The reactivity of molecular oxygen and reactive oxygen species with [FeFe] hydrogenase biomimetics: reversibility and the role of the second coordination sphere†

Vincent C.-C. Wang,^a Charlène Esmieu,^b Holly J. Redman,^b Gustav Berggren^b and Leif Hammarström^a

The development of oxygen-tolerant H₂-evolving catalysts plays a vital role for a future H₂ economy. For example, the [FeFe] hydrogenase enzymes are excellent catalyst for H₂ evolution but rapidly become inactivated in the presence of O₂. The mechanistic details of the enzyme's inactivation by molecular oxygen still remain unclear. Here, two H₂-evolving diiron complexes [Fe₂(μ-SCH₂NHCH₂S)(CO)₆] (**1^{adt}**) and [Fe₂(μ-SCH₂CH₂CH₂S)(CO)₆] (**2^{pdt}**), inspired by the active site of [FeFe] hydrogenase, were investigated for their reactivity with molecular oxygen and reactive oxygen species. A one-electron reduced and oxygenated **1^{adt}** species was identified and characterized spectroscopically, which can be directly generated by reacting with molecular oxygen and chemical reductants at room temperature but it is unstable and gradually decomposes. Interestingly, the whole process is reversible and the addition of protons can facilitate the deoxygenation process and prevent further degradation at room temperature. This new identification of intermediate species serves as a model for studying the reversible inactivation and degradation of oxygen-sensitive [FeFe] hydrogenases by O₂, and provides chemical precedence for such processes. In comparison, the complex lacking the nitrogen bridgehead, **2^{pdt}**, exhibits reduced reactivity towards O₂ in the presence of reductants, highlighting that the importance of the second coordination sphere on modulating the oxygenation processes. These results provide new directions to design molecular electrocatalysts for proton reduction operated at ambient conditions and the re-engineering of [FeFe] hydrogenases for improving oxygen tolerance.

Introduction

In the past decade, the development of noble-metal-free complexes for H₂ evolution has been a very active research field. A variety of metal complexes inspired by hydrogenases, both functional¹ or structural² mimics, has been prepared to generate synthetic catalysts for H⁺/H₂ interconversion and to understand key feature for catalysis. However, most of these molecular complexes are oxygen-sensitive under catalytic turnover conditions. For example, Ni-bis(diphosphine) complexes developed by the Dubois group^{3,4} and diiron complexes based on the active site of [FeFe] hydrogenases,^{5,6} have been shown to

be incompatible with air-operated conditions. Therefore, it is important to understand the damage processes by molecular oxygen during H₂ evolution, in order to provide new ideas for re-engineering of catalysts to achieve improved oxygen-tolerance. To gain further insight into this chemistry, we have probed two biomimetic molecular electrocatalysts, Fe₂(adt)(CO)₆ (adt = azadithiolate), **1^{adt}** and Fe₂(pdt)(CO)₆ (pdt = propanedithiolate), **2^{pdt}** (Fig. 1),^{5–9} and investigated their reactivity with molecular oxygen. Both complexes are structurally similar to the diiron subsite of the catalytic cofactor of oxygen-sensitive [FeFe] hydrogenases (the “H-cluster” as shown in Fig. 1).^{10–13} However, they differ in the nature of the bridgehead atom in the dithiolato ligand, and thus provide insight into the influence of proton relays for the reactivity of the low valence metal center towards O₂.

The reactivity of analogues of **1^{adt}** and **2^{pdt}** towards O₂ under electrocatalytic conditions has previously been reported.^{5,6} However, under such conditions, it is challenging to characterize the true species that attack molecular catalysts and the corresponding engaged state from catalysts. For

example, a variety of reactive oxygen species (ROS) can be generated directly from the electrode as suggested in eqn (1)–(3) before proton reduction reaction takes place (eqn (4) and Fig. S1†).

Herein, we report on spectroscopic investigations of the reactivity of these two complexes towards molecular oxygen. More specifically, the distinct vibrational absorption bands for carbonyl groups (ν_{CO}) from **1^{adt}** and **2^{pdt}** allow to monitor changes in the electronic and geometric structure of the diiron center by IR spectroscopy. Chemical reductants were employed to address the influence of the redox states on the reaction. This alternative approach enabled the generation of one-electron reduced and oxygenated **1^{adt}** and **2^{pdt}** by adding O₂ in combination with reductants that have a more positive reduction potential than those of the respective diiron complexes (Fe^IFe^I/Fe^IFe⁰). The whole process for **1^{adt}** is reversible, although the reduced and oxygenated species is unstable at room temperature. The addition of protons prevents further damage and facilitates the deoxygenation process to regenerate the starting material. The chemical process may be biologically relevant to the reactivity of [FeFe] hydrogenase towards molecular oxygen and represent a general oxygenation and reactivation scheme for this class of complexes.

Results and discussion

Reactivity of **1^{adt}** and **2^{pdt}** towards O₂ under reducing conditions

The reactivity of **1^{adt}** and **2^{pdt}** with molecular oxygen was probed in the absence and presence of chemical reductants,

i.e. bis(benzene)chromium (Cr(bz)₂), cobaltocene (CoCp₂) and bis(pentamethylcyclopentadienyl)cobalt (CoCp₂^{*}). The reduction potential for these reductants are respectively $E = -1.15 \text{ V}$ (all potentials reported herein are against Fc/Fc⁺), $E = -1.33 \text{ V}$ and $E = -1.94 \text{ V}$, compared to the reduction potential of -1.6 V for **1^{adt}** and **2^{pdt}** (Fig. S1 and Table S1†). Recently, some reductants, such as CoCp₂ and CoCp₂^{*} have been applied to study H₂-evolving mechanism with related diiron complexes *via* transient spectroscopy.^{14,15} As expected in light of their respective reduction potentials, **1^{adt}** and **2^{pdt}** did not react with CoCp₂, Cr(bz)₂ or molecular oxygen in isolation. Upon addition of the chemical reductants or purging with O₂, the IR spectra featured ν_{CO} bands of **1^{adt}** and **2^{pdt}** at 2074, 2033, 2000 and 1989 cm⁻¹, which are indiscernible from the starting material (Fig. 2). In comparison, multiple new ν_{CO} bands from the two

Fig. 2 Infrared spectra obtained from a mixture of **1^{adt}** (a) (or **2^{pdt}** (b)) and cobaltocene upon exposure to the excess of O₂. The complex **1^{adt}** (0.5 mM) or **2^{pdt}** (0.5 mM) was mixed with different equivalents of CoCp₂ first and then molecular oxygen was added to a mixture solution. The intensity of red line is stronger than that of black line because solvent (dichloromethane, DCM) was purged away by O₂ during the reaction.

Fe complexes were observed at lower wavenumbers, between 1970 cm^{-1} and 1850 cm^{-1} (Fig. S2†), when mixing with the stronger reducing agent, CoCp_2^* . These features indicate the dimerization of one-electron reduced 1^{adt} or 2^{pdt} species as reported from earlier studies.¹⁶

Unexpectedly, we noticed that two new peaks at 1957 and 1946 cm^{-1} appeared when a mixture of CoCp_2 and 1^{adt} was exposed to air under ambient conditions. When mixing more than two equivalents of CoCp_2 (or $\text{Cr}(\text{bz})_2$) and 1^{adt} with excess O_2 , the four bands attributed to 1^{adt} almost disappeared and four new distinct bands for ν_{CO} were observed at lower wavenumbers, 2038 , 1997 , 1957 and 1946 cm^{-1} as shown in Fig. 2a and 3. This new spectrum is distinctly different from one-electron reduced species of 1^{adt} reported before (Table S2†). Still, the red-shift of the four bands by *ca.* $35\text{--}45\text{ cm}^{-1}$ relative to the starting material 1^{adt} suggests that the newly formed species is reduced. In control experiments, no new peaks were observed when adding oxygen-free DI water (Fig. S3†) to a mixture of CoCp_2 and 1^{adt} (or 2^{pdt}), which exclude the formation of a protonated and reduced species. In comparison, a mixture of 2^{pdt} and CoCp_2 exhibited less reactivity toward O_2 . Still, new bands for ν_{CO} were observed at 2020 , 1960 and 1891 cm^{-1} and a broad shoulder peak spanned between 1950 and 1910 cm^{-1} (Fig. 2b). The multiple number of new and broad peaks from 2^{pdt} suggest at least two different species coexist after reacting a mixture of CoCp_2 and 2^{pdt} with O_2 and likely dimerization occurred comparing to IR spectra from mixing CoCp_2^* and 2^{pdt} . In both cases, black precipitates were observed after introducing O_2 into a mixture of reductants and 1^{adt} or 2^{pdt} . These precipitates were also observed when adding O_2 to a solution containing only CoCp_2 , and were thus not analyzed in detail. The newly formed IR bands from these new species gradually decayed in *ca.* 20 minutes under anaerobic conditions, indicating that they were unstable at room temperature. Critically, the ν_{CO} bands for as-prepared 1^{adt} were partially recovered again, while full degradation occurred for the new species generated from 2^{pdt} (*vide infra* and Fig. S18†). Thus, distinct differences were observed between 2^{pdt} and the more biologically relevant 1^{adt} . The latter revealed not only a more defined product in the reaction with O_2 , with only four distinct new ν_{CO} peaks, but also showed a high degree of reversibility, as compared to mixed products and irreversibility observed for 2^{pdt} .

Spectroscopic characterization of transient species

The minute-scale lifetime of the transient species at room temperature allowed for a more detailed spectroscopic characterization to explore its geometric and electronic structure. The resulting product directly obtained by reacting a mixture of 1^{adt} and $\text{Co}(\text{Cp})_2$ (or $\text{Cr}(\text{bz})_2$) with O_2 showed a mass peak at m/z 401.76 amu, detected by electron-spray mass spectroscopy, assigned to $[\text{O} + 1^{\text{adt}} - \text{H}]$, indicated that an oxygenated species, $\text{O-}1^{\text{adt-}}$ was formed (Fig. S4 and S5†). Indeed, a shift of two amu units for $\text{O-}1^{\text{adt-}}$ was observed when $^{18}\text{O}_2$ was introduced to a mixture of CoCp_2 and 1^{adt} (Fig. S6†). Similarly, a mass peak for $[\text{O} + 2^{\text{pdt-}}$] at 402.6 amu was also observed (Fig. S7†). Earlier work conducted by Darensbourg and co-

workers has demonstrated that *meta*-chloroperoxybenzoic acid (mCPBA) can oxygenate 2^{pdt} to generate a mono-oxygenated 2^{pdt} ($\text{O-}2^{\text{pdt}}$), through an oxygen atom transfer reaction to a thiol ligand of 2^{pdt} .¹⁷ Consequently, we explored the possibility of the oxygen atom binding to a S atom of 1^{adt} as well. Indeed, an IR band assigned to $\nu_{\text{S=O}}$ from $\text{O-}1^{\text{adt-}}$ was observed at 1030 cm^{-1} and the peak displayed the expected isotope shift to 993 cm^{-1} when $^{18}\text{O}_2$ was used in the oxygenation reaction (Fig. 4). The IR bands assigned to $\nu_{\text{S=O}}$ are in excellent agreement with the DFT-simulated IR spectrum (1028 cm^{-1} for ^{16}O and 996 cm^{-1} for ^{18}O) for a one-electron reduced and oxygenated species featuring an oxygenated thiol group (S=O) (Fig. 4c). Noticeably, these two peaks disappeared in *ca.* 25 minutes, which is in line with the disappearance of the 1946 cm^{-1} (ν_{CO}) peak assigned to $\text{O-}1^{\text{adt-}}$ (Fig. S17†).

To characterize the electronic structure of $\text{O-}1^{\text{adt-}}$, electron paramagnetic resonance (EPR) spectroscopy was employed. A new EPR signal for $\text{O-}1^{\text{adt-}}$ was observed at $g \sim 2.14$ and 2.02 compared to EPR-silent 1^{adt} , confirming that $\text{O-}1^{\text{adt-}}$ is a one-electron reduced species. Spin quantification of the double integral spectrum using Cu-EDTA as a standard, suggested that 50% of the initial 1^{adt} complex converted to this one-electron reduced species (Fig. S8†). In the case of 2^{pdt} , the yield of the oxygenated reduced species was limited to *ca.* 30%. The formation of $\text{O-}1^{\text{adt-}}$ also results in the appearance of a new absorption peak at 605 nm in the UV-visible spectrum (Fig. S9a†). In contrast, $1^{\text{adt-}}$ shows absorption bands around 560 and 700 nm .^{14,15} As this new signal at 605 nm disappears with a half-life time ($t_{1/2}$) of ~ 3.6 minutes, which coincides with the concomitant decreasing intensity of IR peaks at 1957 and 1946 cm^{-1} ($t_{1/2}$ avg 5.4 min , Fig. S9†), we attribute the absorption band at 605 nm to $\text{O-}1^{\text{adt-}}$.

The instability of $\text{O-}1^{\text{adt-}}$ has so far precluded its characterization by X-ray crystallography. Nevertheless, the mass spectrometry, EPR, UV-visible and FTIR data, in combination with

Fig. 3 The formation of a new species, $\text{O-}1^{\text{adt-}}$ by mixing 1^{adt} , O_2 and reductants, CoCp_2 or $\text{Cr}(\text{bz})_2$. The complex 1^{adt} (0.36 mM) was first mixed with 4 eq. of CoCp_2 or 2 eq. of $\text{Cr}(\text{bz})_2$ and then 4 eq. of O_2 from O_2 -saturated DCM solution was added.

Fig. 4 (a) The IR spectra of $\nu_{\text{S=O}}$ from isotope $^{18}\text{O}_2$ vs. $^{16}\text{O}_2$ experiments. A mixture of 1^{adt} (4.44 mM) and 5 eq. of CoCp_2 reacted with $^{18}\text{O}_2$ and $^{16}\text{O}_2$ respectively. The IR spectra were collected at 1 min (magenta and red traces) and 25 min (grey and black traces) after addition of O_2 , respectively. (b) Zoom of the IR peak region for $\nu_{\text{S=O}}$. (c) Comparison of the $\nu_{\text{S=O}}$ peak from experiments with that from DFT calculations based on the structure shown in the figure.

the DFT calculations allow us to converge on a structural model for $\text{O-1}^{\text{adt-}}$. First, the μ -oxo diiron ($\text{Fe}^{\text{II}}\text{Fe}^{\text{II}}$), end-on peroxide diiron ($\text{Fe}^{\text{II}}\text{Fe}^{\text{II}}$) and bis(μ -oxo) diiron ($\text{Fe}^{\text{III}}\text{Fe}^{\text{III}}$) species can be ruled out due to the observed red shift of the IR spectrum. Moreover, the observed EPR signal underscores that the formed product, $\text{O-1}^{\text{adt-}}$, is paramagnetic. Three low valent ($\text{Fe}^{\text{I}}\text{Fe}^{\text{0}}$) and oxygenated species were further examined: ligand-based oxygenation at the bridgehead N atom or the thiolate S atom, or metal-based oxygenation producing a μ -oxo diiron state. For the first postulated structure, geometry optimization by DFT calculation methods could not be made to converge. For the low valent μ -oxo diiron state, the simulated IR spectrum based on DFT calculations revealed five ν_{CO} bands, in contrast with experimental results (Fig. S20[†]). In addition, no peaks between 1200 and 800 cm^{-1} were observed from the simulated IR spectrum of the μ -oxo diiron ($\text{Fe}^{\text{I}}\text{Fe}^{\text{0}}$) state. Finally, the electron-rich μ -oxo diiron ($\text{Fe}^{\text{I}}\text{Fe}^{\text{0}}$) center would be expected to be highly reactive at room temperature. Therefore, we assign $\text{O-1}^{\text{adt-}}$ to a $\text{Fe}^{\text{I}}\text{Fe}^{\text{0}}$ species with a retained $\text{Fe}_2(\text{CO})_6$ core and an oxygenated ligand derived S-atom (Scheme 1). Indeed, the IR-spectrum for this species is in good agreement with the vibrational spectrum obtained from DFT calculations (Fig. 4 and Fig. S19–20[†]), and all aforementioned spectrometry and spectroscopic analysis.

Scheme 1 Summary of the mechanism for oxygenation/deoxygenation processes and the catalytic cycle for H_2 evolution catalyzed by 1^{adt} . The red character, E is the reduction potential.

Reactivity towards O-atom transfer reagents

As described above, the reaction of mCPBA with 2^{Pdt} generates O-2^{Pdt} via an oxygen atom transfer reaction, which allowed us to explore whether the formation of $\text{O-1}^{\text{adt-}}$ or $\text{O-2}^{\text{Pdt-}}$ could be achieved via such oxygenated intermediates. The formation of O-2^{Pdt} proceeded smoothly upon mixing 2^{Pdt} with 2 eq. of mCPBA (Fig. S12[†]).¹⁷ In contrast, no new peaks in the CO region were observed when treating 1^{adt} with 2 eq. of mCPBA, and larger excess of mCPBA led to diminishing ν_{CO} peaks from 1^{adt} , with concomitant appearance of only two weak peaks at 2082 and 2040 cm^{-1} (Fig. S12[†]). The new peaks remained after 1-hour incubation for both reactions. In addition, no apparent change in ν_{CO} peaks was observed when adding CoCp_2 into a mixture of 2^{Pdt} (or 1^{adt}) and mCPBA. This is attributable to the lower reduction potential for O-2^{Pdt} , -1.58 V.¹⁷ Thus, the preparation of O-1^{adt} or O-2^{Pdt} by mCPBA do not appear to be intermediate species during the formation of the reduced oxygenated species ($\text{O-1}^{\text{adt-}}$, $\text{O-2}^{\text{Pdt-}}$) reported here.

The role of ROS

We further examined whether these oxygenated adducts can be prepared through ROS generated from reacting CoCp_2 with O_2 . In addition, the reactivity of ROS with these reduced and oxygenated adducts was studied as well. The reaction of $\text{O}_2^{\cdot-}$ with 1^{adt} and 2^{Pdt} respectively, resulted in the appearance of a broad shoulder band between 1980 cm^{-1} and 1900 cm^{-1} in both cases (Fig. S13[†]). The newly formed peaks remained for

20 hours, in contrast to the reversible formation of $\text{O-1}^{\text{adt-}}$. Thus, superoxide is highly unlikely to be involved in the formation of $\text{O-1}^{\text{adt-}}$. Furthermore, no new peaks were observed when mixing H_2O_2 with 1^{adt} and 2^{pdt} respectively, which is similar with the earlier report.⁶ However, the ν_{CO} peaks for $\text{O-2}^{\text{pdt-}}$ diminished after mixing H_2O_2 with $\text{O-2}^{\text{pdt-}}$, while no apparent decrease in ν_{CO} absorption was observed for $\text{O-1}^{\text{adt-}}$ after mixing with H_2O_2 (Fig. S14†). Critically, the formation of $\text{O-1}^{\text{adt-}}$ was also observed using the reducing agent, $\text{Cr}(\text{bz})_2$ which has a more positive reduction potential (~ 0.12 V, Table S1†) than the $\text{O}_2/\text{O}_2^{\cdot-}$ couple (Fig. 3). In combination, these results suggest that ROS is highly unlikely to be involved in the formation of neither $\text{O-1}^{\text{adt-}}$ nor $\text{O-2}^{\text{pdt-}}$.

Reactivity of $\text{O-1}^{\text{adt-}}$

Incubation of $\text{O-1}^{\text{adt-}}$ under a glovebox atmosphere for 20 hours at room temperature, resulted in recovery of approximately 30% of 1^{adt} (Fig. 5). Multiple new high-wavenumber bands were observed during the deoxygenation process from $\text{O-1}^{\text{adt-}}$ to 1^{adt} , indicating the formation of intermediate species during the reaction (Fig. S9†). Additionally, the distinct IR peaks for H_2O accumulated during deoxygenation (Fig. S10†). The $\text{O-1}^{\text{adt-}}$ species could subsequently be regenerated by addition of fresh cobaltocene and O_2 as shown in Fig. 5. In comparison, much lower amount of reformed 1^{adt} ($< 5\%$) was observed when $\text{O-1}^{\text{adt-}}$ samples were placed at ambient conditions, while samples were stable for 20 hours inside the glovebox at -30 °C (Fig. S11†).

The role of protons

The reactivity of $\text{O-1}^{\text{adt-}}$ and $\text{O-2}^{\text{pdt-}}$ towards protons was further probed with two acids, chloroacetic acid ($\text{p}K_{\text{a}} = 18.8$ in

Fig. 6 The reactivity of acids with $\text{O-1}^{\text{adt-}}$. A solution with four equivalents of CoCp_2 and an equivalent of 1^{adt} was mixed with four equivalents of O_2 (red line). Then two equivalents of acid against the starting concentration of 1^{adt} (0.36 mM), chloroacetic acid (magenta color) and trichloroacetic acid (olive color), were added later respectively. The samples were stored in the glovebox at room temperature.

acetonitrile) and trichloroacetic acid ($\text{p}K_{\text{a}} = 10.7$ in acetonitrile),¹⁸ both of which have been used as proton source in electrocatalytic H_2 evolution studies with the two complexes.^{2,7,9} It has been suggested that the bridgehead N atom of 1^{adt} can be protonated by trichloroacetic acid but not chloroacetic acid.⁹ The reformed 1^{adt} species was observed rapidly upon the addition of either of the acids with $\text{O-1}^{\text{adt-}}$, as shown in Fig. 6. Compared to reformation of 1^{adt} in the absence of acids, the deoxygenation process is faster and the yield is higher in the presence of acids (*ca.* 60% recovery *vs.* 30% in the absence of acids). Similarly, the conversion from $\text{O-2}^{\text{pdt-}}$ to 2^{pdt} was also accelerated under acidic conditions (Fig. S15†). Thus, in both cases, the addition of protons facilitates the deoxygenation process and prevents further damage at room temperature. As opposed to the clear effect of acid, no apparent increase in the amount of regenerated 1^{adt} was observed by adding excess of reduced CoCp_2 to facilitate the deoxygenation process (*i.e.* electron source) (Fig. S16†).

Discussion

Herein, the one-electron reduced and oxygenated species, $\text{O-1}^{\text{adt-}}$ and $\text{O-2}^{\text{pdt-}}$, were prepared and investigated. Recent studies by Dey, Darensbourg and co-workers have shown that similar analogues of 1^{adt} and 2^{pdt} attached on the electrode surface are capable of catalyzing the O_2 reduction reaction (ORR) in aqueous solution, albeit with gradual degradation during electrochemical catalysis.^{5,6} Noticeably, the onset current for O_2 reduction was observed more positive (~ 0.1 V) than the first reduction potential of the studied 1^{adt} analogues, which suggests that electron transfer can occur at the more

Fig. 5 The stability and reversibility of $\text{O-1}^{\text{adt-}}$ at room temperature. Samples were prepared and stored in the glovebox at room temperature and covered with tin foil to prevent photodissociation. Red line: mix 4 eq. of CoCp_2 and 1 eq. of 1^{adt} (0.36 mM) with 4 eq. of O_2 . Blue line: 3 hours after mixing. Magenta line: 20 hours after mixing. Olive line: addition of 10 eq. fresh CoCp_2 and O_2 to re-generate 1^{adt} to $\text{O-1}^{\text{adt-}}$.

positive potential through coupling chemical steps. This observation is firmly supported by the formation of $\mathbf{O-1^{adt-}}$ through chemical reductants in the presence of molecular oxygen reported here. Since the reduction potential for $\text{Fe}^{\text{I}}\text{Fe}^{\text{I}}$ to $\text{Fe}^{\text{I}}\text{Fe}^{\text{0}}$ is significantly more negative ($\sim ca.$ 0.4 V) than the reduction potential of the mildest reductant, $\text{Cr}(\text{bz})_2$, it is highly unlikely that reduction chemistry occurs prior to the oxygenation reaction (*i.e.* the chemical step). Instead, the most likely scenario is that a pre-equilibrium exists with reversible binding of O_2 to $\mathbf{1^{adt}}$ or $\mathbf{2^{pdt}}$ before reduction chemistry takes place, although the association constant for the complex, $[\text{O}_2 \cdots \mathbf{1^{adt}}]$ or $[\text{O}_2 \cdots \mathbf{2^{pdt}}]$, must be very small. The formation of a complex of $[\text{O}_2 \cdots \mathbf{1^{adt}}]$ or $[\text{O}_2 \cdots \mathbf{2^{pdt}}]$ provides an anodic shift of the reduction potential of the diiron center and facilitates sequential redox and oxygenation reactions.

Although the bridgehead atoms are different (*i.e.* N *vs.* C), the two diiron center complexes, $\mathbf{1^{adt}}$ and $\mathbf{2^{pdt}}$, have a similar electronic structure. Still, the protonatable aza group in the second coordination sphere in this family of complexes generally improves their catalytic properties. Analogously, their reactivity with O_2 in the presence of reductants led to different oxygenated structures and the reactivity of $\mathbf{2^{pdt}}$ was more sluggish. Noticeably, the oxygenated $\mathbf{2^{pdt}}$ complex has more ν_{CO} peaks than the four distinct peaks observed for $\mathbf{O-1^{adt-}}$, suggesting the formation of multiple products. When mCPBA was used as the oxygen donor, the oxygenated, non-reduced, adduct of $\mathbf{2^{pdt}}$ was formed, whereas $\mathbf{1^{adt}}$ was much less reactive and did not form the corresponding complex. Thus, the present results suggest that the second coordination sphere also modulates the reactivity of oxygenation. However, upon addition of protons, no apparent differences between these complexes were observed in the deoxygenation process. Both $\mathbf{1^{adt}}$ and $\mathbf{2^{pdt}}$ were rapidly regenerated after addition of acids. Water was observed as the product during the deoxygenation process of $\mathbf{O-1^{adt-}}$ and attempts to detect H_2O_2 *via* three various methods were not successful. Based on the oxygenation/deoxygenation processes of $\mathbf{1^{adt}}$ discovered here and the mechanism for H_2 evolution suggested by earlier studies,^{2,9,15} a schematic catalytic cycle of $\mathbf{1^{adt}}$ for H_2 evolution in the presence of molecular oxygen is summarized in Scheme 1.

As pointed out in the introduction, the formation of ROS, expected to irreversibly damage the catalyst, is thermodynamically more favorable than proton reduction. Nevertheless, examples where proton reduction occurs under ambient conditions, have been reported. In nature, $[\text{Fe}_4\text{S}_3]$ -containing $[\text{NiFe}]$ hydrogenases have been shown to catalyze H_2 oxidation in the presence of O_2 . The oxygen-tolerant property from this subset of hydrogenases is generally ascribed to the unique $[\text{Fe}_4\text{S}_3]$ cluster that accommodates three oxidation states and acts as electron reservoirs for the reduction of O_2 to harmless water instead of the formation of ROS.^{19,20} Therefore, one way to prevent such oxygen-induced damage is to develop bifunctional catalysts that can catalyze ORR to water. Cobalt diimine-dioxime, one of few known oxygen-tolerant H_2 -evolving catalysts, demonstrates this bifunctionality.²¹ Here, we show that $\mathbf{1^{adt}}$ can react reversibly with O_2 in the pres-

ence of reductants and previous electrochemical results from similar complexes also revealed the capacity for ORR chemistry albeit with limited stability during electrocatalysis. Further improvement of these diiron thiolate complexes are expected to enhance their stability during ORR and thus decrease oxygen sensitivity. Indeed, very recently, it was reported that the ORR and oxygen-tolerance of $\mathbf{1^{adt}}$ can be greatly improved *via* substitutions of the N-bridgehead atom, resulting in improving proton shuttling.²²

Specifically with regards to $[\text{FeFe}]$ hydrogenases, several O_2 inactivated structures have been reported, many of which are considered to result in irreversible inactivation.^{23,24} For example, the oxygenation of sulfur at cysteine 169 (*i.e.* the formation of sulfenic acid) near the diiron center was observed after O_2 exposure to $[\text{FeFe}]$ hydrogenases from *C. reinhardtii*. However, Léger, Blumberger and co-workers have suggested that the reaction between O_2 and $[\text{FeFe}]$ hydrogenases is a multi-step process. The initial species formed upon exposure to O_2 can be either reactivated, *i.e.* suggesting a reversible deoxygenation process, or further proceed to yield an irreversibly inactivated dead-end species.^{25,26} Here, we provide chemical precedence for such a direct oxygenation processes of the thiolate S atom *via* molecular oxygen, as well as the reversible deoxygenation process and degradation of oxygenated $\mathbf{1^{adt}}$. Considering the structural similarities between $\mathbf{1^{adt}}$ and the H-cluster, this reactivity may also be relevant to $[\text{FeFe}]$ hydrogenase.

Conclusions

In summary, this study reports on the oxygenation of two low valent diiron complexes, mimicking the $[\text{FeFe}]$ hydrogenase cofactor, under reducing conditions. The preparation of $\mathbf{O-1^{adt-}}$ and $\mathbf{O-2^{pdt-}}$ provides a new venue for exploring the reactivity between molecular oxygen and H_2 -evolving catalysts. The results presented herein underscore the influence of the bridgehead nitrogen in the reaction towards O_2 , and the importance of protons for the reversibility of the process. Insights learned from studying these systems are expected to provide new guidelines for the design of oxygen-tolerant catalysts for H_2 evolution and the engineering of $[\text{FeFe}]$ hydrogenases. Detailed investigations of the oxygenation and deoxygenation mechanisms of these two complexes at low temperature conditions are currently ongoing.

Experimental methods

Chemicals

Bis(cyclopentadienyl)cobalt(II), bis(pentamethylcyclopentadienyl)cobalt(II), potassium superoxide, hydrogen peroxide (30% w/w in water) and $^{18}\text{O}_2$ (97%) were purchased from Sigma-Aldrich. Chloroacetic acid (>99.0%), trichloroacetic acid (> 99.0%) and 3-chloroperbenzoic acid (mCPBA) were also obtained from Sigma-Aldrich. The molecular oxygen (99.9%) from Air Liquide

was used for this study. Bis(benzene)chromium was purchased from Alfa Aesar.

Precursor to 1^{adt}

The synthesis of the precursor to 1^{adt} , $\text{Fe}_2(\mu\text{-S})_2(\text{CO})_6$ was adapted from literature procedures.²⁷ A 500 mL three-necked round-bottom flask was equipped with a mechanical stirrer and a bubbler. To this was added iron(0) pentacarbonyl (6.3 mL, 47.9 mmol). Degassed methanol (32 mL) was added to the reaction vessel, followed by a freshly prepared and degassed 50 wt% aqueous solution of potassium hydroxide (20 mL). The reaction mixture was stirred for 30 minutes and then cooled to 0 °C. Sulfur (8.1663 g, 0.25 mol) was added to the reaction mixture over the course of 5 minutes. This mixture was stirred for one hour at 0 °C. Degassed water (60 mL) and degassed pentane (180 mL) was added to the reaction vessel. Ammonium chloride (21.8366 g, 0.41 mol) was added to the reaction mixture very slowly and in portions because the reaction produces lots of hydrogen sulfide gas. The reaction vessel was allowed to warm to room temperature, and stirred for 16 hours. After 16 hours, the reaction could be seen to form two layers, one black sticky aqueous phase, and a deep red pentane phase. The reaction mixture was passed through a 100 mL pad of Celite and washed with pentane until the black precipitate collected in the flask appeared slightly grey. The organic fraction was split into smaller volumes of 300 mL and washed with equal volumes of water. The organic phases were then dried over magnesium sulfate, filtered and pentane was evaporated under reduced pressure. The crude product was recombined and re-dissolved in a small volume of pentane before passing it through a silica column with pentane eluent. The solvent was removed under reduced pressure to produce a brown solid ($\text{Fe}_2(\mu\text{-S})_2(\text{CO})_6$, 2.7625 g, 8.03 mmol, 16% yield). FTIR (MeCN) 2002, 2041, and 2083 cm^{-1} .

Synthesis of 1^{adt} and 2^{pdt}

The synthesis of 1^{adt} and 2^{pdt} followed literature procedures.^{28,29}

Reactions of 1^{adt} and 2^{pdt} with molecular oxygen in the presence of reductants

All chemical solvent (mainly, dichloromethane) used in this study were obtained from solvent stills. Oxygen-free DCM was prepared by at least four freeze–pump–thaw cycles. Oxygen-free DI H_2O or H_2O_2 were prepared by purging with N_2 for an hour. The oxygen-saturated DCM was prepared by purging O_2 for an hour and the concentration of saturated oxygen in DCM is estimated to be *ca.* 9 mM according to literature.^{30,31} The superoxide radicals were prepared by mixing potassium superoxide and 18-crown-6 ether (Sigma-Aldrich). All mixtures of 1^{adt} or 2^{pdt} with reductants (such as CoCp_2 , CoCp_2^* and $\text{Cr}(\text{Bz})_2$) in DCM were prepared inside an Ar-containing glovebox (0.5 ppm < O_2 and 0.5 ppm < H_2O). Molecular oxygen was either introduced from the oxygen-saturated DCM inside the glovebox or directly added excessive O_2 into a sealed vial containing a mixture of 1^{adt} or 2^{pdt} and reductants outside the glove box.

When reacting with superoxide, hydrogen peroxide and mCPBA, all experiments were conducted inside the glovebox. When samples were stored inside the glovebox, the sample vial was wrapped with tin foil to prevent photodissociation.

Spectroscopic characterization

Nuclear magnet resonance measurements were recorded with a JEOL (400 YH magnet) Resonance 400 MHz. Infrared spectrum was collected with a Bruker IFS 66 v/S FT-IR spectrometer, in which the DLATGS detector was employed with 2 cm^{-1} resolution. Sample solution was prepared inside a gas-tight IR cell with CaF_2 or KBr as windows. For UV-visible spectrum, the Carry 5000 spectrometer was used and the sample solution was placed in a gas-tight UV-visible cuvette. The mass spectrum was collected in a negative mode with a Thermo Finnigan LCQ Deca XP Max LC/MS spectrometer through the direct injection mode. EPR spectra were recorded at X-band at 9.28 GHz, modulation frequency 100 kHz and modulation amplitude 5 Gauss on a Bruker ELEXYS E500 using an ER049X SuperX microwave bridge in a Bruker SHQ0601 cavity equipped with an Oxford Instruments continuous flow cryostat and an ITC 503 temperature controller (Oxford Instruments). A 1 mM CuSO_4 and 10 eq. of EDTA dissolved in water was employed as a standard sample for spin counting.

DFT calculation methods

The computational methods were followed as the previous reports.^{32,33} In brief, DFT calculations were conducted with the Gaussian 97 package using BP86 functionals with the Def2TZVP basis set³² or cc-pVDZ/cc-pVTZ/SDD basis set.³³ Both basis sets were used to calculate similar molecular systems before. All geometry-optimized structures obtained in the gas phase were further optimized with the SMD solvation model for DCM solvent. The final optimized structure was used to simulate IR spectra. Compared to experimental IR spectra, both basis sets yielded the same trends for all simulated molecular complexes based on 1^{adt} or 2^{pdt} structure but the Def2TZVP basis set resulted in the less deviation of the absorption of carbonyl groups from 1^{adt} and 2^{pdt} . Here, only results from the method (BP86 functionals and Def2TZVP basis) are shown.

Conflicts of interest

There are no conflicts to declare.

Acknowledgements

This work was financially supported by the Swedish research Council (contract no. 621-2014-5670) and ERC (contract no. 714102, to G. B.). We acknowledge postdoc grants to V. W. and C. E. from the Wenner-Gren Foundations. We are very grateful to Jakob Thyr and Prof. Tomas Edvinsson, who made initial efforts on Raman spectroscopy and provided inspiration on IR

measurements. We also thank Dr Patrícia Raleiras for conducting spin counting experiments and MSc. Robin Tyburski for supporting DFT calculations through his funding.
