-infrared emitting DNA-stabilized silver nanocluster (DNA-AgNC) with an unusually high fluorescence quantum yield is presented. The steady-state and time-resolved fluorescence properties of the DNA-AgNC were characterized, together with its ability to generate optically activated delayed fluorescence (OADF) and upconversion fluorescence (UCF).

DNA-AgNCs are a relatively new class of emitters, first introduced in 2004.1 DNA-AgNCs are composed of a limited number of silver atoms and cations (typically 2–30) wrapped in one or more DNA strands.2,3 The easiest way to tune the optical properties is by varying the DNA sequence, which has an effect on the type of silver cluster that can be stabilized.3–5 Not all DNA sequences yield DNA-AgNCs with useful properties, e.g. high brightness or photostability. In order to shed light on the relationship between DNA-AgNCs, we have in recent years focused on studying the photophysical properties of HPLC-purified DNA-AgNCs; this step of purification ensures that a single type of emissive DNA-AgNC species is studied.6–9 Recently, crystal structure data of DNA-AgNCs has appeared in the literature, which will become a key part in understanding the relationship between DNA sequence and optical properties of the DNA-AgNCs.10,11

In this paper, we have studied the photophysical properties of a NIR-emitting DNA-AgNC, stabilized by the sequence 5'-CCCAGAAAG-3'. This 10-base DNA oligomer was initially reported by Copp et al. in a study on the relationship between emission color and DNA sequence.4 The NIR part of the electromagnetic spectrum is of particular interest for imaging biological material due to regions of high transparency.12 However, a drawback of designing fluorophores in the NIR range is that, due to the small energy gap between excited state and ground state, non-radiative decay pathways tend to out-compete the radiative pathways, resulting in low fluorescence quantum yields. Thus, it is especially notable that the NIR-emitting DNA-AgNC presented in this paper has an unusually high fluorescence quantum yield of 73%.13

The DNA-AgNCs were synthesized by mixing 5'-CCCAGAAAG-3' with AgNO3 in a 10 mM ammonium acetate (NH4OAc) solution. After 15 minutes, NaBH4 was added in order to reduce the silver cations. The ratio of the components in the final mixture was [DNA]:[Ag⁺]:[BH4⁻] = 20 μM:100 μM:50 μM. A single fraction with a retention time around 12 minutes was collected by HPLC purification. Further information can be found in the (ESI†). Fig. 1 shows the absorption and emission spectra of the HPLC-purified DNA-AgNCs. The DNA-AgNC has an absorption maximum at 640 nm and an emission maximum centered at 721 nm at 25 °C. Fig. 1B indicates a single type of emissive species, since no shift in the emission maximum versus excitation wavelength is found.14,15

Absorption and emission maxima recorded at different temperatures can be found in Table 1, which show no significant changes in the 5 to 30 °C range. Next, we determined the fluorescence quantum yield (Q) at 25 °C which has a high value of 73%. In order to test the temperature stability of the NIR-emitting DNA-AgNC, we applied several heating and cooling cycles to the DNA-AgNCs in a 10 mM NH4OAc solution. Fig. 2A shows 5 heating and cooling cycles from 10 to 40 °C. From 5 to 30 °C the fluorescence intensity changes linearly and reversibly with temperature. Above 30 °C an irreversible loss in the overall fluorescence intensity is observed (see also Fig. S3, ESI†). To confirm the reversibility in the 5–30 °C range, we repeated the experiment and the results can be seen in Fig. 2B. Fig. 2B demonstrates that the fluorescence intensity can be
Conceptually, this can be rationalized by the smaller energy gap that starts to favor non-radiative decay over radiative decay. This can be explained by internal conversion from the excited state to a lower energy state. As the energy gap between ground and excited state narrows, their respective absorption and emission maxima overlap more and more. This is especially pronounced for organic dyes made from light elements that can form bonds with high vibrational frequencies, compared to heavier elements. A possible explanation for the high fluorescence quantum yield in our case is that the AgNC is weakly bound to the DNA scaffold (agreeing with the observed limited thermal stability), limiting solvent and/or DNA-mediated non-radiative decay. This could be a very important discovery, opening up the possibility to find other DNA-AgNCs that emit even further in the NIR, while retaining a high fluorescence quantum yield. Such fluorophores are currently missing and in high demand since they could find uses for in vivo tissue imaging. Time-resolved anisotropy measurements revealed that the NIR-emitting DNA-AgNC has a hydrodynamic volume of 19.6 nm$^3$ (see Fig. S4, ESI†), indicating that two, if not three, DNA strands stabilize this AgNC. The latter argument is based on comparing the hydrodynamic volume of another NIR-emitting DNA-AgNC composed of 16 silver atoms stabilized by two 10-base oligonucleotides$^8$ which has a hydrodynamic volume of 10.5 nm$^3$.

Coming back to the reversible fluorescence intensity change in the 5 to 30 °C range, the most obvious explanation for a temperature-dependent change in fluorescence intensity would be a change in $Q$ due to a temperature dependent non-radiative decay pathway. However, we just argued that this might not be the case here. One way to probe this is to measure the fluorescence decay at different temperatures, since the fluorescence intensity is normalized to the starting fluorescence at 5 °C.
decay time was observed for this NIR-emitting DNA-AgNCs in the 5–30 °C range (see Table 1). An intensity-weighted average fluorescence decay time of 3.72 ns was found at 25 °C. It was shown before that longer DNA oligonucleotides (19–30 bases) generate DNA-AgNCs characterized by multi-exponential fluorescence decays due to slow spectral relaxation on the time scale of the fluorescence decay time. However, this NIR-emitting DNA-AgNC, like another previously reported 10-base DNA-AgNC,\(^8\) seems to have an almost negligible amount of slow spectral relaxation, as can be seen in the time-resolved emission spectra (TRES) in Fig. S6 (ESI†) and the reduced \(\chi^2\) values for mono-exponential fits in Table S1 (ESI†). Based on a phenomenological model of the electronic states presented by Cerretani et al. and Krause et al.,\(^7,20\) this could mean that the temperature dependent change of fluorescence intensity is due to either a temperature-dependent quantum yield of the emissive state formation (\(Q_{D1}\)) or due to a change in absorption with temperature and hence lowering the overall fluorescence, or a combination of both. Another scenario would be that the radiative and non-radiative rates change in opposite direction so that the sum is unaltered (this seems rather unlikely looking at the decay time measurements at −78 °C and −196 °C discussed below and listed in Table 1).

Fig. S3 (ESI†) shows a minor drop in the absorption from 10 to 25 °C of about 2.8%. In this temperature range the fluorescence decreases about 7.9%. This indicates that not all the loss of fluorescence can be attributed to a change in absorption, but there should also be an additional drop in \(Q\). The change in absorption could be due to a temperature-dependent molar extinction coefficient or a reversible partial dissociation of the DNA-AgNCs. We did not determine \(Q\) at different temperatures since the expected change is too small to be determined accurately. Instead, we decided to freeze the DNA-AgNCs to evaluate if very low temperatures affected the decay time in a way that could help interpret the photophysical properties. DNA-AgNCs in 10 mM NH\(_4\)OAc were frozen in an NMR tube and the fluorescence decay times and emission spectra were recorded at −78 °C (acetone/dry ice mixture) and −196 °C (liquid nitrogen). The results of these experiments can be found in Fig. 3 and Table 1. Surprisingly, the \((\tau_w)\) is nearly unchanged with a value of 3.74 ns at −78 °C. The emission spectrum narrows and blue shifts to a maximum centered at 710 nm. Interestingly, the fluorescence decay time becomes multi-exponential, as can be seen by the rise in the average decay time as a function of emission wavelength in Fig. 3B and the TRES in Fig. S7 (ESI†). The freezing restricts the conformational flexibility of the DNA-AgNC and the slow spectral relaxation on the timescale of the fluorescence decay time becomes visible again. This observation is in line with a previous report where changing the viscosity dramatically enhanced the slow spectral relaxation.\(^8\) However, it is still remarkable that even when the DNA-AgNC studied here is frozen solid, slow spectral relaxation occurs. The effect becomes even more pronounced at −196 °C (see Fig. 3B). The emission spectrum narrows further and the maximum is now centered at 706 nm. The \((\tau_w)\) at −196 °C is 3.63 ns, which is comparable to, but about 0.1 ns shorter than \((\tau_w)\) at room temperature. These observations lead us to conclude that non-radiative decay from the emissive state due to internal conversion must be negligible. Based on previous phenomenological photophysical models of DNA-AgNCs, we assume that \(Q\) is the product of the quantum yield of emissive state formation (\(Q_{D1}\)) from the Frank–Condon state and the fluorescence quantum yield from the emissive state (\(Q_{fl}\)).\(^7\)

It has been previously demonstrated for a large number of DNA-AgNCs that dark state formation from the Frank–Condon state is a common process.\(^20–27\) This dark state can be optically excited by a secondary NIR laser that pumps the dark state to the emissive state in a process termed optically activated delayed fluorescence (OADF).\(^20,23\) We performed OADF measurements, since this allows to estimate the minimum value for the quantum yield of dark state formation (\(Q_{D1}\)), as was previously demonstrated for a red-emitting DNA-AgNC.\(^20,28,29\) After determining the OADF and upconversion fluorescence (UCF) contributions to the secondary fluorescence (SF, see ESI† for details) and normalizing it to the primary fluorescence (PF), a minimum \(Q_{D1}\) value of 4.3% was found.\(^20\) This value is very similar to the minimum \(Q_{D1}\) value of 3.9% previously found for a red-emitting DNA-AgNC.\(^20\) Interestingly, the contribution of UCF to the SF seems much higher here than for the red emissive DNA-AgNC.\(^20\) As demonstrated before,\(^20\) the UCF signal is not due to a coherent two-photon absorption process, but a consecutive photon absorption process, since a rather linear relationship can be found for the UCF signal versus secondary excitation intensity (see Fig. 4A).\(^28\) The easily detectable OADF and UCF signals of this NIR-emitting DNA-AgNC make it an interesting candidate for anti-Stokes fluorescence imaging.\(^20\) Besides dark state formation, the Frank–Condon state could partially undergo ultrafast ground state recovery, as was demonstrated previously for red-emitting DNA-AgNCs.\(^21\)
In summary, we present a NIR-emitting DNA-AgNC with an unusually high fluorescence quantum yield of 73% at 25 °C. This result suggests that there may exist more DNA-AgNCs further out in the NIR range that can maintain their high fluorescence quantum yield. These high fluorescence quantum yield NIR emitters are new and promising candidates for tissue imaging in the biological transparent NIR windows. We hypothesized that low coupling of the AgNC to the DNA bases could be the reason for both the high fluorescence quantum yield and the limited thermal stability. The NIR emitter converts irreversibly to a non-emissive compound upon prolonged heating above 30 °C. Additionally, we demonstrated that this DNA-AgNC can produce easily detectable OADF and UCF signals that make it potentially suitable for anti-Stokes fluorescence imaging.
