Sustainable catalytic protocols for the solvent free epoxidation and *anti*-dihydroxylation of the alkene bonds of biorenewable terpene feedstocks using H₂O₂ as oxidant†‡

William B. Cunningham,^{a,b} Joshua D. Tibbetts,^{id a,b} Marc Hutchby,^{a,b} Katarzyna A. Maltby,^{b,c} Matthew G. Davidson,^{a,b} Ulrich Hintermair,^{id a,b} Pawel Plucinski^{b,c} and Steven D. Bull^{id *a}

A tungsten-based polyoxometalate catalyst employing aqueous H₂O₂ as a benign oxidant has been used for the solvent free catalytic epoxidation of the trisubstituted alkene bonds of a wide range of biorenewable terpene substrates. This epoxidation protocol has been scaled up to produce limonene oxide, 3-carene oxide and α -pinene oxide on a multigram scale, with the catalyst being recycled three times to produce 3-carene oxide. Epoxidation of the less reactive disubstituted alkene bonds of terpene substrates could be achieved by carrying out catalytic epoxidation reactions at 50 °C. Methods have been developed that enable direct epoxidation of untreated crude sulfate turpentine to afford 3-carene oxide, α -pinene oxide and β -pinene oxide. Treatment of crude epoxide products (no work-up) with a heterogeneous acid catalyst (Amberlyst-15) results in clean epoxide hydrolysis to afford their corresponding terpene-*anti*-diols in good yields.

Introduction

The development of efficient processes that enable biorenewable feedstocks to be converted into fine chemicals, drugs and polymers that are currently sourced from petroleum feedstocks is a key challenge for the 21st century. Consequently, much attention has been focused on the use of biopolymers (*e.g.* lignocellulose, chitin, *etc.*) as potential biorenewable feedstocks for sustainable chemical production.¹ However, use of oxygenated biopolymers as chemical feedstocks currently requires the use of chemical/microbial hydrolytic processes to enable their efficient depolymerization.² Separation methods are then required to purify complex mixtures of highly oxygenated products, which can be difficult to achieve economically on a large scale. Most of the oxygen-rich bioproducts produced are incompatible with industrial catalytic technologies used to upgrade the aryl and alkene functionalities of hydrocarbon-based petrochemical feedstocks. This means that further

microbial fermentation is required to convert these oxygenated products into relatively low value organic products (*e.g.* fermentation of glucose into bioethanol).³ Alternatively, new catalytic transformations (*e.g.* catalytic deoxydehydration reactions) have been developed to access new chemical products (*e.g.* conversion of fructose into 5-hydroxymethyl-furfural) for which new chemical supply chains need to be developed.⁴ However, significant technological barriers still need to be overcome and further investment will be required before oxygenated biopolymers become established as replacement biorenewable feedstocks for the industrial synthesis of chemical products.

Monoterpenes (and monoterpenoids) represent a large and diverse set of secondary metabolites produced by plants, insects and microbes that exhibit a wide range of biological activity. They are produced from reactions of C₅ isoprene-containing precursors that afford lightly oxygenated unsaturated acyclic/cyclic C₁₀ frameworks containing one or more alkene functionalities.⁵ The hydrocarbon nature of terpenes means they are easy to purify/derivatize using existing petrochemical technologies and so can be considered as potentially attractive non-polymeric biorenewable feedstocks for the sustainable synthesis of chemical products.⁶ Global biogenic production of terpenes is estimated to be around 10⁹ tons per year, although most terpenes are currently only available in relatively small amounts and so are not suitable as bulk feedstocks for industrial chemical synthesis. However, large volumes of a defined sub-set of bulk monoterpene feedstocks (*e.g.* α -pinene, β -pinene, 3-carene and

limonene) are currently available as low-cost waste by-products of the agricultural and forestry industries.⁵

An estimated annual volume of around 330 000 tonnes of terpene feedstocks are produced worldwide,⁷ which is sufficient quantity to consider using terpenes as biorenewable feedstocks for the sustainable synthesis of selected chemical products. Turpentine represents the cheapest and largest volume monoterpene feedstock available that is produced by the forestry and paper industries. Annual worldwide turpentine production ranges between 300 000–310 000 tonnes,⁸ with turpentine comprised of α -pinene and β -pinene, and different amounts of other terpenes, such as 3-carene, camphene, (–)-limonene and terpinolene, whose ratios are dependent on the geographical origin of the tree extracts.⁹

Crude sulfate turpentine (CST) is the cheapest source of turpentine available in bulk quantities (two thirds of world supply, \$220 per metric tonne),^{8,9} which is produced as a by-product of the Kraft process used to produce pulp for paper production.¹⁰ Current applications of CST involve burning it as a fuel to provide energy for the paper mill, or carrying out desulfurization/processing to enable it to be used as paint-thinner or cleaning fluids (e.g. α -terpineol). Alternatively, fractional distillation can be carried out to afford its individual terpene components (e.g. α -pinene, β -pinene and 3-carene) that can then be sold as biorenewable feedstocks for the synthesis of value-added products (e.g. flavours and fragrances). The remainder of the turpentine that is commercially available is gum turpentine, which is produced from distillation of resin obtained from the renewable tapping of tree plantations (mainly pine), which currently retails at around \$1000–1500 per tonne.

Other commercial bulk terpene sources include (+)-limonene which is available in smaller volumes as a by-product of waste fruit peel from the citrus juice industry. Global production levels of (+)-limonene are currently estimated to be around 70 000 tonnes per year, which retails at a more volatile price of between \$3300–10 000 per tonne.¹¹ Promising industrial biotechnology developments have recently revealed the potential of synthetic biology to engineer metabolic pathways into microbes/plants for the industrial production of economically important higher terpenes such as farnesene and squalene.¹² Monoterpenes are relatively toxic to microbial cells, which has typically limited their maximum titre levels to around 1 g L⁻¹ or less, which potentially limits their commercial production on a large scale. However, a recent report has described the creation of a recombinant bacteria expressing a metabolic pathway incorporating 27 enzymes that can transform glucose into α -pinene (or limonene) at titres of up to 15 g L⁻¹.¹³ The impact of these biotechnological processes is potentially significant, because they can potentially provide geographically flexible processes that enable low-cost lignocellulosic waste streams to be converted into terpene based feedstocks on a large scale.

The volumes and prices of commercial turpentine (and derived products) supplies suggest that a scalable biorefinery industry based on biorenewable terpene feedstocks is poten-

tially feasible.⁸ Terpenes and terpenoids are already widely used for the production of flavours, fragrances, cleaning agents and medicinally active compounds,⁵ with the widespread use of α -pinene and β -pinene as biorenewable feedstocks for the synthesis of camphor, menthol and rose oil particularly noteworthy. Monoterpenes have often been used as chiral building blocks for impressive natural product and drug syntheses, albeit on a comparatively small scale.¹⁴ However, many of the reactions used to transform terpenes into more complex high-value products do not conform to the principles of green chemistry, with many of these transformations relying on waste generating reactions, stoichiometric reagents, expensive catalysts and environmentally unfriendly solvents.¹⁴ Therefore, a concerted effort to identify sustainable catalytic transformations that can be used to transform biorenewable monoterpene feedstocks into value-added chemical products on a large scale is urgently required.¹⁵

The unsaturated hydrocarbon nature of monoterpenes means that access to catalytic oxidative protocols that enable selective functionalization of their alkene functionalities is necessary. Epoxides are widely used as privileged functional groups in organic synthesis, with many regio- and stereo-selective protocols available for their transformation into a wide range of functional groups.¹⁶ Indeed, the synthetic utility of many terpene epoxides has already been demonstrated, including their use as chiral building blocks for the synthesis of a wide range of fragrances, natural products, polymers, vitamins, pharmaceuticals, insecticides and natural products.¹⁷ However, the development of scalable epoxidation reactions of terpene substrates is challenging, because terpenes (and their epoxides) readily undergo competing ring-opening, rearrangement and hydrolysis reactions to give unwanted product mixtures that are difficult to separate.¹⁸ Alkene selectivity is also an important issue, because many key terpene substrates (e.g. limonene) contain trisubstituted and disubstituted alkenes that often need to be selectively epoxidized. Therefore, the development of sustainable catalytic protocols that enable the selective epoxidation of terpene feedstocks on a large scale is challenging, particularly when the catalytic epoxidation process must be capable of tolerating the multiple sulfur compounds (e.g. Me₂S, Me₂S₂) present in untreated CST.

Polyoxometalate (POM) catalysts and H₂O₂ have been widely used in catalytic epoxidation reactions, because these protocols exhibit low peroxide disproportionation that maximize oxygen atom transfer from H₂O₂ to the alkene substrate.¹⁹ In this respect, tungsten oxide based Venturolo phase transfer catalysts (VPTCs) have previously been used to epoxidize trisubstituted, disubstituted and monosubstituted alkenes in a variety of organic solvents.²⁰ These easily prepared catalysts contain lipophilic quaternary counter-ions that facilitate alkene epoxidation at the interface of biphasic aqueous-organic mixtures. Their catalytic epoxidation reactions exhibit similar reactivity profiles to those of stoichiometric peracid epoxidation reactions, with more substituted alkenes normally being epoxidized from their least hindered face. These VPTC systems have been shown to exhibit good functional group

compatibility, use H₂O₂ as a cheap, environmentally friendly oxidant with the use of immobilised catalysts potentially allowing for catalyst recycling.^{19,21} Consequently, VPTC based systems represent a highly promising candidate for the development of catalytic epoxidation protocols for biorenewable terpene substrates within a biorefinery context.

VPTCs have previously been used for catalytic epoxidation of the alkene bonds of a range of terpene substrates to give their corresponding epoxides in acceptable to good yields.²¹ These previous terpene epoxidation reactions have employed a wide range of conditions, including the use of homogeneous (preformed and *in situ* generated) and heterocyclic catalysts, varying catalyst loadings ranging from 1–8 mol%, 30–50% solutions of H₂O₂ of varying pH (3.0–7.0), different temperatures (rt–90 °C), varying reaction times (1.5–72 h), and different organic co-solvents (*e.g.* benzene, toluene, CHCl₃, *t*-BuOH, acetone). Furthermore, a number of reports have also described the use of additives [*e.g.* NH₂CH₂PO₃H₂ (1–2 mol%), PhP(O)(OH)₂ (4–10 mol%), Na₂SO₄ (30 mol%), imidazole (5 mol%)] to increase the rate of epoxidation and/or prevent unwanted acid catalysed hydrolysis of terpene epoxides into their corresponding *anti*-diols.^{21–28} However, a systematic study to identify optimal conditions for the VPTC mediated epoxidation of a wide range of terpene substrates has not been carried out. Building on previous literature precedent, we now report the development of practically simple and broadly applicable solvent-free epoxidation protocols that employ a cheap preformed homogeneous tungsten based VPTC for the selective epoxidation of the trisubstituted alkene bonds of a wide range of biorenewable terpene/terpenoid substrates. These sustainable epoxidation conditions have been scaled up to safely produce limonene oxide, 3-carene oxide and α -pinene oxide on multigram scales, with recycling studies showing that the catalyst can be recycled three times for the solvent free production of 3-carene oxide. Use of elevated temperatures (up to 50 °C) enables epoxidation of terpenes containing less electron-rich disubstituted alkene functionalities, which enabled both alkene bonds of limonene to be epoxidized in good yield. Optimal VPTC/H₂O₂ epoxidation conditions have been applied for the first direct epoxidation of the major components of crude CST (non-desulfurized) to afford mixtures of 3-carene oxide, α -pinene oxide and β -pinene oxide that could be separated by distillation. Finally, treatment of crude epoxide mixtures with a heterogeneous Lewis acid catalyst (Amerlyst-15) has enabled a tandem ‘one-pot’ stepwise catalytic epoxidation/epoxide hydrolysis protocol to be developed that enables Prilezhaev dihydroxylation of the alkene bonds of terpenes to give their corresponding *anti*-diols in good yield.

Results and discussion

Solvent free VPTC/H₂O₂ mediated epoxidation of the alkene bonds of biorenewable terpenes and CST

Our goal was to develop practically simple protocols that used preformed VPTC/H₂O₂ system for the scalable catalytic epoxi-

dation of a wide range of terpenes, including untreated CST. Consequently, a preformed VPTC was first prepared by stirring a solution of tungstic acid in 30 wt% aqueous H₂O₂ at 60 °C for 1.5 h, followed by cooling to rt and addition of 85% orthophosphoric acid. A solution of Aliquat 336 [mixture of MeN⁺(C₈H₁₇)₃Cl⁻ and MeN⁺(C₁₀H₂₁)₃Cl⁻, £0.08 per mL (Merck), phase transfer catalyst (PTC)] in CH₂Cl₂ was then added and the resultant mixture stirred vigorously for 1 h at rt, before the organic phase was concentrated under vacuum to give a Venturello-A336 catalyst (PW₄O₂₄[PTC]₃) as a viscous, transparent yellow syrup in 70% yield on a multigram scale.²⁹

Limonene was chosen as a model terpene for the initial reaction optimisation phase,²⁸ because it enabled the selectivity of the VPTC for epoxidation of its trisubstituted alkene over its disubstituted alkene to be determined. 1 mol% of PW₄O₂₄[PTC]₃ was dissolved in neat limonene, followed by dropwise addition of 1.0 equiv. of 30% aqueous H₂O₂ (pH 4.0) and vigorous stirring of the resultant biphasic reaction mixture at rt. This resulted in complete consumption of limonene after 1 h, affording a ~1 : 1 mixture of diastereomeric 1,2-limonene oxides **1a/1b** in 71% yield, along with 25% of the corresponding limonene-*anti*-1,2-diols (1 : 1 mixture of diastereomers), and a small amount (<5%) of limonene bis-epoxide (mixture of all four stereoisomers). The unwanted 1,2-diols formed in this reaction are formed by competing hydrolysis of their corresponding 1,2-epoxides **1a/1b**, which we subsequently discovered was caused by the acidic nature of commercial 30% aqueous H₂O₂ (pH 3.0–4.0). Consequently, the pH of the hydrogen peroxide solution was preadjusted to pH 7.0 using 0.5 M NaOH solution, and the catalytic epoxidation reaction repeated to give a 57 : 43 mixture of 1,2-limonene oxides **1a/b**, with <5% of their corresponding diols now present (Scheme 1). Isolation of the crude reaction product was achieved by simply decanting off the upper organic layer of the biphasic reaction which ¹H NMR spectroscopic analysis revealed was comprised of limonene oxides **1a/b** (containing 1 mol% catalyst) in >95% purity. The crude limonene oxides **1a/b** were then purified by chromatography (or distillation *in vacuo*) to afford pure limonene-1,2-oxide **1a/b** in 94% isolated

Scheme 1 Solvent free catalytic epoxidation of the bulk commodity terpenes – limonene, 3-carene and α -pinene.

yield (average of 5 repeat epoxidation reactions),³⁰ with no diol or bis-epoxide contaminants present.

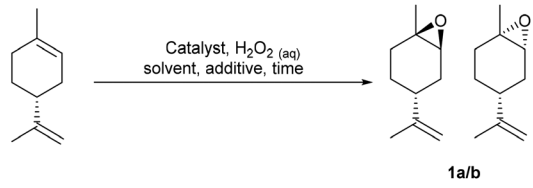

We then explored application of this solvent free protocol for the epoxidation of the trisubstituted alkene functionalities of the bulk commodity terpenes 3-carene and α -pinene that are major components of CST. 3-Carene was cleanly epoxidized using 1 mol% VPTC and 30% H₂O₂ (pH 7.0) under solvent free conditions at rt to afford 3-carene oxide **2** as a single diastereomer in 92% isolated yield after 7 h (Scheme 1).³¹ Epoxidation reactions of α -pinene are known to be potentially problematic, because its epoxide can undergo competing acid catalysed rearrangement, fragmentation and hydrolysis reactions that result in low yields of α -pinene oxide **3**. Indeed, epoxidation of α -pinene using the standard conditions developed for limonene proved unsuccessful, affording complex mixtures of α -pinene and *anti*-diols, with no α -pinene oxide **3** present. Sato and coworkers, had previously reported that addition of 0.3 equiv. of Na₂SO₄ to VPTC mediated epoxidation protocol gave good yields of α -pinene oxide **3**, suggesting that competing epoxide hydrolysis at the biphasic interface is minimized by the increased ionic strength of the aqueous layer.²⁶ Therefore, we repeated the catalytic epoxidation reaction of α -pinene in the presence of 0.3 equiv. of Na₂SO₄ which resulted in clean epoxidation to afford α -pinene oxide **3** as a single diastereomer after 8 h in 85% isolated yield (Scheme 1).³² The excellent diastereoselectivities observed for epoxidation of both 3-carene and α -pinene are consistent with both their alkene bonds being epoxidized from their least-hindered faces.

The epoxidation reactions of limonene, α -pinene and 3-carene were then scaled up to demonstrate the potential of using these protocols for the large-scale synthesis of bulk terpene epoxides containing trisubstituted alkenes. Preliminary scale-up reactions revealed that our solvent free epoxidation conditions were associated with a potentially dangerous exotherm that could result in a dangerous delayed onset thermal runaway reaction occurring. However, modifi-

cation of the experimental conditions enabled safe solvent free epoxidation of limonene to be carried out on a larger scale. This involved slow dropwise addition of a 30% H₂O₂ solution (pH 7.0) to a rapidly stirred solution of limonene (500 rpm) containing 1 mol% catalyst, whilst ensuring that the temperature of the reaction was maintained between 35 and 50 °C through external cooling. This modified protocol enabled the safe and reproducible solvent free epoxidation of 100 g of limonene to afford 95 g of limonene oxide **1** after 2 h in 85% isolated yield. This scaled-up procedure was then used to epoxidize 15 g of 3-carene to afford 11.4 g of 3-carene oxide **2** in 76% isolated yield and epoxidise 15 g of α -pinene (2 mol% catalyst, 30 mol% Na₂SO₄) to afford 12.8 g of α -pinene-oxide **3** in 85% isolated yield. A representative range of catalytic epoxidation reactions of limonene using H₂O₂ as an oxidant are shown in Table 1. These results clearly show that our catalytic solvent and additive free system affords higher yields of limonene oxide in shorter reaction times.^{28,33}

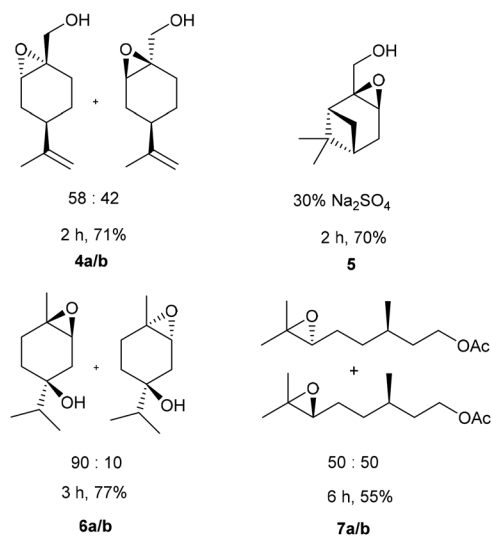

The potential of these protocols to catalyse epoxidation of the trisubstituted alkene bonds of a range of other naturally occurring cyclic monoterpene alcohols was then investigated (Scheme 2). Perillyl alcohol was monoepoxidized to give a clean mixture of its corresponding α -/ β -epoxides **4a/b** in a 58 : 42 ratio after 2 h in 71% yield, with no epoxidation of its terminal alkene or oxidation of its primary alcohol occurring. Similarly, myrtenol was cleanly epoxidized (30 mol% Na₂SO₄) to give a single diastereomeric epoxide **5** after 2 h in 70% yield, with epoxidation occurring exclusively on the face opposite to its more bulky 1,1-dimethyl substituent. The homoallylic alkene bond of carvomenthenol was successfully epoxidized to give a mixture of epoxide diastereomers **6a/b** in 77% yield, with the 90 : 10 selectivity for the *cis* epoxide due to the directing effect of the tertiary alcohol group. Attempts to epoxidize citronellol under these conditions resulted in a low 35% yield of its corresponding epoxides, however, epoxidation of *O*-acetyl-citronellol was more successful, affording a 50 : 50 mixture of epoxides **7a/b** in an improved 55% isolated

Scheme 2 Solvent free catalytic epoxidation of the trisubstituted alkene bonds of a series of cyclic and acyclic terpene alcohols/esters.

yield. This mixture of epoxides **7a/b** could then be methanolized (5 equiv. K_2CO_3 , MeOH, 12 h) to afford a 50 : 50 mixture of their corresponding deprotected citronellol oxides in 80% yield.

Our standard catalytic epoxidation protocol was then applied to a series of monoterpene, sesquiterpene, diterpene and triterpene substrates that contain multiple alkene bonds (Scheme 3). The non-conjugated trisubstituted alkene bond of acyclic myrcene was epoxidized to give the monoepoxide (*rac*)-**8** in 82% yield after 3 h, with its less reactive synthetically useful diene fragment remaining intact. Similarly, selective epoxidation of the fused tricyclic alkene bond of the sesquiterpene valencene gave a 76 : 24 mixture of exocyclic and endocyclic monoepoxides **9a/b** after 24 h, with no epoxidation of its isopropenyl group observed. The non-conjugated trisubstituted alkene functionality of (*rac*)- α -ionone was selectively epoxidized at 50 °C to afford an 80 : 20 mixture of its α -/ β -mono-epoxides (*rac*)-**10a/b** in 79% yield after 4 h. The more electron-rich tetra-substituted γ,δ -alkene of β -ionone was selectively epoxidized at 50 °C to afford its (*rac*)-epoxide **11** in 84% yield. Use of two equiv. of H_2O_2 enabled both trisubstituted alkene functionalities of γ -terpinene to be simultaneously epoxidized to afford (*rac*)-*cis*-bis-epoxide **12** in 86% yield and >90% de. In this case, unselective epoxidation of one of the trisubstituted alkene bonds of γ -terpinene affords two monoepoxide intermediates, whose oxygen atoms then direct epoxidation of their remaining trisubstituted alkenes to the same face. The catalytic epoxidation protocol was then used for the epoxidation of farnesene and squalene, because both these ter-

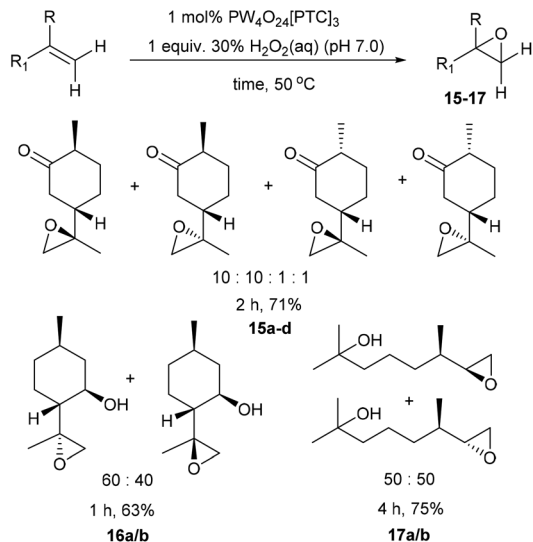

Scheme 3 Solvent free catalytic epoxidation of the trisubstituted alkene bonds of a range of biorenewable terpene substrates.

penes are currently produced on a large scale using industrial biotechnology processes.^{34,35} Use of 2.0 equiv. of H_2O_2 resulted in both trisubstituted alkene bonds of farnesene being selectively epoxidized to afford a 50 : 50 mixture of its diastereomeric bis-epoxides **13a/b** in 86% yield after 18 h, with its synthetically valuable diene fragment untouched.

Even more impressively, treatment of squalene with 1 mol% Ishii-Venturello catalyst and 6 equiv. of H_2O_2 under solvent free conditions gave a mixture of diastereomeric hexa-epoxides **14** in 89% yield after 12 h. Global epoxidation of all the alkene bonds of squalene was confirmed by HPLC-MS analysis that revealed the presence of a single broad peak (multiple hexaepoxy diastereomers) with a correct HPLC-HRMS molecular ion of 529.3628 *m/z*.

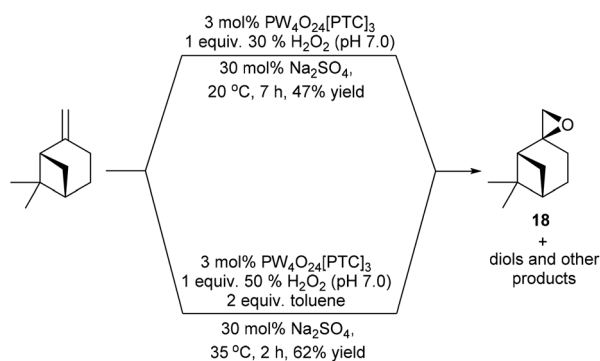

Scheme 4 Solvent free catalytic epoxidation of the disubstituted alkene bonds of a series of monoterpene substrates.

We next turned our attention to determining whether use of higher temperatures might enable epoxidation of terpenes containing less reactive disubstituted alkenes (Scheme 4). Epoxidation of dihydrocarvone (4:1 mixture of *trans*:*cis* isomers) using 1 mol% catalyst and 1 equiv. of H_2O_2 at $50\text{ }^\circ\text{C}$ for 2 h, resulted in formation of a 10:10:1:1 mixture of four diastereomeric epoxides **15a-d** in 71% isolated yield. The disubstituted alkene bond of isopulegol was epoxidised at $50\text{ }^\circ\text{C}$ to give a 60:40 mixture of diastereomeric epoxides **16a/b** in 63% yield after 1 h, whilst acyclic dihydromyrcenol was epoxidised at $50\text{ }^\circ\text{C}$ to afford a 50:50 ratio of its corresponding diastereomeric epoxides **17a/b** in 75% yield after 4 h.

Attempts to epoxidise the bulk monoterpene β -pinene were less successful, due to the lower reactivity of its sterically hindered disubstituted alkene bond and the propensity of β -pinene oxide **18** to undergo facile ring-opening reactions.³⁶ For example, treatment of β -pinene with 3 mol% VPTC and 1 equiv. of 30% H_2O_2 at $20\text{ }^\circ\text{C}$ in the presence 30 mol% Na_2SO_4 for 7 h on a 1 g scale, only gave β -pinene oxide in 47% isolated

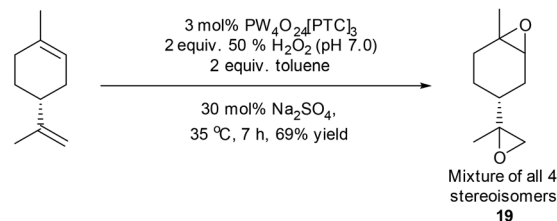

Scheme 5 Catalytic epoxidation of β -pinene using modified conditions designed to reduce ring-opening of β -pinene oxide **18**.

yield (Scheme 5).³⁷ The mass balance from this epoxidation reaction was found to be a complex mixture of by-products, with previous unsuccessful β -pinene epoxidation reactions reported to produce up to 9 possible by-products (*e.g.* pinocarveol).³⁸ Consequently, it was decided to modify the epoxidation conditions to try and increase the rate of epoxidation of β -pinene and minimize hydrolysis of β -pinene-oxide **18** at the aqueous interface. Gratifyingly, use of 3 mol% VPTC, 1 equiv. of a more concentrated commercial 50% H_2O_2 solution, increasing the temperature of the epoxidation reaction to $35\text{ }^\circ\text{C}$ and employing 2 equiv. of toluene as an organic cosolvent resulted in β -pinene epoxide **18** being produced to a more satisfactory 62% isolated yield after only 2 h.

Limonene has proven to be a popular terpene feedstock for the production of a range of biorenewable polymers, with 1,2-limonene oxide **1a/1b** having been copolymerised with carbon dioxide for the production of polycarbonates, or copolymerised with cyclic anhydrides for the production of polyesters.³⁰ The use of limonene bis-epoxide **19** as a bifunctional monomer for biopolymer synthesis is less well explored, however it has recently been reacted with carbon dioxide to afford cyclic bis-carbonates that were polymerised to afford biorenewable polyurethanes and polycarbamates.^{39,40} Attempts to catalyse the simultaneous epoxidation of both alkene bonds of limonene using our standard mono-epoxidation conditions for longer periods of time (or at higher temperatures) proved unsuccessful, affording complex mixtures of epoxides, diols and tetrol products. However, use of the modified conditions developed to epoxidize β -pinene (50% H_2O_2 , 30 mol% Na_2SO_4 , toluene) resulted in initial formation of a mixture of diastereomeric 1,2-limonene mono-epoxides **1a/1b** after 20 minutes, with further epoxidation of their disubstituted alkenes then occurring to afford limonene bis-epoxide **19** (mixture of all four possible stereoisomers) after 7 h in 69% isolated yield (Scheme 6).

We then decided to challenge our catalytic protocols for the direct catalytic epoxidation of the major terpene components of untreated CST, which would require alkene epoxidation in the presence of multiple sulfur contaminants (*e.g.* Me_2S) that are known to deactivate many metal-based catalysts. Non-desulfurized industrial grade CST was obtained from the Södra Forestry Cooperative based in Southern Sweden, whose composition was analysed by ^1H NMR spectroscopy and GCMS analysis. The major terpene components of this CST were found to be 49% α -pinene, 39% 3-carene and 12% β -pinene, which is

Scheme 6 Modified conditions applied to epoxidation of both alkenes in limonene to afford bis-epoxide **19**.

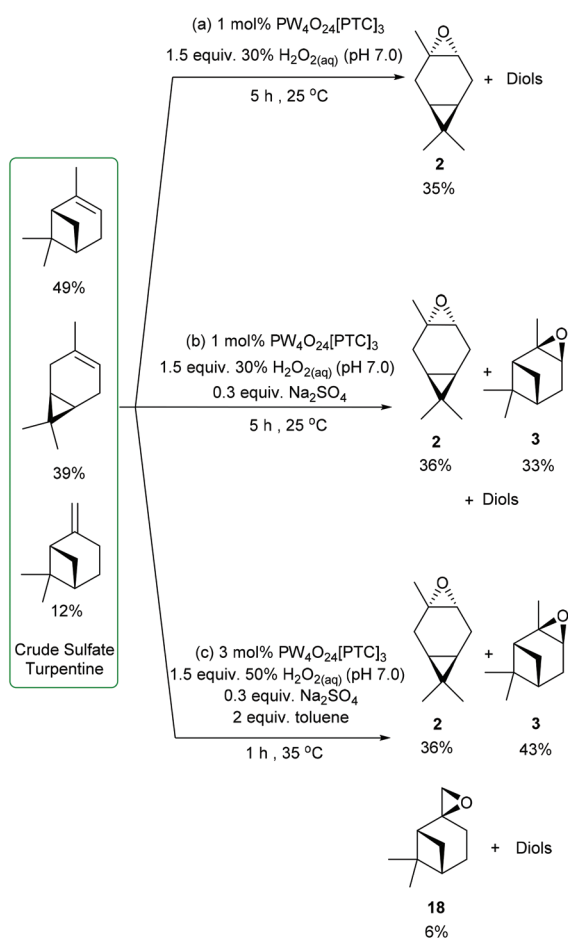

a typical terpene distribution for North European sources of CST that generally exhibit a high 3-carene content. Treatment of this industrial CST with 1 mol% of VPTC and 1.5 equiv. of neutralised 30 wt% H_2O_2 (pH 7.0) under solvent free conditions at rt resulted in 90% consumption of its three major terpene components after 5 h. Analysis revealed that its 3-carene fraction had been converted into 3-carene oxide **2**, whilst α - and β -pinene had been transformed into their corresponding diols (and other ring-opened products). The crude product (no sulfurous odour) was purified by fractional distillation (or chromatography) to afford 3-carene oxide **2** (bp 87 °C at 50 mm Hg) in 30% overall yield (77% theoretical yield) (Scheme 7a). Repeating this CST epoxidation reaction using 1 mol% of catalyst with 1.5 equiv. of 30 wt% H_2O_2 (pH 7.0) and 30 mol% Na_2SO_4 for 5 h gave 36% (92% theoretical) and 37% yields (76% theoretical) of 3-carene oxide and α -pinene oxide, respectively, with all the β -pinene component converted into its corresponding diol (and other products) (Scheme 7b).

Finally, CST was subjected to the more forcing epoxidation conditions (3 mol% catalyst, 50% H_2O_2 , 30 mol% Na_2SO_4 , toluene) developed for β -pinene, which gave 3-carene oxide,

α -pinene oxide and β -pinene oxide in 36% (92% theoretical), 43% (88% theoretical) and 6% (50% theoretical) yields, respectively (Scheme 7c). These epoxides could be separated by fractional distillation under reduced pressure to afford 3-carene oxide (bp 87 °C at 50 mm Hg), followed by α -pinene oxide (bp 102 °C at 50 mm Hg) and then β -pinene oxide (bp 112 °C at 50 mm Hg).

Catalyst recycling studies

We next investigated the possibility of recycling the catalyst for use in consecutive epoxidation reactions, with 3-carene chosen as a model substrate because its relatively fast epoxidation rate and the fact that it affords a single epoxide diastereomer that is easily purified by distillation. Epoxidation of 3-carene was carried out using 1 mol% catalyst using our standard solvent/additive free conditions using 1.0 equiv. of 30% H_2O_2 , which resulted in 100% consumption of 3-carene after 7 h. Separation and ^1H NMR spectroscopic analysis of the resultant biphasic aqueous/organic layers revealed that the organic layer contained the VPTC species. Distillation of the crude organic layer afforded 3-carene oxide in 73% isolated yield, with the recovered distillation residue containing the catalyst then reused for epoxidation of a fresh batch of 3-carene. This second epoxidation reaction required 24 h to proceed to completion, with distillative purification affording 3-carene oxide in a comparable 76% yield. A third epoxidation run using the recovered catalyst distillate took 100 h to reach 90% conversion, with distillation affording unreacted 3-carene (9%) and 3-carene oxide in 66% yield. Finally, a fourth run using the recycled catalyst distillate only gave 13% conversion of 3-carene after 100 h, indicating that the recycled VPTC had lost most of its activity after the third epoxidation run (Fig. 1). The mass of the recovered distillate residue was found to effectively double after each run, with ^1H NMR spectroscopic analysis (see ESI† for details) revealing the presence of high boiling/oligomeric/polymeric terpene residues accumulating over time to deactivate the catalyst. Additionally, the POM anion (or its

Scheme 7 Catalytic epoxidation of CST to selectively afford (a) 3-carene oxide; (b) 3-carene oxide and α -pinene oxide; (c) 3-carene oxide, α -pinene oxide and β -pinene oxide.

Fig. 1 Graph showing the conversion of 3-carene over time with 1 mol% catalyst recycled through four reactions.

degradation products) was presumed to be leaching into the aqueous phase of each subsequent reaction to some extent, as has been previously observed by other groups.⁴¹ This was confirmed by ¹H and ³¹P NMR spectroscopy which revealed retention of PTC species but the absence of any phosphorous-containing POM anion species in the organic layer after the fourth run. However, the first three catalytic recycling runs gave acceptable 66–75% yields of 3-carene oxide under solvent free conditions, suggesting that catalyst recycling is potentially feasible, particularly if distillative purifications of terpene oxides are carried out at lower temperatures/higher pressures that are available on an industrial scale. These recycling results are in accordance with previous studies by other groups using similar homogeneous polyoxotungsten-based epoxidation catalysts, who also described a significant drop in activity after successive epoxidation runs.^{42,43} Efficient recycling has been achieved using polyoxotungsten-based catalysts immobilised on graphene and polymer supports,^{44,45} however, these heterogeneous systems generally require longer reaction times and higher temperatures for epoxidation to occur. Finally, we found that the catalyst distillate residue isolated after the fourth run was highly flammable, which affords the opportunity of burning it for energy and recovering its tungsten metal content (Fig. 2).

One-pot catalytic epoxidation/hydrolysis protocol for Prilezhaev *anti*-dihydroxylation of biorenewable terpenes

Since a number of our catalytic epoxidation experiments had resulted in competing *in situ* hydrolysis of epoxides to afford *anti*-1,2-diols, it was decided to develop a one-pot stepwise protocol for carrying out Prilezhaev *anti* dihydroxylation of the alkene bonds of terpenes.³⁸ Venturello *et al.* have previously reported that low loadings of a preformed Venturello-PTC catalyst could be used to catalyse tandem epoxidation/hydrolysis reactions of aryl- and alkyl-alkene substrates (no terpenes) using benzene as a solvent to afford their corresponding *anti*-

diols.³⁸ Attempts to employ Venturello's conditions³⁸ for the epoxidation/hydrolysis of limonene produced variable results, with replacement of benzene with a range of cosolvents (*e.g.* toluene) resulting in complex mixtures of limonene, limonene-1,2-oxide and limonene *anti*-1,2-diols. Consequently, we devised an alternative stepwise one-pot *anti*-dihydroxylation protocol, involving catalytic epoxidation of limonene (1 mol% catalyst, 30 wt% H₂O₂ (pH 3–4)) to afford a crude epoxidation product (no work-up) that was then treated with the heterogeneous Lewis acid catalyst Amberlyst-15 (0.1 mol%) at rt. Although initial hydrolysis of the crude mixture of limonene oxide proceeded smoothly, the viscosity of this solvent free system was found to increase dramatically as the percentage of diols **20a/b** present exceeded 25%, with inefficient stirring/mixing resulting in the hydrolysis reaction stalling at around 50% epoxide conversion. Consequently, the epoxidation reaction was repeated on a 5 mmol scale, using 1.0 mL of EtOAc (10 mmol, 2.0 equiv.) as a co-solvent, which enabled efficient stirring and complete hydrolysis of the limonene epoxides in the second Amberlyst-15 hydrolysis step. Filtering off the heterogeneous Amberlyst-15 catalyst and removal of the EtOAc solvent *in vacuo* enabled a mixture of diastereomeric limonene-1,2-*anti*-diols **20a/b** to be obtained in 68% yield (Scheme 8). Attempts to carry out this Prilezhaev reaction by including Amberlyst-15 at the start of the epoxidation reaction produced inferior results, leading to significantly lower rates of epoxidation which resulted in complex mixtures of products. Attempts to recover and recycle the Amberlyst-15 were unsuccessful due to rapid stirring of the biphasic mixture resulting in mechanical degradation of the resin.

This catalytic one-pot stepwise epoxidation/hydrolysis method was then applied to the dihydroxylation of a range of nine cyclic and acyclic terpene substrates to afford their respective *anti*-diol derivatives **21–28** in 56 to 77% isolated yields (Scheme 8).⁴⁶ Reaction of 3-carene gave *anti* 3,4-carene diol **21** as a single diastereoisomer in 73% isolated yield, with <5% of 3-carene (or its corresponding epoxides) present in the crude reaction product. The *anti*-dihydroxylation reactions of 3-carene and γ -terpinene were carried out on a larger 10 g scale, allowing their corresponding diol **21** and tetrol (*rac*)-**22** to be obtained in 55% and 62% isolated yields, respectively. *Anti*-dihydroxylation of the exocyclic disubstituted isopropylidene bond of isopulegol (epoxidation at 50 °C) gave the corresponding triols **23a/b** as a 60 : 40 mixture of diastereomers in 65% yield. Epoxidation/hydrolysis of dihydrocarvone (4 : 1 mixture of isomers) gave a 10 : 10 : 1 : 1 mixture of diastereomeric diols **24a–d** in 62% yield. *Anti*-dihydroxylation of perillyl alcohol and carvomethenol gave 58 : 42 and 90 : 10 mixtures of triols **25a/b** and **26a/b** in 56% and 77% yields, respectively. *Anti*-dihydroxylation of the non-conjugated alkene bond of α -ionone gave α -ionone *anti*-diols (*rac*)-**27a/b** as an 80 : 20 mixture of *cis*-/*trans*-diastereomers in 70% yield, whilst *anti*-dihydroxylation of the trisubstituted γ,δ -alkene bond of β -ionone gave (*rac*)-diol **28** in 55% yield.

Unsurprisingly, attempts to apply these epoxidation (0.3 equiv. Na₂SO₄)/hydrolysis (Amberlyst-15) conditions to

Fig. 2 Image of recycled catalyst residue burning vigorously after being ignited using an open flame.

Scheme 8 Solvent free catalytic epoxidation/hydrolysis protocol for the *anti*-dihydroxylation of selected monoterpenes.

α -pinene were only partially successful, affording a mixture of α -pinene-diol **29** (39%) and the ring-opened products – campholenic aldehyde **30** (15%), *trans*-sobrerol **31** (31%) and *cis*-sobrerol **32** (13%) (Scheme 9).²⁵ Epoxidation/hydrolysis of β -pinene was not carried out because of the relatively low yield

Scheme 9 Solvent free catalytic epoxidation/hydrolysis of α -pinene affords a mixture of four products.

of its epoxidation step and the fact that β -pinene oxide **18** readily undergoes acid catalysed ring-opening reactions to afford mixtures of myrtenal, myrtenol and perillyl alcohol.⁴⁷ Attempts to apply our epoxidation/hydrolysis protocol to untreated CST resulted in formation of a complex mixture of oxygenated products, with 3-carene-diol **21** (~20% yield) being the only identifiable product detected by ^1H NMR spectroscopic/GCMS analysis. Nevertheless, the *anti*-dihydroxylation results reported in Scheme 8 clearly demonstrate that Amberlyst-15 can be used as a heterogeneous acid catalyst for catalysing hydrolysis of a of crude terpene epoxide mixtures, without unwanted dehydration/rearrangement reactions occurring.

Conclusions

An inexpensive and easily prepared tungsten based polyoxometalate VPT catalyst has been used for the solvent free catalytic epoxidation of the trisubstituted alkene bonds of fourteen biorenewable terpene substrates using aqueous 30% H_2O_2 as a cheap and benign stoichiometric oxidant at rt. These scalable sustainable epoxidation conditions have been applied for the synthesis of α -pinene oxide, 3-carene oxide and limonene oxide (85 g) on a multigram scale. Carrying out this catalytic epoxidation reaction at higher temperatures enabled the less reactive disubstituted alkene bonds of terpenes to be epoxidized in good yields. These catalytic conditions have been used for the direct epoxidation of untreated CST for the first time, affording mixtures of 3-carene oxide, α -pinene oxide and β -pinene oxide that could be separated by distillation. The VPTC could be recycled three times for the catalytic solvent free epoxidation of 3-carene affording 3-carene oxide in 64–75% yield. Treatment of the crude epoxide products (no work-up) with a heterogeneous acid catalyst (Amberlyst-15) results in clean epoxide hydrolysis to afford their corresponding terpene-*anti*-diols in good yields. Therefore, we believe these green, sustainable and scalable catalytic epoxidation and *anti*-dihydroxylation protocols provide valuable synthetic tools for transforming cheap biorenewable terpene feed-

stocks into valuable chemical building blocks for the synthesis of valuable chemical products within a biorefinery context.

Experimental

Preparation of modified Ishii–Venturello catalyst

Tungstic acid [H₂WO₄] (15 g, 60 mmol) was added to 30 wt% aqueous H₂O₂ (30 mL) in distilled H₂O (12 mL) and the bright yellow mixture stirred for 1.5 h at 60 °C until a cloudy pale-yellow solution formed. The solution was cooled to room temperature and a solution of 85% orthophosphoric acid (H₃PO₄) (1.86 mL) in distilled water (1.86 mL) added, followed by addition of 180 mL of distilled H₂O. The reaction mixture was stirred for 30 min at rt, followed by dropwise addition of a solution of Aliquat 336 (13.7 mL, £0.80 per 10 mL (Fisher Scientific)) in CH₂Cl₂ (240 mL) over a period of 15 min. The resulting mixture was then stirred vigorously at room temperature for 1 h, with the organic phase separated off, washed with distilled H₂O, dried (MgSO₄), and concentrated under vacuum to give the Venturello-A336 catalyst as a viscous, transparent yellow syrup (16.5 g, 70%).

Solvent free catalytic epoxidation of terpene substrates

A terpene (5 mmol, 1.0 equiv.) and PW₄O₂₄[PTC]₃ (0.11 g, 2259 g mol⁻¹, 0.05 mmol, 1 mol%) were added to a 20 mL glass tube and the resultant suspension stirred rapidly for 10 minutes to fully dissolve the catalyst. 30% aqueous H₂O₂ solution (0.5 mL, 5 mmol, preadjusted to pH 7.0 using 0.5 M NaOH) was then added dropwise to the neat terpene that was stirred slowly at ~50 rpm. CAUTION – Exothermic runaway needs to be prevented by controlling the rate of H₂O₂ addition and cooling the reaction flask using an external water bath. The epoxidation reaction was then stirred (~100 rpm) at room temperature until tlc indicated that all the terpene had been consumed. The top organic layer of the biphasic reaction was then collected and purified *via* column chromatography (or fractional distillation under reduced pressure) to produce the desired epoxide as a clear oil.

Experimental variants of the general epoxidation protocol are as follows

(a) Incorporation of 0.3 equiv. Na₂SO₄ into the catalytic epoxidation protocol was achieved by dissolving 0.3 equiv. of Na₂SO₄ in the hydrogen peroxide solution (pH 7.0) prior to its dropwise addition to the stirred terpene solution.

(b) Higher catalyst loadings were used for epoxidation of less reactive terpenes, with the catalyst loadings employed for each terpene substrate reported on their respective reaction schemes.

(c) Elevated temperatures of 35–50 °C were used to epoxidize terpene substrates that contained less reactive di-substituted alkenes.

(d) Incorporation of toluene (2 equiv.) into the catalytic epoxidations was achieved by dissolving the terpene substrate and catalyst in the solvent prior to addition of H₂O₂.

(e) Higher concentration H₂O₂ (50 wt%) was used for substrates where hydrolysis of epoxidation products to their corresponding *anti*-diols occurred under standard conditions.

(f) One equiv. of H₂O₂ was used to for every alkene bond present in the terpene substrate. For example, the six tri-substituted alkene bonds of squalene were epoxidized using six equiv. of H₂O₂.

(g) Large scale batch epoxidations were stirred at a faster stirring rate of 500 rpm to take into account the larger volumes of terpene substrate used, with hydrogen peroxide added in small portions using a dropping funnel.

Catalyst recycling study for epoxidation of 3-carene

3-Carene (3.26 g, 24 mmol) and PW₄O₂₄[PTC]₃ (0.55 g, 2259 g mol⁻¹, 0.24 mmol, 1 mol%) were added to a 20 mL glass tube and the resultant suspension stirred rapidly for 10 minutes to fully dissolve the catalyst. 30% aqueous H₂O₂ solution (2.5 mL, 24 mmol, preadjusted to pH 7 using 0.5 M NaOH) was then added dropwise to the terpene mixture that was stirred slowly at ~50 rpm. CAUTION – Exothermic runaway needs to be prevented by controlling the rate of H₂O₂ addition and cooling the reaction mixture using an external water bath. The reaction was then stirred (~100 rpm) at room temperature and monitored by ¹H NMR spectroscopy, with the epoxidation reaction complete after 7 h. The top organic layer of the biphasic reaction was then collected and purified *via* fractional distillation under reduced pressure to produce 3-carene oxide as a clear oil (2.65 g, 73%). The same amount of 3-carene (3.26 g, 24 mmol) was then added to the recovered catalyst residue and the epoxidation reaction repeated using the same amount of H₂O₂ (1 equiv.). This epoxidation/catalyst recycling procedure was carried out for a total of four experiments, giving 3-carene oxide yields of 73% for run 1, 76% for run 2, 66% for run 3 (+9% recovered 3-carene) and 11% for run 4 (+65% recovered 3-carene).

Prilezhaev *anti*-dihydroxylation reaction of terpene substrates

A terpene substrate (5 mmol, 1.0 equiv.), PW₄O₂₄[PTC]₃ (0.11 g, 2259 g mol⁻¹, 0.05 mmol, 1 mol%) and EtOAc (10 mmol, 1 mL) were stirred in a 20 mL glass tube for 10 minutes to afford a homogeneous solution. 30% aqueous hydrogen peroxide solution (0.5 mL, 5 mmol, pH 3.0–4.0) was then added, with slow stirring carried out at ~50 rpm for the duration of peroxide addition. CAUTION – exothermic runaway needs to be prevented by controlling the rate of H₂O₂ addition and cooling the reaction mixture using an external water bath. The reaction was then stirred as a faster rate (~100 rpm) at room temperature until tlc indicated that the epoxidation reaction was complete. Amberlyst-15 (0.13 mol%, 140 mg, 4.6 mmol g⁻¹) was then added directly to the crude reaction mixture which was then stirred (50 rpm) for 7–8 h at room temperature, with tlc analysis used to determine when epoxide hydrolysis was complete. The reaction mixture was then filtered to remove Amberlyst-15, extracted with EtOAc (3 × 10 mL), the combined organic layers dried (MgSO₄) and solvent removed *in vacuo* to give a crude product that

was purified by chromatography to afford the desired terpene-*anti*-diol.
