Large-scale comparison of 3d and 4d transition metal complexes illuminates the reduced effect of exchange on second-row spin-state energetics†

Density functional theory (DFT) is widely used in transition-metal chemistry, yet essential properties such as spin-state energetics in transition-metal complexes (TMCs) are well known to be sensitive to the choice of the exchange–correlation functional. Increasing the amount of exchange in a functional typically shifts the preferred ground state in first-row TMCs from low-spin to high-spin by penalizing delocalization error, but the effect on properties of second-row complexes is less well known. We compare the exchange sensitivity of adiabatic spin-splitting energies in pairs of mononuclear 3d and 4d mid-row octahedral transition-metal complexes. We analyze hundreds of complexes assembled from four metals in two oxidation states with ten small monodentate ligands that span a wide range of field strengths expected to favor a variety of ground states. We observe consistently lower but proportional sensitivity to exchange fraction among 4d TMCs with respect to their isovalent 3d TMC counterparts, leading to the largest difference in sensitivities for the strongest field ligands. The combined effect of reduced exchange sensitivities and the greater low-spin bias of most 4d TMCs means that while over one-third of 3d TMCs change ground states over a modest variation (ca. 0.0–0.3) in exchange fraction, almost no 4d TMCs do. Differences in delocalization, as judged through changes in the metal–ligand bond lengths between spin states, do not explain the distinct behavior of 4d TMCs. Instead, evaluation of potential energy curves in 3d and 4d TMCs reveals that higher exchange sensitivities in 3d TMCs are likely due to the opposing effect of exchange on the low-spin and high-spin states, whereas the effect on both spin states is more comparable in 4d TMCs.

1. Introduction

Approximate density functional theory (DFT) is widely used in studying the catalytic1–6 and materials7–13 properties of open-shell transition-metal complexes.14 The well-localized d or f electrons of open-shell transition-metal centers impart unique properties but also can lead to a significant number of low-energy spin and oxidation states that are challenging to describe on equal footing using approximate electronic structure methods. For DFT in particular, presently available exchange–correlation (xc) approximations suffer from one- and many-electron self-interaction errors,15–19 commonly referred to as delocalization error20–22 (DE).

The high earth abundance and prevalence of 3d transition metals in enzymatic systems has motivated the widespread study16,23–41 of electronic structure method accuracy in first-row transition-metal complexes. For 3d transition-metal chemistry, DE can lead to pronounced errors in calculated bond dissociation energies,16,23–27 barrier heights28,29 and properties of the density30–33 within a given spin state as well as the relative
energetic ordering of spin states. While in some cases, it is possible to use higher accuracy methods such as correlated wavefunction theory, such methods have their own challenges in open-shell transition-metal complex (TMC) property prediction accuracy and remain cost-prohibitive for large-scale discovery of new TMCs.

Although less earth abundant than 3d metals, 4d transition metals often form catalysts with superior catalytic activity and turnover number (e.g., Ru for water oxidation and Mo for hydrogen evolution) and are excellent photosensitizers. Despite this importance of 4d transition metals, comparatively less is known about the relative accuracy of electronic structure methods for these TMCs. While we can anticipate that there should be some transferable observations between 3d and 4d metals, a more detailed understanding of the relationship between 3d and 4d TMC sensitivity to method choice is needed.

Broadly, the need to balance cost and accuracy has motivated a number of strategies aimed at efficiently eliminating DE in approximate DFT by recovering the derivative discontinuity lacking from pure (e.g., generalized gradient approximation or GGA) functionals. Approaches have included self-interaction corrections and related DFT+$U$ or $U$ corrections, tailoring higher order terms in the xc functional, or incorporating an admixture of Hartree–Fock (HF) exchange globally or with range-separation in a GGA. All such strategies generally behave similarly in TMCs by decreasing covalency or dative bonding and localizing density away from the metal. Functional tuning for either 3d or 4d transition-metal chemistry is challenged by the limited availability of reference data and the highly system- and property-specific nature of optimal functional choice, although physically motivated tuning approaches have been developed for select cases. Still, tuning the global amount of HF exchange in a GGA hybrid remains one of the most widely used approaches to improving approximate DFT errors.

For 3d midrow, octahedral TMCs, it is well known that the ground state is highly sensitive to the fraction of HF exchange due to the near-degeneracy of multiple spin states in these complexes as well as the close relationship between spin-state stabilization and DEs in approximate DFT. Pure, semi-local GGA functionals consistently stabilize overly-delocalized, strongly coherent states, tending to favor the increased bonding in low-spin (LS) over high-spin (HS) states. This manifestation of DE leads GGA to predict incorrect ground states as well as relative energies between spin states (e.g., adiabatic HS to LS spin splitting, $D_{H-I}$). Hybrid functionals counteract the bias for LS states, but the appropriate fraction of HF exchange is strongly system-dependent. For 3d TMCs, conflicting proposals of low (as little as $a_{HF} = 0.0$) and high $a_{HF} = 0.4–0.5$ fractions have been recommended, but 4d TMCs do not have similar heuristics.

In this work we apply our pragmatic approach of understanding the linearized exchange sensitivity of spin-splitting energies simultaneously to 3d and 4d TMC spin-state energetics. In 3d TMCs, this spin-state ordering exchange sensitivity is correlated to the ligand field strength of coordinating ligands, with bare ions exhibiting reduced sensitivities in comparison to strong-field ligands. For common ligands in mid-row, 3d TMCs, this exchange sensitivity can be significant, leading to a change in $\Delta E_{H-I}$ on the order of 10–20 kcal mol$^{-1}$ for a change in HF exchange from $a_{HF} = 0.15$ (e.g. in B3LYP) to $a_{HF} = 0.25$ (e.g., in PBE). While the form of the pure GGA xc being tuned (e.g., BLYP vs. PBE) can influence $\Delta E_{H-I}$, the HF exchange sensitivity has been shown to be invariant to GGA choice in 3d TMCs. These strong relationships between chemical structure and method sensitivity in 3d TMCs have enabled the development of machine learning models to predict exchange sensitivity and exchange-dependent properties, enlarging understanding of how changes in functional definition can influence large-scale discovery efforts.

Although these relationships have been established and fruitfully applied for 3d TMCs, the sensitivity of second-row (i.e., 4d) TMCs to HF exchange is not well known. In this work, we carry out a large-scale study of hundreds of mononuclear octahedral TMCs to understand broad relationships among first- and second-row spin-state ordering and exchange sensitivity. In Section 2, we describe how we construct a data set in which both the 3d and an isovalent 4d metal complex’s properties and sensitivity to exchange are known for mid-row transition metals in low-, intermediate- and high-spin states. In Section 3, we discuss our results on quantifying distinct behavior in ground state preference and sensitivity to HF exchange fraction for the second-row complexes. We identify sources for this difference by noting distinct effects of exchange on each spin state’s potential energy surface in 3d and 4d TMCs. Finally, in Section 4, we provide our conclusions.

## 2. Computational details

### a. Data set construction

We studied the effect of HF exchange on the spin-state ordering of octahedral TMCs with a single mid-row transition-metal center. We compared properties of TMCs comprised of first-row (i.e., 3d valence) Cr, Mn, Fe, and Co to second-row (i.e., 4d valence) Mo, Tc, Ru, and Rh (Fig. 1). In all cases, we calculated properties of metal centers in formal M(II) or M(III) oxidation states to ensure differences in spin state correspond to differences in d orbital occupations (Fig. 1). The TMCs were evaluated in up to three spin states: low-spin (LS), intermediate-spin (IS), and high-spin (HS), where we defined the IS and HS states as those that differ from the LS state (i.e., with $Ls$ unpaired electrons) by two more ($Ls + 2$) or four more ($Ls + 4$) unpaired electrons, respectively. We then computed the gas-phase, adiabatic spin-splitting energy: between the LS and HS states, $\Delta E_{H-I}$, as well as between the IS state and either the HS or the LS state (i.e., $\Delta E_{H-I}$ and $\Delta E_{I-H}$). The nominally $d^3$ Cr(II)/Mo(III) and $d^7$ Co(II)/Rh(III) were evaluated only in LS doublet and IS quartet spin multiplicities (i.e., also the highest accessible spin state), and only $\Delta E_{I-H}$ was computed (Fig. 1). The $d^5$ metals...

(i.e., M(II)/Tc(II) or Fe(III)/Ru(III)) were studied in LS doublet, IS quartet, and HS sextet states (Fig. 1). Analogously, d⁴ (i.e., M(II)/Tc(II) or Cr(II)/Mo(II)) and d⁷ (i.e., Fe(III)/Ru(III) or Co(III)/Rh(III)) metals were calculated in LS singlet, IS triplet, and HS quintet states (Fig. 1).

We calculated properties of complexes formed from combinations of ten small, monodentate ligands that spanned ligand field strengths and coordinating element identities. Negatively charged halides (Cl⁻ and F⁻) ions are known to have among the weakest field strengths, while several others (i.e., phospine, carbonyl, and cyanide) have among the highest field strengths (Fig. 1). Intermediate behavior is expected of the remaining (i.e., water, ammonia, hydrogen sulfide, acetoniitride, and methyl isocyanide) ligands (Fig. 1). In addition to homoleptic complexes, heteroleptic complexes were formed from up to two ligands (i.e., L₁ and L₂). Both M(L₁)₂(L₂) TMCs with the two minority L₁ ligands either trans (i.e., aligned 180° in the TMC) or cis (i.e., 90° in the TMC) were studied along with M(L₁)₃(L₂) TMCs.

b. Electronic structure calculations

Calculations on mononuclear, octahedral TMCs studied in this work followed an established protocol. All initial structures were generated using molSimplify, which employs OpenBabel as a backend for ligand structure generation. These calculations were automated and checked for fidelity with molSimplify automatic design (mAD). All TMCs were geometry optimized with DFT using a development version of TeraChem. For the geometry optimizations, the standard B3LYP global hybrid functional was employed along with modified forms in which the Hartree–Fock exchange fraction (αHF) was varied from its default value of 0.20 to as low as αHF = 0.00 (i.e., a pure BLYP GGA) or as high as αHF = 0.30 in increments of 0.05 while holding the LDA/GGA exchange ratio fixed, 37,116 As in 3d TMCs, 37,39,40 sensitivities from αHF variations using PBE as the GGA xc functional are comparable to a representative 4d TMC (ESI† Table S1). All calculations employed the LANL2DZ effective core potential for transition metals and the 6-31G* basis for all other atoms. Only singlet calculations were carried out in a spin-restricted formalism, with all other spin multiplicities carried out unrestricted. Level shifting was employed to aid self-consistent field (SCF) convergence with the majority spin and minority spin virtual orbitals each shifted by 0.25 Ha. The default SCF convergence threshold of 3 × 10⁻⁵ for the largest component of the DIIS vector was employed. Geometry optimizations were carried out in translation rotation internal coordinates using the L-BFGS algorithm to default tolerances for the gradient of 4.5 × 10⁻¹ Hartree Bohr⁻¹ and energy difference between steps of 10⁻¹ Hartree. Geometric properties from a representative case optimized with a larger triple-ζ basis set and the resulting exchange sensitivities preserves trends (ESI† Table S1).

For the mAD calculation workflow, calculations were run for 24-hour increments and resubmitted for up to five additional runs. At each resubmission, mAD applies loose geometric criteria and abandons any calculations that fail these checks (ESI† Table S2). In this workflow, the B3LYP (αHF = 0.20) geometry optimization was carried out first. If the B3LYP geometry optimization converged, we used the converged structure and wavefunction to initialize geometry at the adjacent increased (i.e., 0.25) and decreased (i.e., 0.15) αHF values, as in prior work. If these calculations converged, their structures and wavefunctions were then used for the next adjacent (e.g., increased to 0.30 or decreased to 0.10) αHF value geometry optimizations. However, if an optimization failed to converge, the next αHF value was not attempted.

For all converged calculations, automated data fidelity checks were employed based on refinements of prior geometric and electronic structure criteria (ESI† Table S2). Specifically, complexes were retained if their structure was deemed to be intact based on tighter geometric criteria than were employed during the optimization (ESI† Table S3). The electronic structure criteria required that the deviation of the S² expectation value from its anticipated value (i.e., S(S + 1)) was below 1 and the Mulliken metal atomic spin density was within 1 μB of the total spin of the molecule (ESI† Table S3).

Linearized exchange sensitivities, S, were obtained from linear fits of the dependence of the relevant property (e.g., ΔE₃h-1) on αHF. The resulting sensitivity (e.g., S(ΔE₃h-1)) is reported as the change in property over the range from αHF = 0.0 to 1.0, which we refer to as HFX as in prior work. As long as a single, qualitatively consistent electronic state has been converged over all points, this linear approximation is known to be good for a range of properties, both energetic (e.g., spin splitting and reaction energies) and electronic in nature. To ensure that linearized exchange sensitivities could be quantitatively obtained from collected data points, we applied a series of constraints and filtering steps; this procedure and its results are

detailed in ESI,† Table S4. All raw data, resulting $R^2$ values, computed sensitivities, and reasons for eliminating points or sensitivities are provided in the ESI.†

Potential energy curves (PECs) of 3d Fe(u) and 4d Ru(u) in LS singlet and HS quintet states were obtained for homoleptic complexes of He atoms and CO ligands also using TeraChem and B3LYP/LACVP* with modified $\alpha_{\text{HF}}$ values. These PECs were obtained by rigidly shifting all six He atom (CO) ligands from distances as short as 1.70 Å (1.80 Å) to as long as 2.90 Å (2.80 Å) in 0.01 Å (0.02 Å) increments, with calculations at longer bond lengths starting from the converged wavefunction at the shorter bond lengths. The He atom was selected following recent work\textsuperscript{13} that showed it is a representative weak field ligand, and a single He atom is simpler to translate during PEC evaluation than a typical non-linear weak-field ligand (i.e., H$_2$O or NH$_3$). The CO bond length was fixed to 1.125 Å, its value in relaxed TMCs. These calculations were repeated for $\alpha_{\text{HF}}$ fractions increasing from 0.0 to 0.45 in increments of 0.05, with wavefunctions always initializing from shorter bond lengths and lower $\alpha_{\text{HF}}$ values. All total energies and computed sensitivities are provided in the ESI.†

3. Results and discussion

a. Ligand field sensitivity trends in homoleptic TMCs

To understand the extent to which previous observations\textsuperscript{35–38,40,126,131} in first-row transition metals are likely to be generalizable to the second row, we first compared spin-splitting properties for a subset of homoleptic complexes. Depending on the field strength of the ligand, 3d Fe(u) TMCs are known to favor distinct ground states.\textsuperscript{146} For example, d$^6$ Fe(u) TMCs with intermediate-field nitrogen-coordinating ligands commonly exhibit spin crossover (SCO)\textsuperscript{158} phenomena by changing from an LS singlet to HS quintet state with increasing temperature. The $\Delta E_{\text{H–L}}$ for these complexes is sensitive to HF exchange fraction, becoming more negative with increasing $\alpha_{\text{HF}}$. The combination of this physical phenomenon with sensitivity to DFT functional parameters means that different $\alpha_{\text{HF}}$ values can predict the same complex to have either an LS or HS ground state.\textsuperscript{35–38,40,126,131}

Indeed, for the complexes studied in this work, homoleptic complexes of Fe(u) with acetonitrile or cyanide have near-degenerate LS and HS states when evaluated with B3LYP and thus are predicted to be LS with lower HF exchange (i.e., $\alpha_{\text{HF}} = 0.1$) but HS with higher fractions (i.e., $\alpha_{\text{HF}} = 0.3$, Fig. 2). Consistent with prior observations,\textsuperscript{36,37,138} the magnitude of this typically negative exchange sensitivity, $S$, generally increases with field strength. This means that a hexa-carbonyl Fe(u) complex that is strongly LS with B3LYP can become HS with higher exchange fractions (ca. $\alpha_{\text{HF}} = 0.4$), whereas weak-field hexa-aqua Fe(u) is uniformly HS for all $\alpha_{\text{HF}}$ values (Fig. 2).

In comparison to their first-row counterparts, the isovalent 4d Ru(u) TMCs are considerably low-spin shifted, with almost all Ru(u) complexes strongly favoring LS states over HS states except for the weakest field (i.e., hexa-fluoride) cases (Fig. 2). The Ru(u) homoleptic complexes also exhibit uniformly reduced exchange sensitivities (Fig. 2). Thus, complexes with modest \textsuperscript{8}B3LYP $\Delta E_{\text{H–L}}$ values (e.g., hexa-aqua Ru(u), ca. 25 kcal mol$^{-1}$) are not predicted to change their ground state with varied $\alpha_{\text{HF}}$ in contrast to Fe(u) homoleptic complexes (Fig. 2). Despite these differences, qualitative trends with ligand field strength appear preserved from Fe(u) to Ru(u), with increasing exchange sensitivity apparent with increasing ligand field (Fig. 2).

Given the strong LS shift of 4d Ru(u) TMCs with respect to their 3d Fe(u) TMC counterparts, we identified d$^4$ Tc(u) as a possible metal/oxidation state where TMCs could be expected to favor HS or LS states depending on field strength (Fig. 2). The 4d Tc(u) singlet LS and quintet HS states are in fact close in energy with B3LYP for weak-field (i.e., hexa-aqua) and intermediate-field (i.e., hexa-acetonitrile) complexes (Fig. 2). The isovalent Mn(u) complexes are comparatively HS shifted, with only the homoleptic methyl-isocyanide with a pure BLYP (i.e., $\alpha_{\text{HF}} = 0.0$) GGA coming close to spanning the LS–HS transition (Fig. 2). The exchange sensitivity of all Mn(u) homoleptic TMCs is reduced with respect to the Fe(u) TMCs but follows a consistent trend of increasing with increasing ligand field strength (Fig. 2). Consistent with 3d/4d observations from Fe(u)/Ru(u), Tc(u) homoleptic TMCs have reduced exchange sensitivity compared to isovalent Mn(u) (Fig. 2). This means that even though a number of 4d Tc(u) TMCs have modest B3LYP $\Delta E_{\text{H–L}}$ (<25 kcal mol$^{-1}$) values, the only ground state assignment change for Tc(u) in this series would be for the
Unlike the isovalent 3d TMCs (Fig. 3), spin-state orderings change for the 4d TMCs (Fig. 2). Overall, reduced exchange sensitivities in these 4d TMCs consist of the smallest of the three (Fig. 3). The trend holds for all 3d TMCs (Fig. 3). Spin-state orderings change with $a_{HF}$ due to high $S$ for several of the 3d TMCs (i.e., HS–IS/HS–LS Fe(n)(CO)$_6$I$^-$ and IS–LS Fe(n)(H$_2$O)$_6I$$^-$ and HS–IS Mn(n)(CO)$_6I$$^-$ but only one of the 4d TMCs (i.e., HS–LS Tc(n)(H$_2$O)$_6$) in part due to the reduced exchange sensitivity of 4d TMCs (Fig. 3).

For all spin-splitting energies, the hexa-aqua exchange sensitivities are lower than those for hexa-carbonyl in both 3d and 4d TMCs (Fig. 3). As can be expected, there are a few noteworthy exceptions where the 4d TMC sensitivity is higher than its 3d TMC counterpart, namely: (i) in weak-field, hexafluoro complexes of Mn(n)/Tc(n) ($S(3d)$ ca. $-35$ vs. $S(4d)$ $-50$ to $-70$ kcal mol$^{-1}$ HFX$^{-1}$) and (ii) in stronger fields (e.g., Mn(n)(NCCH$_3$)$_4$(CNCCH$_3$)$_2$) where the 3d TMC sensitivity is typical but the Tc(n) value is among the largest evaluated for 4d TMCs (ESI,† Table S5). The strong net negative charge on the halide complexes also results in other types of outliers: Ru(n) hexafluoride and a Cl$^-$-containing Mo(n) complex are the only two 4d TMC cases for which the $S(AE_{H-L})$ is weakly (ca. 20–45 kcal mol$^{-1}$ HFX$^{-1}$) positive (ESI,† Table S8). In both 4d...

**b. Global comparison of 3d and 4d TMCs**

We next expanded our comparison of HS–LS energies and their sensitivities to include heteroleptic complexes for an overall set of more than 200 d$^3$–d$^6$ TMC pairs. Over all of these 3d/4d TMC pairs, the 4d $S(AE_{H-L})$ was consistently reduced with respect to that for 3d TMCs (Fig. 4). The largest (i.e., most negative) 3d $S(AE_{H-L})$ values are larger than those of 4d TMCs by around 50 kcal mol$^{-1}$ HFX$^{-1}$ (i.e., around 40% larger, ESI,† Table S6). For each 3d metal/oxidation state, average exchange sensitivities also vary, i.e., highest for Mn(n) or Fe(n) and lowest for Cr(n), with similar trends for the isovalent 4d metal/oxidation states (ESI,† Table S6). The overall reduced sensitivities of 4d TMCs become more apparent the larger the 3d TMC $S$ values are (Fig. 4). Based on prior analysis and our observations on homoleptics, this should mean that strong-field 3d TMCs are much more sensitive to HF exchange than 4d TMCs while weak-field 3d and 4d TMCs complexes have more similar exchange sensitivity (Fig. 4). Indeed, the sensitivities of the prototypical strong-field hexa-carbonyl and weak-field hexa-aqua homoleptics largely reside at extremes of the overall relationship between 3d and 4d TMC $S$ values (Fig. 4).

There are a few noteworthy exceptions where the 4d TMC $S$ exceeds that of its 3d TMC counterpart, namely: (i) in weak-field, hexafluoro complexes of Mn(n)/Tc(n) ($S(3d)$ ca. $-35$ vs. $S(4d)$ $-50$ to $-70$ kcal mol$^{-1}$ HFX$^{-1}$) and (ii) in stronger fields (e.g., Mn(n)(NCCH$_3$)$_4$(CNCCH$_3$)$_2$) where the 3d TMC sensitivity is typical but the Tc(n) value is among the largest evaluated for 4d TMCs (ESI,† Table S7). The strong net negative charge on the halide complexes also results in other types of outliers: Ru(n) hexafluoride and a Cl$^-$-containing Mo(n) complex are the only two 4d TMC cases for which the $S(AE_{H-L})$ is weakly (ca. 20–45 kcal mol$^{-1}$ HFX$^{-1}$) positive (ESI,† Table S8). In both 4d...
TMCs, the corresponding 3d TMC still has a negative, albeit small $S$ value (ESI, Table S8).

Trends for the 2-electron $\Delta E_{H^{-1}}$ are largely consistent with those for the 4-electron $\Delta E_{H^{-1}}$. Although overall $S(\Delta E_{H^{-1}})$ values for both 3d and 4d TMCs are lower than $S(\Delta E_{3d})$, 3d TMC sensitivities nearly always exceed their 4d TMC values (Fig. 4 and ESI, Table S6). The 3d/4d metal/oxidation states with the highest average $S(\Delta E_{H^{-1}})$ (i.e., Mn(n)/Tc(n) and Fe(n)/Ru(n)) also have the highest $S(\Delta E_{3d})$ values (ESI, Table S6). On average, best-fit lines relating $S(4d)$ vs. $S(3d)$ for $\Delta E_{H^{-1}}$ and $\Delta E_{3d}$ have comparable ratios of change in $S(4d)$ per change in $S(3d)$ of 0.55 and 0.65, respectively (ESI, Table S6). As in the case of $\Delta E_{H^{-1}}$, a small number of 4d TMC $\Delta E_{3d}$ sensitivities exceed their 3d TMC counterparts and typically correspond to Mn(n) complexes with strong-field equatorial ligands (CO or NCCN) expected to have strong Jahn–Teller distortion (ESI, Table S7).

We also analyzed 2-electron $\Delta E_{H^{-1}}$, pair trends, which additionally include $d^3$ Cr(n)/Mo(n) and $d^7$ Co(n)/Rh(n) TMCs in their doublet LS and quartet IS states (see Fig. 1). As in the other two cases of spin-splitting energetics, 4d TMCs exhibit reduced exchange sensitivity with respect to 3d TMCs (Fig. 4 and ESI, Table S6). For the $d^3$/$d^7$ TMCs for which only $\Delta E_{H^{-1}}$ is defined, $S(4d):S(3d)$ ratios from best-fit lines of 0.42 for $d^7$ and 0.64 for $d^3$ are consistent with the ratios observed in $d^3$-$d^7$ TMCs (ESI, Table S6). Several more 4d TMC outliers that are close to parity are observed, typically Mn(n)/Tc(n) complexes with equatorial chlorides or Cr(n)/Mo(n) complexes with equatorial ammonia ligands (Fig. 4 and ESI, Table S7). Far more positive 4d TMC sensitivities are observed for several Rh(n) complexes with a range of weak- and strong-field ligands (ESI, Table S9). A handful of 3d TMCs (e.g., in Fe(n) complexes with CN⁻ ligands) also have positive sensitivities, but the equivalent, isovalent Ru(n) TMCs have weakly negative sensitivities (ESI, Table S9). These observations on $\Delta E_{H^{-1}}$ are distinct from $\Delta E_{3d}$ and $\Delta E_{H^{-1}}$ where only one cis Mo(n)(NH₃)₄(Cl⁻) complex had positive 4d TMC sensitivities for both quantities (ESI, Table S8).

c. Analysis of a heteroleptic complex series

Given the diversity of TMC chemistry in these larger data sets, we simplified our analysis to understand the extent to which trends in $\Delta E$ and $S(\Delta E)$ were additive in a narrower subset of representative 3d and 4d TMC complexes. To assess the additive nature of ligand contributions, we chose a subset of the data consisting of homoleptic complexes of a weak-field ligand (H₂O), the homoleptic complexes of a strong-field ligand (CO), and the heteroleptic complexes with both ligands present. In addition to their differing field strengths, H₂O and CO were chosen for their neutral charge, eliminating the need to compare TMCs of differing net charge. For a fixed metal, oxidation state, and principal quantum number, the full set can contain up to six mixed H₂O/CO complexes between the homoleptic hexa-aqua and hexa-carbonyl limits. This includes two cases where a single ligand of the minority type is in the complex (i.e., 5 + 1: (CO)₅(H₂O) or (H₂O)₅(CO)) as well as four cases where two ligands of the alternate type are included in either a cis (i.e., equatorial/axial adjacent) or trans (i.e., axial) conformation (e.g., (CO)₅(H₂O)₂ or (H₂O)₅(CO)₂). Although the exchange sensitivity of homolectic 3d TMCs has been widely studied, the expected exchange sensitivity of heteroleptic TMCs is not well established for either 3d or 4d TMCs.

There is a smooth, nearly monotonic increase in $\Delta E_{H^{-1}}$ with increasing number of strong-field CO ligands for Fe(n) or Ru(n) complexes (Fig. 5). For the Fe(n) TMCs, B3LYP LS states become stabilized over HS states for four or more CO ligands, whereas all Ru(n) complexes are uniformly LS (Fig. 5). The trend of increasing $\Delta E_{H^{-1}}$ with increasing CO number is largely consistent between Ru(n) and Fe(n), but B3LYP $\Delta E_{H^{-1}}$ for Ru(n) is more sensitive to the number of CO ligands (Fig. 5). Interestingly, the only exception to the monotonic trend is the trans (H₂O)₅(CO)₂ isomer, with an $\Delta E_{H^{-1}}$ closer to that for the mono-carbonyl complexes (Fig. 5 and ESI, Tables S10, S11). The cis (H₂O)₅(CO)₂ isomer has been filtered from the dataset, prohibiting broader conclusions about cis/trans isomers (see ESI†). For the Fe(n) TMCs, all mixed H₂O/CO complexes span the LS/HS transition between $\alpha_{HF} = 0.0$ and 0.4 (Fig. 5). While Fe(n) TMC $S$ values are significantly larger than for Ru(n) TMCs, both 3d and 4d complexes appear to have a monotonic increase in sensitivity with the addition of more strong-field ligands (Fig. 5 and ESI, Table S12).

For the series of $d^1$ Mn(n)/Tc(n) TMCs, reduced overall ligand field dependence of both $\Delta E_{H^{-1}}$ and $S$ is observed with
respect to Fe(n)/Ru(u) TMCs (Fig. 5 and ESI† Tables S10, S12). The 3d Mn(n) TMCs are uniformly HS-favored regardless of $a_{HF}$ value (Fig. 5). Both $\Delta E_{H-L}$ and $S$ values appear to reach a maximum for Mn(n) complexes once all four equatorial ligands are CO with no effect of added CO axial ligands (Fig. 5). This likely occurs because of the reduced ligand field sensitivity of Mn(n) and non-monotonic geometric changes for the most CO-saturated Mn(n) complexes (see ESI† data). Overall trends are consistent between Tc(n) and Mn(n), although the 4d TMCs are again marked by reduced $S$ values with respect to the isovalent 3d TMCs (Fig. 5). Given the reduced sensitivities of 4d TMCs, only the homoleptic aqua Tc(n) complex spans the LS-to-HS transition, whereas even the modest $\Delta E_{H-L}$ ($< 15$ kcal mol$^{-1}$) in the mono-carbonyl Tc(n) complex remains LS-favored over all $a_{HF}$ values (Fig. 5). Across an expanded series of TMCs with more metals (i.e., d$^3$ Fe(n)/Ru(n) and Mn(n)/Tc(n)), addition of strong-field carbonyl ligands has a largely monotonic, linearly increasing effect on $S$ values starting from the lower extreme of homoleptic hexa-aqua TMCs and moving toward the upper extreme of hexa-carbonyl TMCs (Fig. 6 and ESI† Table S12). The most significant deviations in $S$ between 3d/4d TMC pairs occurs for the Fe(n)/Ru(n) cases (i.e., up to a 60 kcal mol$^{-1}$ HFX$^*$ difference) but remains substantial for most metals, excluding only the low-$S$ Mn(n)/Tc(n) pairs (Fig. 6). Over this broad set, we confirm the cis $\text{H}_2\text{O}_4\text{(CO)}_2$ complexes have significantly higher sensitivities for both 3d and 4d metals than their trans counterparts, with the exception of Mn(n)/Tc(n) (Fig. 6).

We also analyzed this ligand series for $\Delta E$ and $S(\Delta E)$ trends in the 2-electron HS–IS and IS–LS spin state splitting. For $\Delta E_{H-L}$, increasing the number of CO ligands shifts the B3LYP preference from HS to IS for most 3d metals (i.e., excluding only Mn(n) and Fe(n)), but the 4d TMC preference remains uniformly IS regardless of complex composition (ESI† Tables S13 and S14). Although $S(\Delta E_{H-L})$ is lower than $S(\Delta E_{H-L})$, the 3d TMC spin-state preference can still shift depending upon $a_{HF}$ value (e.g., trans Fe(n)($\text{H}_2\text{O}_4\text{(CO)}_2$) is IS-favoring for $a_{HF} = 0.15$ but HS for B3LYP, ESI† Table S13). The relationships of 3d and 4d TMC $S(\Delta E_{H-L})$ values are similar to that for $S(\Delta E_{H-L})$: (i) the smallest and largest $S$ magnitudes are typically bounded by the homoleptic hexa-aqua and hexa-carbonyl complexes, respectively, and (ii) mixed complexes with more CO ligands have larger sensitivities especially in 3d versus 4d TMCs (ESI† Fig. S1 and Table S15). For $\Delta E_{H-L}$, multiple d$^3$ Cr(n)/Mo(n) and d$^4$ Co(n)/Rh(n) complexes could also be compared in their LS doublet and IS quartet (i.e., $S_{L} + 2$) states (ESI† Tables S16 and S17). Reduced exchange sensitivity for IS–LS pairs mean that few ground state assignments change in either 3d or 4d TMCs with change in functional (ESI† Table S15). Across all metals, the trend of increasing deviation of 3d and 4d $S$ values with increasing ligand field strength is consistent with HS–LS and HS–IS behavior for mixed-ligand complexes, but non-monotonic behavior with CO ligand number is observed and several of the Rh(n) complexes have positive $S(\Delta E_{H-L})$ values (ESI† Fig. S2). The $S$ values are also relatively comparable and modest for early d$^3$ Cr(n)/Mo(n) and d$^4$ Mn(n)/Tc(n) complexes (ESI† Fig. S2).

As a possible explanation for the distinct behavior of IS–LS spin splitting trends among complexes, we considered differences in closed-shell LS states (i.e., for d$^3$ and d$^4$) and open-shell ones (i.e., for d$^5$) but observe no significant difference (ESI† Fig. S2). The greater variability is likely due to noise in evaluating the lower IS–LS $S$ values, in line with prior observations, and the larger range of metals and oxidation states. Despite some differences for IS–LS in comparison to HS–IS or HS–LS spin-splitting energies, the ligand series analysis suggests overall that there are consistently greater differences in the effect of exchange on 3d compared to 4d TMCs that grow with ligand field strength.

d. **Effect of exchange on spin-state ordering**

TMC spin-state splitting sensitivities depend both on row (3d vs. 4d) and electron configuration (e.g., d$^4$ vs. d$^5$) of the metal atom as well as on the strength of the ligand field. The combined effect of these differences can be further understood by evaluating how the distribution of $\Delta E_{H-L}$ shifts with HF exchange fraction. For this comparison, we chose 64 Fe(n)/Ru(n) and 51 Tc(n)/Mn(n) metal/oxidation state pairs where 3d TMCs and 4d TMCs span the HS–LS transition, respectively (Fig. 7). For Fe(n) TMCs, increasing HF exchange from a pure GGA to 30% has a strong effect on the distribution of $\Delta E_{H-L}$ values (Fig. 7). Because complexes with strong-field ligands have more negative sensitivities than complexes with weak-field ligands, the width of the Fe(n) $\Delta E_{H-L}$ distribution decreases monotonically from $a_{HF} = 0.0$ (−75 to 80 kcal mol$^{-1}$) to $a_{HF} = 0.3$ (−90 to 30 kcal mol$^{-1}$, Fig. 7). We note that a complex with $|\Delta E_{H-L}| \leq 5$ kcal mol$^{-1}$ could be a spin crossover (SCO) complex. Using this definition, the number of potential Fe(n) SCOs is maximal for moderate, $a_{HF} = 0.1–0.2$ exchange and decreases again at

![Figure 6](image-url)
Fe(II) TMCs (19%).

but this reduction (12%) is smaller than was observed for the comparison to Fe(II) TMCs (Fig. 7). The range of the Ru(II) complexes have a limited effect on the shape of the distribution in a more even distribution of HS and LS ground states (Fig. 7).

Modest differences in exchange sensitivity across Ru(II) complexes from 12 to 49 of 64 complexes (Fig. 7 and ESI,† Table S18). The Mn(III) ΔE_H–L values span a smaller range than the Fe(II) TMCs, meaning that even though the width of the Mn(III) ΔE_H–L distribution narrows only slightly with increasing HF exchange (a_HF = 0.0: −50 to 5 kcal mol$^{-1}$ vs. a_HF = 0.3: −25 to −70 kcal mol$^{-1}$), this 18% reduction is roughly comparable to that for Fe(II) (Fig. 7). For the Tc(III) ΔE_H–L distribution, there is no change in the width due to sensitivities of outliers in the distribution tails (Fig. 7). Nevertheless, both Tc(III) and Mn(III) distributions become more peaked at intermediate values of the ΔE_H–L range, and the effect of a_HF on the shape of both distributions is more modest than for Fe(II) but more significant than for Ru(II) TMCs (Fig. 7).

Over all 3d/4d metal/oxidation state pairs for which ΔE_H–L was calculated, trends are similar to those observed for Fe(II)/Ru(II) and Tc(III)/Mn(III) (ESI,† Table S18). The HS–LS preference of 3d TMCs is highly sensitive to exchange, with an even number of LS-favoring 3d TMCs at a_HF = 0.0 becoming predominantly (90%) HS at a_HF = 0.3 or higher (ESI,† Table S18). The 4d TMCs almost exclusively favor LS states at a_HF = 0.0, and a much smaller number (i.e., 28) of TMCs, typically with Tc(III) and to a lesser extent Tc(III) or Mo(III), becoming HS-favored at a_HF = 0.3 (ESI,† Table S18). Thus, based on this analysis, the 4d TMC HS preference makes the 4d TMC HS preferences significantly less sensitive to a_HF values.

Ultimately, to quantify the effect of HF exchange on 3d/4d TMC ground state (GS) assignment, we extended the comparison of spin-state energetics to include IS states. There are 155 d$^4$–d$^8$ 3d/4d TMC pairs for which all three (i.e., HS, IS, and LS) spin states and the spin-splitting energy sensitivities are computed. We combine these pairs with the 92 d$^1$–d$^7$ 3d/4d TMC pairs for which only two states were accessible (i.e., IS and LS), and their energies are computed. Over this 247-complex set, significant differences in the sensitivity of GS assignment to a_HF are apparent between 3d and 4d TMCs (Fig. 8). Namely, the number of HS ground states rises from around one in five at a_HF = 0.0 to over half at a_HF = 0.3 for 3d TMCs, whereas none of the 4d TMCs have a HS GS at any a_HF value (Fig. 8 and ESI,† Tables S19, S20). The proportion of IS states remains roughly constant for 3d TMCs over this range, although their identities shift with added exchange to predominantly d$^6$/d$^7$ TMCs (i.e., excluding only two Mn(III) and one Cr(II) complex, ESI,† Table S19). The 4d TMCs differ from 3d TMCs because most have either an IS (ca. 35%) or LS (ca. 65%) GS, with almost no change in this distribution with a_HF value (Fig. 8 and ESI,† Table S19). While all 3d metal/oxidation states have at least one GS change from a_HF = 0.0 to 0.3, only a small number (i.e., 5 of 45) of d$^6$ Mo(III) 4d TMCs change from LS to IS over this range (Fig. 8 and ESI,† Table S19). This change in GS is somewhat larger than

higher exchange values (Fig. 7). From a_HF = 0.0 to 0.3, the population of HS-favored Fe(II) TMCs also increases dramatically from 12 to 49 of 64 complexes (Fig. 7 and ESI,† Table S18).

The isovalent Ru(II) TMCs span nearly as wide a range for a_HF = 0.0 (30 to 150 kcal mol$^{-1}$) as the 3d TMCs, but none are HS at any exchange fraction (Fig. 7 and ESI,† Table S18). Modest differences in exchange sensitivity across Ru(II) complexes have a limited effect on the shape of the distribution in comparison to Fe(II) TMCs (Fig. 7). The range of the Ru(II) ΔE_H–L distribution for a_HF = 0.3 (20 to 125 kcal mol$^{-1}$) is reduced, but this reduction (12%) is smaller than was observed for the Fe(II) TMCs (19%).

For the Tc(III)/Mn(III) isovalent pairs, the 4d TMCs have a more even distribution of HS and LS ground states (Fig. 7).
for the Cr(III) TMCs, which are all IS for $a_{\text{HF}} = 0.2$ or above (Fig. 8 and ESI,† Table S19). The d$^5$ Mo(n) and Tc(n) TMCs favor IS ground states exclusively, whereas most of the 3d isovalent Cr(n) or Mn(n) TMCs are HS-favoring especially with increasing $a_{\text{HF}}$ values (ESI,† Table S19). Thus, overall 4d TMC GS assignment is significantly less likely to be affected by a change in functional than an equivalent 3d TMC although the sensitivity of predicted energies to exchange fraction is only on average reduced by around one third from the first- to second-row TMCs.

e. Relationships between energetic sensitivity and structure

In 3d TMCs, increasing spin multiplicity typically leads to longer metal–ligand bond lengths as antibonding states become preferentially occupied over states with bonding character, and this effect is more significant with increasing ligand field. Bond lengths do not change significantly with $a_{\text{HF}}$ value,138 and thus structural differences between spin states are also invariant. To determine if structural differences between 3d and 4d TMC pairs could explain distinct exchange sensitivities due to the different sizes of 3d and 4d metals (ESI,† Fig. S3 and Table S21).

As in previous work,138 we facilitate comparison by focusing on relative metal–ligand bond lengths, $d_{\text{rel}}$:

$$d_{\text{rel}}(M–L) = \frac{d(M–L)}{r_M + r_L}$$

obtained by computing the ratio of the bond length, $d$, obtained from B3LYP with respect to the substituent metal (M) or ligand (L) atoms’ covalent radii, $r$ (ESI,† Table S21). The $d_{\text{rel}}$ values averaged over all six metal–ligand bonds have a similar range of values for both 3d and 4d TMCs; this averaging works better for the more symmetric LS states than HS or IS states (ESI,† Fig. S4–S6 and Tables S22, S23). For all TMCs, the $d_{\text{rel}}$ values increase on average by 0.1 from LS to HS states and increase by about half (ca. 0.05) that amount from LS to IS states (ESI,† Fig. S4 and Tables S22, S23).

For 3d TMCs, the $d_{\text{rel}}$ difference, $\Delta d_{\text{rel}}$, between HS and LS states is well correlated ($R^2 = 0.86$) with $S(\Delta E_{\text{HF}–\text{L}})$ values (Fig. 9 and ESI,† Table S24). The Fe(n)(CO)$_6$ $\Delta d_{\text{rel}}$ is among the largest, consistent with the large magnitude (ca. –175 kcal mol$^{-1}$ HFX$^{-1}$) of its $S(\Delta E_{\text{HF}–\text{L}})$, while Mn(n)(H$_2$O)$_6$ has both a much lower $S(\Delta E_{\text{HF}–\text{L}})$ (ca. –50 kcal mol$^{-1}$ HFX$^{-1}$) and $\Delta d_{\text{rel}}$ of 0.04 (Fig. 9). In line with these observations, the overall largest HS–LS $\Delta d_{\text{rel}}$ values are observed for the cases with the most positive $S(\Delta E_{\text{HF}–\text{L}})$ values (ESI,† Fig. S7). As with HS–LS, a similar relationship can be observed for $S(\Delta E)$ and $\Delta d_{\text{rel}}$ for the 3d TMC HS–IS or LS–IS splittings (ESI,† Fig. S8 and Table S24). In fact a single good correlation ($R^2 = 0.81$) can be fit through all three sets of $\Delta E$ and $\Delta d_{\text{rel}}$ values for 3d TMCs (Fig. 9 and ESI,† Fig. S8 and Table S24). Taken together with our prior findings,29 these observations suggest that increasing $a_{\text{HF}}$ penalizes the delocalized, highly bonded lower-spin states more strongly than higher-spin states. When this bonding difference is larger, the sensitivity to $a_{\text{HF}}$ is also higher.

For the second-row transition metals, there is also a good correlation ($R^2 = 0.71$) between $S(\Delta E)$ and $\Delta d_{\text{rel}}$ for the HS–LS states of the 4d TMCs (Fig. 9 and ESI,† Fig. S9, Table S24).
The slope of the relationship however is reduced with respect to the value for 3d TMCs (Fig. 9 and ESI,† Table S24). Indeed, Δd_{rel} values across all spin-state pairs in 4d TMCs are as large as those for the 3d TMCs. Thus, more diffuse 4d orbitals do not change Δd_{rel} value trends and cannot be used to explain the reduced exchange sensitivity of 4d TMCs (ESI,† Fig. S4). A weaker, but somewhat unified, relationship can be observed between the LS state d_{rel}, which is generally longer in some but not all 4d TMCs, and S(ΔE_{HS-LS}) across both 3d and 4d TMCs (Fig. 9 and ESI,† Table S24, Fig. S4).

To understand the origins of this relationship, we obtained potential energy curves (PECs) with varied metal–ligand bond length and varied a_{HF} values for 3d Fe(II) and 4d Ru(II) TMCs in their quintet HS and singlet LS states. We contrasted homoleptic helium-atom 3d/4d complexes as a simplified example of the weak-field limit with strong-field, hexa-carbonyl 3d/4d TMCs, in which we rigidly displaced the CO ligands (see Section 2). The closed-shell He atoms act as very weak field ligands, with the 3d/4d TMCs both strongly favoring the HS state over the LS state (B3LYP ΔE_{HS-LS} for Fe(II) ca. −64 kcal mol⁻¹ and Ru(II) ca. −31 kcal mol⁻¹, Fig. 10 and see ESI,† Table S25). The S(ΔE_{HS-LS}) values are both small and comparable (Fe(II): −47 vs. Ru(II): −43 kcal mol⁻¹ HFX⁻¹), consistent with small S(ΔE_{HS-LS}) values (hexa-aqua Fe(II): −53 vs. Ru(II): −38 kcal mol⁻¹ HFX⁻¹) from other weak-field TMCs (ESI,† Tables S12 and S25).

Despite these comparable exchange sensitivities, the dependence on a_{HF} of individual PECs of Ru(II) and Fe(II) TMCs is distinct (Fig. 10). Both HS and LS Ru(II)(He)₆ PECs are stabilized with increasing a_{HF}, but the HS relative energy is more sensitive to exchange (Fig. 10). For Fe(n)(He)_₆, on the other hand, the HS PEC is stabilized with increasing a_{HF} while the LS is destabilized (Fig. 10). For individual LS or HS states, Ru(II) TMCs PECs have higher sensitivities than the Fe(II) counterparts (Fig. 10 and ESI,† Table S25). The negative S(ΔE_{HS-LS}) for Fe(n)(He)_₆ arises from additive sensitivities of the HS and LS states, while for Ru(n)(He)_₆ the simultaneous LS and HS stabilization leads to a comparable net S(ΔE_{HS-LS}) (Fig. 10 and ESI,† Table S25).

The He complexes are weakly bound, with the small covalent radius of the He atom leading to a very long estimated d_{rel} values in LS states for both 3d and 4d TMCs (Fe(II): d_{rel} = 1.08 vs. Ru(II): d_{rel} = 1.11) despite moderate absolute bond lengths of 1.84 and 1.93 Å, respectively (Fig. 10 and ESI,† Tables S21, S25). The HS states are even more weakly bound, with large Δd_{rel} values of 0.16 for Fe(n) and 0.24 for Ru(n), and these observations are insensitive to a_{HF} (Fig. 10 and ESI,† Table S25). Since we can obtain the exchange sensitivity over a wide range of M–He bond lengths in these TMCs, we also evaluated the extent to which S values vary at points away from equilibrium (Fig. 10). The vertical HS–LS sensitivity evaluated at the LS geometry for Ru(n) or Fe(n) is comparable to that for the adiabatic case, despite the fact that the LS–HS ordering is inverted at the LS case (Fig. 11 and ESI,† Table S25). When stretched to the HS geometry, the S values decrease significantly for both Ru(n) and Fe(n) (Fig. 10 and ESI,† Table S25).

While the ground state preferences for model strong-field complexes of both Fe(n) and Ru(n) are uniformly LS (B3LYP ΔE_{HS-LS} for Fe(n) ca. 30 kcal mol⁻¹ and Ru(n) ca. 116 kcal mol⁻¹), the exchange sensitivity trends are comparable to the weak-field He case (Fig. 11 and ESI,† Table S26). That is, larger total energy sensitivity in the HS Ru(n) PEC still leads to a lower overall S(ΔE_{HS-LS}) magnitude compared to Fe(n) because exchange destabilizes the LS 3d TMC while weakly stabilizing the LS 4d TMC (Fig. 11 and ESI,† Table S26). The only significant distinction observed for the strong-field CO ligands is that S for each PEC and the splitting is much more dependent on bond length, with the effect of significantly reducing (> 50%) S values for vertical spin-state energetics with respect to adiabatic S(ΔE_{HS-LS}) values (Fig. 11 and ESI,† Table S26).

From the set of all 3d/4d TMC pairs, over 25 3d TMCs have positive sensitivities of the LS total energies whereas only one of the 4d TMCs does (ESI,† Table S27). While average sensitivities of the total energy with respect to a_{HF} are higher for both states in 4d TMCs, they are more likely to be similar in magnitude between LS and HS states. Thus, distinct geometric and electronic structure of the LS states of 3d TMCs likely contributes to their higher exchange sensitivity (ESI,† Table S27).

4. Conclusions

We have carried out a comprehensive study of the extent to which established trends in 3d TMC exchange sensitivity and spin-state ordering have analogies in equivalent, isovalent 4d TMCs. From ten ligands covering a wide range of ligand field

---

**Fig. 10** Potential energy curves (PECs, in kcal mol⁻¹) with M–He distance (in Å) for Fe(n)(He)_₆ (left) and Ru(n)(He)_₆ (right) in LS singlet (red) and HS quintet (blue) spin states. Solid center lines (red for LS and blue for LS, as indicated in inset legend) correspond to the B3LYP ΔE_{rel} = 0.2 PEC, the outer solid line (maroon for LS and dark blue for HS) corresponds to a_{HF} = 0.0, and the outer dashed line corresponds to a_{HF} = 0.4 (as indicated also in inset legend). The inner shaded regions correspond to the a_{HF} = 0.1–0.3 range, and the outer shaded region to a_{HF} = 0.0–0.4. The relative energies have been aligned to set the minimum of the B3LYP PEC to zero, and a zero line is shown. A circle indicates the minimum of the PECs for a_{HF} = 0.0, 0.2, and 0.4.
sensitivity of 
sensitivities. We observed consistently increasing exchange 
2-electron (\(22\)) for all metals and oxidation states considered, and this devia-
tion between 3d and 4d TMCs increased with increasing ligand 
field strength.

(3) Despite 4d TMC energetics being less sensitive than their 
3d TMC counterparts, variations by as much as 10 kcal mol\(^{-1}\) 
per 10% change in HF exchange were still observed, which 
could have a significant effect on energetic predictions.

(4) Combined with the significant LS-shifting of 4d TMCs 
with respect to their equivalent 3d TMCs, the reduced 4d TMC 
exchange sensitivity led to a much lower likelihood of change in 
spin-state ordering than for their 3d TMC counterparts. While 
over the range of \(a_{\text{HF}}\) = 0.0 to 0.3 many 3d TMCs changed 
ground states from LS to IS or HS states, a very small number of 
4d TMCs shifted from LS to IS and none were HS.

(5) Delocalization does not explain the reduced exchange 
sensitivity of 4d TMCs. The 3d and 4d bond length differences 

between spin states were comparably large but could not 
explain the reduced sensitivity of 4d TMCs.

(6) Analysis of PECs of representative complexes indicated 
the higher spin-splitting exchange sensitivities of 3d TMCs is 
likely due to the opposing effects of exchange on the two spin 
states, despite higher exchange-sensitivity of the total energy in 
4d TMCs.

Overall, we find that while spin-state energetics of 4d TMCs 
are roughly two-thirds as sensitive as those of 3d TMCs, this 
study suggests it is unlikely for HF exchange tuning to alter 
ground state predictions for 4d TMCs. This does not guarantee 
that common DFT functionals are always capable of predicting 
the ground state spin but does suggest that conventional 
tuning approaches that work in 3d TMCs to reproduce experi-
mental spin state ordering will not be applicable in 4d TMCs.
