Surface immobilized copper(I) diimine photosensitizers as molecular probes for elucidating the effects of confinement at interfaces for solar energy conversion.

Heteroleptic copper(I) bis(phenanthroline) complexes immobilized on nanoporous metal oxide substrates are responsive to the external environment and provide a new strategy to control charge transfer processes for efficient solar energy conversion.

Heteroleptic copper(I) bis(phenanthroline) complexes with surface anchoring carboxylate groups have been synthesized and immobilized on nanoporous metal oxide substrates. The species investigated are responsive to the external environment and this work provides a new strategy to control charge transfer processes for efficient solar energy conversion.

Copper(I) coordination complexes have attracted interest for integration in solar energy conversion schemes because of their broad absorption in the visible region and the relative ease of redox of copper compared to the ruthenium centre of the prototype molecular photosensitizer [Ru(bpy)3]2+. Recent work focused on ligand designs of Cu(I) photosensitizers has demonstrated the potential for these earth-abundant complexes to initiate light-driven H2 catalysis in multimolecular systems. Herein, we describe a fundamentally new strategy for controlling and directing photochemical processes through dimensional control of a metal oxide environment.

For Cu(I) bis(phen) complexes, substitution of the phen ligands and accompanied distortions to the ideal tetrahedral symmetry profoundly influence their ground- and excited-state properties. By comparing Cu(i)(dmp)2 and Cu(i)(dtbp)2 (where dmp = 2,9-dimethyl-1,10-phen, dtbp = 2,9-di-tert-butyl-1,10-phen), we know that increasing the steric bulk at the 2,9-phen position from methyl to tert-butyl results in a 29 nm blue shift of the absorbance feature assigned to MLCT from \( \lambda_{\text{max}} = 454 \text{ nm} \) to \( \lambda_{\text{max}} = 425 \text{ nm} \) and a 0.20 V increase in the Cu(I)/Cu(II) oxidation potential. Both observations are explained by the bulkier substituents yielding a more idealized D2d symmetry in the Cu(I) state, increasing the Cu–N bond length, and restricting flattening in the Cu(II) MLCT state and minimizing Cu(II)–solvent interaction. These general design principles are well-established for homoleptic Cu(i) bis(phen) complexes, and the same trends apply to heteroleptic Cu(i) bis(phen) complexes.

Short excited-state lifetimes are problematic for diffusional reactions, but electrode surface immobilization provides a direct, well-defined pathway for interfacial electron transfer. A group has shown that Cu(i) diimine complexes anchored to TiO2 substrates inject photogenerated electrons from the Cu(i) state to the conduction band of TiO2. In the non-coordinating solvent CH2Cl2, the \( \lambda_{\text{max}} \) decay for Cu(i)(dmp)2 is \( \sim 90 \text{ ns} \), but increases to 1.9 \( \mu \text{s} \) for Cu(i)(dtbp)2 due to the substituents preventing deactivation pathways associated with structural distortion in the Cu(II) MLCT state and minimizing Cu(II)–solvent interaction. These general design principles are well-established for homoleptic Cu(i) bis(phen) complexes, and the same trends apply to heteroleptic Cu(i) bis(phen) complexes.

The primary goal of this work is to understand whether the structural factors that dominate the solution phase photo-physical properties of Cu(i) diimine complexes also apply in...
heterogeneous environments. To this end, we have synthesized three new heteroleptic Cu(I) bis(phen) (CuHETPHEN) complexes functionalized with carboxylic acid groups which are capable of binding to metal oxide surfaces (Chart 1). These complexes were designed to evaluate two different ligand factors that we anticipate will impact the photophysical properties, particularly when immobilized or confined. Complex 1 has a short anchor which is directly connected to the phen ligand. In contrast, the imidazole-containing anchoring ligand of complexes 2 and 3 is approximately 6.5 Å longer than that of 1 and should allow studies to investigate the effect of distance and packing efficiency on the ground- and excited-state properties. Complexes 2 and 3 differ only in the 2,9-phen substitution on the anchor ligand and provide a direct comparison for how the known solution trends apply to immobilized CuHETPHEN complexes.

Complexes 1, 2, and 3 were synthesized by the two-step one-pot HETPHEN approach that yields kinetically stable complexes with no formation of the homoletic analogues. However, we had to refine the standard synthesis methods because of the poor solubility of the phenanthroline ligands functionalized with carboxylic acids. We dissolved Cu(CH₂CN)₂PF₆ in de-aerated CH₂Cl₂ or THF depending on the target complex, then added a stoichiometric amount of 2,9-dimesityl-1,10-phenanthroline (L) followed by one equivalent of carboxylate-functionalized ligands L₁, L₂, or L₃ to form complexes 1, 2, and 3. The synthesis of 1 was accomplished in neat CH₂Cl₂ but the somewhat more Lewis basic solvent THF was required for synthesis of 2 and 3.

To systematically investigate the ground- and excited-state properties of immobilized CuHETPHEN complexes, we selected nanoporous anodic aluminium oxide (AAO) wafers as the metal oxide platform. AAO wafers are commercially available in a variety of pore sizes ranging from 10 nm to 200 nm, and the controlled pore sizes offer a uniform chemical environment compared to the larger distribution of pore sizes that are present in more conventional metal oxide surfaces such as TiO₂ nanoparticle films. Complexes 1, 2, and 3 were immobilized on AAO wafers by submerging the wafers in a CH₂Cl₂ or CH₃OH solution of each complex overnight. The AAO wafers adopted the characteristic red-orange colour of the CuHETPHEN complexes and upon removal from solution the wafers were rinsed, soaked in pure solvent, and rinsed again to remove any residual weakly adsorbed complex.

UV-Visible absorbance spectra can be used to gather information on the coordination environment of Cu(I) diimine complexes. The AAO-immobilized MLCT band of 1 and 2 blue shift 10–30 nm as compared to each complex in CH₂Cl₂ solution (Fig. S3 and S4, ESI†), which is consistent with increased restriction to geometric changes in the complex. We observe only a minimal shift in the MLCT band for 3 between the immobilized complex and in solution (Fig. 1), which suggests that immobilization has less of an impact on the spectral response than the increased steric of the phen ligand environment. Additionally, we were able to correlate the density of immobilized 1–3 on the surface of the AAO wafers from the UV-Vis absorbance spectra and the AAO pore sizes and densities (Tables S3 and S4, ESI†). We determined that 1–3 were adsorbed on the surfaces at a density of approximately 1–2 complexes per square nanometre which correlates to roughly monolayer coverage based on related immobilized complexes.

To further probe the impact of pore immobilization on molecular and electronic structure, we utilized EPR spectroscopy due to its high sensitivity for paramagnetic centres and ability to elucidate structural and electronic information of the copper centre in the immobilized complexes. Since Cu(I) is diamagnetic and therefore EPR silent, we immobilized 3 on 10, 20, and 40 nm pore size AAO, oxidized the surface bound Cu(i) to the corresponding Cu(II) species using a solution of AgNO₃ in CH₃CN, and recorded X-band EPR spectra at 20 K (Fig. 2). For all of the AAO pore sizes, we observe spectra characteristic of Cu(II) 3d⁶ (S = 1/2), but with noticeable differences in the linewidth of the parallel, low field components as a function of AAO pore size. (We assign the sharp signal at 338 mT to an organic radical/defect, g ≈ 2.005, that we also observed in the bare AAO lacking any immobilized copper species, see Fig. S3, ESI†). The largest pore size of AAO investigated (40 nm) has the smallest linewidth (~290 MHz), which increases as the pore size decreases from 20 nm (~300 MHz) to 10 nm (~550 MHz). Since there is no evidence of a chemical change to 3 in the
Fig. 2 Continuous wave X-band EPR spectra of 3 in the Cu(ii) oxidation state immobilized on 10, 20, and 40 nm AAO recorded at T = 20 K.

different pore sizes, we interpret the broadening as a response to shorter neighbour–neighbour distances between Cu(ii) ions in the smaller pores, which leads to stronger magnetic dipole–dipole interaction. Using the assumption that there is no substantial contribution to line width from spin–spin interactions in glassy frozen dilute solutions of Cu(ii) complexes (see Fig. S7 (ESI†) and associated discussion), we estimate the distance between the immobilized Cu(ii) neighbours to be ~12 Å for the 40 and 20 nm pores, and ~8.5 Å for 10 nm AAO pores. This difference in spin–spin interaction likely arises from decreasing distance between neighbouring chromophore tethering sites with changes in pore size and may also be related in part to increased curvature with decreasing pores size.

Cyclic voltammetry of 1, 2, and 3 was performed in solution as well as immobilized on nanoITO which functions as both a substrate and working electrode since AAO is an insulator (Fig. 3 and Fig. S8, ESI†). The dominant factor in determining the Cu(ii) oxidation potential is the substitution at the 2,9-phen position of the anchor ligand, consistent with previous observations. As expected, the Cu(ii) potential for 3 is substantially more positive than for 1 and 2, both in solution and when immobilized (Fig. 3 and Fig. S8, Table S6, ESI†). Importantly, the potentials of 1 and 2 experience a more significant shift on immobilization than for 3 (230 mV for 1 and 2 vs. 50 mV for 3) which suggests 3 is less influenced by the external environment, consistent with the observations based on UV-vis spectroscopy.

The excited-state dynamics of the AAO-immobilized complexes were measured by ultrafast and nanosecond transient optical spectroscopy. Because of the complicated spectral changes and multiple photophysical processes of Cu(iii) diimine complexes,13,17,29 we used global analysis to fit the transient absorption data over a broad range of wavelengths with multi-exponential functions (complete fitting details are found in the ESI†). Similar to the well-documented photophysical behaviour for related complexes in solution, the transient spectra for the immobilized complexes are characterized by an initial broad featureless excited-state absorbance centred around 540 nm which evolves to a feature with two local λ-maxima at 530 and 570 nm within 30 ps (see for example 3 immobilized on 10 nm AAO in Fig. 4 and Fig. S8–S39, ESI†). As expected from literature precedent, methyl substitution in 3 results in a significant increase in excited-state lifetimes compared to 1 and 2, and the solution data are summarized in Table S7 (ESI†).

We immobilized complexes 1 and 3 on AAO and immersed the wafers in CH2Cl2 to investigate the impact of immobilization and pore size on the excited-state kinetics. Both 1 and 3 showed significantly longer excited-state lifetimes when immobilized on AAO than in solution, suggesting that immobilization restricts the ability of the complexes to undergo a flattening distortion and reduces exposure to solvent following photoexcitation. For complex 1, the 3MLCT lifetime is 1.0 ns in solution and increases to 1.7 ns when immobilized on 20 nm AAO. The average 3MLCT lifetime for 3 in CH2Cl2 is 49 ns, similar to that in 40 nm pores (51 ns), but the average 3MLCT lifetime increases to 69 ns for both 20 nm and 10 nm pores. This trend is similar to that previously observed for Cu(i)(dmp)2 dispersed into a polymer matrix where the 3MLCT lifetime increased from 90 ns in CH2Cl2 to 210 ns with increasing polymer viscosity.35 We interpret our results in a similar fashion: as 3 is immobilized in increasingly smaller pores and in closer proximity to other immobilized Cu centres (as measured by EPR), the typical flattening distortion is restricted which increases the lifetime of the excited state.

As a first step toward investigating the effect of nanoporous confinement on interfacial charge injection, we measured the
electron transfer kinetics of 3 immobilized on mesoporous n-type semiconducting TiO₂ films immersed in CH₂Cl₂ (Fig. S40 and S41, ESI†). Upon photoexcitation at 500 nm, we observe an average lifetime of 75 µs for the recovery of the ground-state bleach, which demonstrates that 3 does inject electrons into TiO₂. The recombination lifetime is comparable to analogous cases of other Cu(ı) species bound to TiO₂.²,⁵,²⁰

Im mobilization of Cu(ı) diimine complexes in nanoporous metal oxide materials presents an interesting opportunity to tune the photophysical properties of these complexes by external environmental factors. Here we have shown that decreasing the pore size of the AAO framework from 40 to 10 nm results in enhanced spin–spin interactions between Cu(ı) centres, as well as a measurable increase in the 3MLCT lifetime, over twice that observed in solution. The increase in 3MLCT lifetime is consistent with inhibited structural flattening as pore size decreases and ongoing work is focused on restricting pore diameter even further to investigate the impact of extreme confinement on Cu(ı) diimine excited-state dynamics. These results present a fundamentally new strategy for controlling and directing photochemical processes.
