Transition metal decorated soft nanomaterials through modular self-assembly of an asymmetric hybrid polyoxometalate†

 Elizabeth Hampson,^a Jamie M. Cameron,^b Julie A. Watts^b and Graham N. Newton^{b*}

An asymmetrically functionalised Wells–Dawson organic–inorganic hybrid polyoxometalate has been post-functionalised by Pt²⁺ coordination, and demonstrates self-assembly into surface-decorated micellar nanostructures. This multifunctional hybrid material is found to be a redox-active soft nanomaterial and demonstrates a new molecular design strategy with potential for applications in photo- or electro-catalysis.

New organic–inorganic hybrid materials, which use molecular design strategies to control their self-assembly into hierarchical structures and fine-tune their chemical properties, have attracted considerable attention in recent years for their wide-ranging potential applications.¹ One of the most effective strategies is the use of tuneable molecular ‘building blocks’ which can confer multiple complimentary organic and inorganic functionalities. Polyoxometalates (POMs) – a class of unique, nanosized, molecular metal-oxide clusters – are particularly attractive in this regard, combining rich photo- and electro-chemical properties with stable, highly modular structures.² In particular, the ability of POMs to covalently incorporate organic groups *via* rational, post-synthetic modification allows their physicochemical properties to be selectively tuned,³ and has facilitated their exploration as novel organic–inorganic amphiphiles (*e.g.* by incorporating long-chain hydrophobic moieties).⁴ This has led to growing interest in the use of organofunctionalised hybrid-POM species as discrete building blocks with great promise for the construction of unique soft-materials with a range of enhanced, switchable functionalities.^{4a,5} The self-assembly of hybrid-POMs into soft nanostructures has also been shown to be dependent on

a number of easily controlled factors (in addition to the design of the POM cluster itself), such as solvent,^{4d,e,6} pH, cations,⁷ or coordination of metal ions,^{6,8} all of which open up a number of wide-ranging material design strategies.

One of the outstanding challenges in the field remains the development of multicomponent molecular building blocks into which a range of structure-directing or functional groups can be incorporated. An emerging strategy is the development of asymmetric hybrid-POMs, in which two (or more) distinct organic groups are covalently bound to the POM core. Due to considerable challenges in the synthesis and purification of such compounds however, only a select few examples have been reported to date,⁹ almost all of which are based on the minimally functional [MnMo₆O₂₄(L)₂]^{3−} Mn-Anderson cluster.¹⁰ Recently, our group reported the simple one-pot synthesis of the first stable, bi-functionalised asymmetric hybrid-POM based on the [P₂W₁₈O₆₂]^{6−} Wells–Dawson cluster.¹¹ This new species, K₄(C₂H₈N)₂[P₂W₁₇O₆₁(P(O)C₂₁H₁₄N₃)(P(O)OC₂₄H₄₁)] (1) (see Scheme 1), demonstrates unique multifunctionality driven by the inclusion of both aliphatic long-chain alkane and metal-chelating terpyridine (TPY) groups, alongside the inherent photo- and redox-activity of the POM core. **1** also shows solvent-dependent self-assembly into low dispersity micellar structures, however, when we attempted to combine this with metal-functionalisation using Fe²⁺ ions, new dimeric clusters formed which were found to aggregate into smaller, more condensed nanostructures resembling those recently reported by Izzet and Proust, and lacking the distinct shape and hollow interior of the micellar species formed by **1**.^{6,12}

To maximise the potential of soft materials based on asymmetric hybrid-POMs, it will be necessary to controllably combine the distinct properties of each component, such that the functionality of each sub-unit is fully exploited. Here, we demonstrate the self-assembly of an entirely new type of multi-functional Pt²⁺-decorated micellar nanostructure based on Pt complexes of the asymmetric POM building block **1**. Pt²⁺-Polypyridyl complexes are known for their unique luminescent

Scheme 1 Preparation of the Pt^{2+} -coordinated hybrid-POM, **Pt-1**, from the asymmetrically functionalised precursor, **1**, showing the ^{31}P NMR spectrum of **Pt-1** in DMSO-d_6 . Colour code: blue polyhedra = $\{\text{WO}_6\}$, pink polyhedra = $\{\text{PO}_4\}$, red spheres = oxygen. Cations and solvent molecules are omitted for clarity.

properties, and find application in photocatalysis and DNA-intercalation,¹³ whilst the unique supramolecular solvent-switchable morphology of the resulting hybrid nanomaterials encodes potential functionality as bespoke catalysts, nanoreactors or molecular-delivery systems.¹⁴

The Pt-functionalised asymmetric hybrid cluster, $\text{K}(\text{C}_2\text{H}_8\text{N}_3)_3[\text{P}_2\text{W}_{17}\text{O}_{61}(\text{P}(\text{O})\text{C}_{21}\text{H}_{14}\text{N}_3\text{Pt}(\text{solv.}))(\text{P}(\text{O})\text{OC}_{24}\text{H}_{41})] \cdot n\text{DMF}$ (**Pt-1**), was prepared from the asymmetric hybrid POM, **1**, which was synthesised according to our previously reported procedure.¹¹ $[\text{Pt}(\text{COD})\text{Cl}_2]$ (COD = cyclooctadiene) was stirred briefly with two equivalents of AgBF_4 in acetone to labilise the Pt^{2+} complex. The resultant AgCl was removed by filtration and the Pt-containing solution was added to a solution of **1** in $\text{DMF-CH}_3\text{CN}$ (1 : 1 v/v) and stirred at room temperature for 72 h. This resulted in a yellow/orange coloured reaction mixture, which is characteristic of many $\{\text{Pt}(\text{TPY})\text{L}\}$ complexes.¹⁵ The reaction mixture was centrifuged to remove any insoluble material, before the solvent was removed *in vacuo*. The final product was obtained by precipitation from minimal DMF using an excess of diethyl ether. The composition and purity of **Pt-1** was confirmed by ^1H , ^{31}P NMR and FTIR spectroscopies, ESI-MS and elemental (CHN) analysis.

The ^{31}P NMR spectrum of **Pt-1** obtained in DMSO-d_6 shows signals for both covalently bound ligand groups, with the terpyridine-containing group (P-TPY) and the alkane-group (P- C_{18}) appearing at 12.55 and 17.00 ppm respectively (Scheme 1). Compared to **1**, the phosphorus nucleus in the P-TPY group is slightly shielded (from 13.40 ppm) due to the effect of the metal ion coordination, and the P- C_{18} phosphorus is very slightly deshielded (from 16.72 ppm), indicative of some electronic communication between groups, possibly mediated by the POM core (Fig. S3, ESI[†]). ^1H NMR peaks for the aromatic protons of P-TPY are shifted downfield relative to those of **1**, suggesting successful coordination of the Pt^{2+} ion (Fig. S1 and S4, ESI[†]).^{13a} The observation of several signals in the ESI-MS spectra of **Pt-1** which closely correspond to the intact cluster additionally confirm successful preparation of the Pt-functionalised hybrid (Fig. S5 and Table S5, ESI[†]).

To explore the multifunctionality of **Pt-1** we first studied its redox-activity. Cyclic voltammetry experiments were conducted

in DMF on a 0.5 mM solution of **Pt-1** with 0.1 M TBA- PF_6 used as the electrolyte. In the potential range of +1.0 to -2.25 V (*vs.* Fc/Fc^+) five quasi-reversible redox processes are observed from -0.5 to -2.25 V as well as an irreversible oxidation at approximately +0.5 V (Fig. 1).

Processes I, II, IV and V are attributed to $\text{W}^{\text{VI}/\text{V}}$ redox couples centred on the POM core and are found to be very slightly negatively shifted relative to those observed in **1**. This indicates some (though very weak) influence on the electronic structure of the POM core by formation of the new Pt-TPY complex. Process III is assigned to TPY/TPY $^{\bullet-}$ redox and has shifted positively due to stabilisation of the TPY radical anion by metal incorporation.¹⁶ The irreversible oxidation observed at +0.476 V can be assigned to the oxidation of Pt^{2+} to Pt^{3+} , as has been observed for some similar Pt(TPY) complexes, though it should be noted that this remains unresolved in the literature.¹⁷ Here, we observe that the oxidation only appears once the potential is taken more negative than *ca.* -1.8 V *vs.* Fc/Fc^+ on sequential scanning (Fig. S11, ESI[†]).

We then studied the solvent-dependent self-assembly of **Pt-1** by dissolving it in a 9:1 (v/v) water-DMF mixture (the compound is first solubilised in DMF, to which was then added

Fig. 1 Overlaid cyclic voltammograms of **Pt-1** and precursor asymmetric POM hybrid, **1**, collected from a 0.1 M solution of TBA- PF_6 in DMF (see ESI[†] for details).

Fig. 2 (a) Cryo-TEM imaging of micellar assemblies of **Pt-1** formed in 1.4 mM water–DMF (9 : 1 v/v) solution; (b) the proposed structure of the micellar assemblies.

water) to prepare a 1.4 mM solution. Dynamic Light Scattering (DLS) experiments indicated the formation of assemblies with a hydrodynamic diameter of approximately 6 nm (Fig. S8, ESI†). Cryo-TEM analysis of the DLS solution when deposited and frozen on a graphene-oxide and holey carbon-supported Cu grid showed spherical structures in good agreement with the DLS analysis, with diameters of 6.7 ± 0.7 nm (Fig. 2a). Interestingly, these are similar in appearance to the ‘worm-like’ aggregates reported previously by Izzet *et al.*, however in this case the micellar structure of **Pt-1** is still clearly visible.⁶ The spherical assemblies formed by **Pt-1** also differ significantly from the randomly shaped aggregates observed in our previous work as a result of the solvent-driven self-assembly of the POM–Fe^{II}–POM dimer derived from **1**.¹¹ The micelle-favouring ‘head-tail’ polarity of **1** is retained upon platinum(II) coordination. In contrast, formation of the dimeric iron(II) complex leads to molecules of ill-defined polarity with restricted capacity to form regular assemblies. The structures of the assemblies formed by **Pt-1** constitute a new, and to the best of our knowledge, entirely unique class of surface-decorated micelles (Fig. 2b). This is logical as the Pt-coordinating TPY-sites can only be directed outwards from the hydrophobic core (comprised of the interior-facing C₁₈ chains) as a result of the high angle (approx. 160°)^{3b} between the two distinct arylphosphonate ligands. This work demonstrates an effective strategy for the preparation of new surface-functionalised soft nanomaterials.

In summary, we have successfully postfunctionalised an asymmetrically functionalised Wells–Dawson hybrid POM by the coordination of a platinum(II) centre using a straightforward and broadly applicable synthetic strategy. This work provides an easily accessible and versatile method for the development of new multifunctional hybrid systems with novel supramolecular architectures and tuneable functionalities for new applications as advanced materials.
