Graphitic carbon nitride and polymers: a mutual combination for advanced properties

Qian Cao. Baris Kumru. Markus Antonietti and Bernhard V. K. J. Schmidt **

The sheet-like material graphitic carbon-nitride (g-C₃N₄) is one of the most promising metal-free photocatalysts and utilized for various purposes, e.g. energy conversion, waste water remediation or organic synthesis. g-C₃N₄ features a suitable band gap in the visible light range and outstanding physicochemical stability. However, g-C₃N₄ features drawbacks such as structural disorder, low conductivity, poor dispersibility and in turn low processability. Amongst the strategies to improve $g-C_3N_4$ properties, combination with polymers is a promising avenue toward advanced materials. The present critical review highlights the development and investigation of g-C₃N₄/polymer combination, including (1) g-C₃N₄ as photoinitiator for polymer snythesis, (2) polymer modified g-C₃N₄ for improved dispersibility, (3) g-C₃N₄/polymer hybrid materials fabricated via physical or covalent attachment and (4) $g-C_3N_4$ based hydrogels. The fabrication methods and application of these areas will be critically reviewed and the advantage of g-C₃N₄/polymer combination comprehensively presented. Moreover, the broad range of applications is highlighted, e.g. photocatalysis, batteries, biosensors, H2 evolution and films. Finally, the review will conclude with a summary and perspective on future directions as well as current challenges of this research area in order to stimulate new research regarding the design and construction of g-C₃N₄/polymer materials.

1. Introduction

Sustainability has an increasing impact both on academia and industry, orienting many research fields such as biomass conversion, batteries, polymers and photochemistry. 1-5 A significant direction

is the integration of free and abundant sunlight into current technology, such as energy harvesting via photovoltaic devices or photo-mediated material synthesis. Semiconductors (such as Si, TiO₂, CdS, hybrid perovskites, polythiophenes) absorb light which results in the formation of excited electrons, and are promising candidates for photovoltaic devices, transistors and for photoinduced reaction catalysis.⁶⁻⁸ Many factors should be considered for the efficiency of a semiconductor materials, such as suitable absorption and bandgap values, lifetime of excited electrons, and charge migration which delays recombination.

Qian Cao

Qian Cao received her BSc in Inorganic Nonmetal Materials and Engineering and MSc in Material Science and Engineering from University of Science and Technology Beijing. She is currently a PhD student under the supervision of Prof. Markus Antonietti and Dr Bernhard V. K. J. Schmidt at the Max Planck Institute of Colloids Interfaces. Her research interests focus on the synthesis and application of carbon nitride as well as polymer hybrid materials.

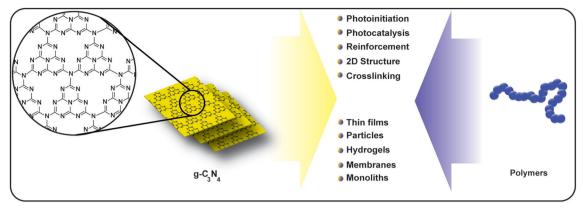

Baris Kumru

Dr Baris Kumru has obtained his chemistry bachelor degree in 2015 and master degree in 2016 at Istanbul Technical University. Later he earned his PhD degree in early 2019 at the Max Planck Institute of Colloids and Interfaces in Potsdam. He will be promoted as young Group Leader at the same institute focusing on colloids, polymers and photochemistry.

Review Materials Horizons

Scheme 1 Structure of $g-C_3N_4$ and properties/materials obtained in combination with polymers showing the features that $g-C_3N_4$ introduces into polymer science (top) and the morphologies achievable via $g-C_3N_4$ /polymer combination (bottom).

Even though excessive research has been conducted on these materials, their metal content, possible toxicity and synthesis from non-abundant sources restrict applications. Therefore, suitable candidates which have at least similar photoactivity but are formed *via* sustainable synthetic conditions are highly sought.⁹

Graphitic carbon-nitride (g- C_3N_4) is a sheet like material that is traditionally formed from a regular arrangement of tri-striazine units (Scheme 1). It features a variety of modifications, which have direct influence on the band gap resulting in photoactivity in the visible and UV range of light. Thus, g- C_3N_4 is utilized frequently as visible light induced heterogeneous photocatalyst, for example for organic transformations, hydrogen evolution, leg- C_3N_4 is utilized in ion transport membranes, hotoever, g- C_3N_4 is utilized in ion transport membranes, hotoelectrochemistry or in organic photovoltaics have as well as for emulsion stabilization. The synthesis of g- C_3N_4 is usually performed from metal-free, oxygen-free, abundant and nitrogenrich precursors, for example cyanamide, sundant and nitrogenrich precursors, for example cyanamide, sundant and hydrochloride, sundant and material guantide hydrochloride, sundant and several methods. Amongst them, thermal

condensation is the most common method for fabrication of bulk g-C₃N₄, which proceeds under inert atmosphere between 400 and 600 °C. Recently, other methods like chemical vapor deposition or electrochemical deposition were introduced for fabricating film or membrane g-C₃N₄. ³⁹ The microwave method was utilized as well, e.g. to produce fluorescent g-C₃N₄. 40,41 However, the type of the precursors and treatment can significantly influence the physicochemical properties of as-prepared g-C₃N₄. Compared to traditional semiconductors which have defined formulas, g-C₃N₄ represents a large family of materials with a variety of properties. For example, one way to obtain welldefined g-C₃N₄ is the utilization of a supramolecular precursor complex of cyanuric acid and melamine that already resembles the final g-C₃N₄ structure. 42,43 As such, porosity, 44-46 surface charge, 47 light absorption, photoluminescence, and band gap 48 can be tailored according to the needs. Recently, also the overall shape of g-C₃N₄ could be tuned via various synthetic methodologies, e.g. a control over precursor crystal structures/shapes. 49-52 As summary, g-C₃N₄ seems to satisfy sustainability requirement as semiconductor by being metal free and synthesized from benign precursors, in addition it possesses tunable properties,

Markus Antonietti

Markus Antonietti is director of Colloid Chemistry of the Max Planck Institute of Colloids and Interfaces. Starting from polymer science, he now works on modern materials chemistry, with sustainable processes and materials are a central theme. Carbon and Carbon–Nitrogen Materials exert a special fascination to him. Besides being a devoted scientist and an academic teacher, he is a passionate chef specialized in fusion cuisine and plays in a Rock'n'Roll band.

Bernhard V. K. J. Schmidt

Bernhard V. K. J. Schmidt completed his PhD in 2013 with Prof. Barner-Kowollik at the Karlsruhe Institute of Technology and a PostDoc with Prof. Hawker at the University of California, Santa Barbara. Afterwards he joined the department of Prof. Antonietti at the Max Planck Institute of Colloids and Interfaces as a Group Leader. Recently, he was appointed as Lecturer in Synthetic Polymer Chemistry at the University of Glasgow. His research focusses on block copolymer self-assembly,

metal-organic framework/polymer hybrids and carbon nitride/polymer hybrid materials.

Materials Horizons

however it has some major drawbacks such as structural disorder, as well as being non-processable in bulk.

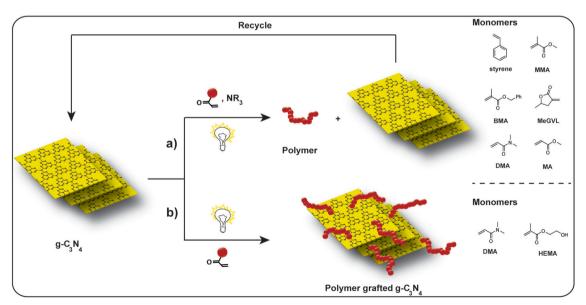

In that sense, a combination of carbon nitride with polymers seems to be a promising avenue for advanced materials (Scheme 1). Polymers can introduce processability (e.g. film formation) into materials as well as enhancing dispersibility. Moreover, a plethora of conducting polymers allows a fine tuning of electron transport process in materials. Therefore, polymers can be utilized to introduce new properties to g-C₃N₄ or to enhance existing properties (e.g. photocatalysis or conductivity). Likewise, incorporation of g-C₃N₄ into polymer materials is an avenue to tailor mechanical properties of the polymer, e.g. in the bulk or in hydrogels. Another promising property of g-C₃N₄ that is of significant interest for polymer science is its inherent property to form radicals under irradiation with visible light. As such it acts as photoinitiator and can be used for polymer synthesis (e.g. polymer particles) in a convenient way. Polymers and g-C₃N₄ have various points of contact, and by hybridization improved or novel materials properties can be synthesized.

In the following review, this combination is discussed. The research in recent years is divided into four parts. At first the photoinitiator properties of g-C₃N₄ and its application in various polymerization systems is discussed. Next, the dispersibility of g-C₃N₄ and polymer- or functionalization-based routes towards improved dispersibility are highlighted. As the main part, g-C₃N₄/ polymer hybrid and composite materials are presented with emphasis on H2 evolution, photocatalysis, biosensors, electrochemical energy storage and solar cells, films, nano particles and polymer properties. Finally, the area of g-C₃N₄-based hydrogels is introduced with a focus on mechanical properties as well as photocatalytic properties. The review is closed with a summary and discussion of future aspects.

2. Carbon nitride as polymerization initiator

Commonly, g-C₃N₄ has been employed as a highly active photocatalyst. As g-C₃N₄ features a suitable bandgap to absorb visible light, it generates electrons and holes under visible light irradiation. In these cases, the formation of reactive species (e.g., OH, O2, and HO2, or also CN-centered species) takes place, which is not only of interest for photocatalysis but for polymerization processes as well (Scheme 2). Therefore, two ways are depicted in Scheme 2 where g-C₃N₄ acts as initiator for photopolymerization, which is accompanied with various advantages. First of all, g-C₃N₄ polymerizations can be operated in the visible light region, which is a benign and abundant trigger. Several monomers were investigated for polymerization via g-C₃N₄ as photoinitiator, such as styrene,⁵³ methyl methacrylate (MMA),⁵⁴ α-methylene-γ-valerolactone (MeGVL),⁵⁵ methyl acrylate (MA).⁵⁶ On top, photopolymerizations have various useful features, like spatial and temporal control. Moreover, g-C₃N₄ is a heterogenous catalyst, which allows easy separation and recycling. Albeit, the conditions can be altered in a way that the growing polymer chains are grafted from g-C₃N₄ and as such recycling or separation is not straight-forward. In this case grafting polymers from g-C₃N₄ opens up various opportunities for hybrid material formation, which also broadens the utilization in bioapplications due to the inherent photoluminescent properties of g-C₃N₄.

As a proof of concept, Yagci and coworkers utilized g-C₃N₄ as visible light photoinitiator for free radical polymerization.⁵⁷ Mesoporous g-C₃N₄ (mpg-C₃N₄) was employed as heterogeneous visible light photoinitiator in the presence of tertiary amine as reactive co-initiator, conducting free radical polymerization with

Scheme 2 Schematic overview of $g-C_3N_4$ mediated photopolymerization and monomers used in the two approaches: utilization of $g-C_3N_4$ as recyclable photoinitiator via radical transfer to an amine compound (top) and g-C₃N₄ initiated grafting of polymers onto the initiator (bottom) (MMA: methyl methacrylate; BMA: benzyl methacrylate; MeGVL: α -methylene- γ -valerolactone; DMA: N,N-dimethylacrylamide; MA: methyl acrylate; HEMA: 2-hydroxyethyl methacrylate).

vinyl monomers such as methyl methacrylate (MMA). Based on the photoredox chemistry of mpg- C_3N_4 , the photopolymerization process was realized by exposing the monomer mixture to visible light in the absence of O_2 . The initiation mechanism is presumably the transfer of the CN-based hole and the amine. The photochemically formed holes oxidize amines to the corresponding radical cations which abstract hydrogen from another amine leading to the formation of initiating radicals. Moreover, mpg- C_3N_4 demonstrated enhanced activity in the polymerization process due to a larger external surface compared to non-porous bulk g- C_3N_4 .

Recently, our group employed g-C₃N₄ as radical photoinitiator for emulsion photopolymerization.⁵⁸ Emulsions of aromatic monomers (styrene and benzyl methacrylate) and MMA in water were formed via g-C₃N₄ (cyanuric acid-melamine-derived g-C₃N₄ (CM) or 1-decene modified CM) as stabilizer. Subsequently, the mixture was exposed to visible light to conduct polymerization. Radicals were formed on the surface of g-C₃N₄. Kinetic studies and in-depth studies of the polymer particles indicated that the g-C₃N₄ surface acted as the reaction locus for polymer chain growth and particle formation. The polymerization mechanism was investigated by addition of hole or electron scavenger to the reaction system, respectively, and it was demonstrated that the emulsion photopolymerization was mainly initiated by the hole. Overall, very well-defined latexes were obtained, which was attributed to the fast nucleation of the latex particles. Moreover, compared to previous works, radicals were formed via holes on the g-C₃N₄ surface directly without co-initiator addition. The direct radical formation leads to crosslinked latex particles directly due to the multifunctionality of g-C₃N₄. Furthermore, our team has employed g-C₃N₄ as heterogeneous photocatalyst for free radical polymerization of MeGVL.⁵⁵ At first MeGVL is efficiently synthesized from renewable resources via continuous flow reaction from γ-valerolactone over hierarchical basic zeolite. MeGVL is structurally similar to methacrylic monomers, and further valorization of this compound via efficient polymerization demonstrates the ability to make novel biomassderived polymer with significant industrial interest.

As a semiconductor, g-C₃N₄ possesses a quite high negative position of the conduction band, thus contributing to a high activity of oxygen capture and reduction. Meanwhile, the moderate oxidation potential of g-C₃N₄ efficiently prevents the decomposition of the prepared polymer by the photogenerated holes. Both effects play a crucial role in the photopolymerization process.^{59,60} Thus researchers introduced g-C₃N₄ as a promoter for electron transfer in reversible deactivation radical polymerization (RDRP). For example, Yagci and coworkers⁵⁶ utilized mpg-C₃N₄ as photoactivator for reduction of initially loaded copper(II) species, for the in situ formation of copper(I) species, which act as catalytic species in atom transfer radical polymerization (ATRP). Subsequently, polymerization was successfully conducted under sunlight or UV-light irradiation. It was shown that the light-induced electron transfer from g-C₃N₄ is due to the large reduction potential ($E_{\rm CB}$) of -1.2 eV. Vinyl monomers such as, methyl acrylate (MA), MMA and styrene were successfully polymerized during the reaction with precise control on

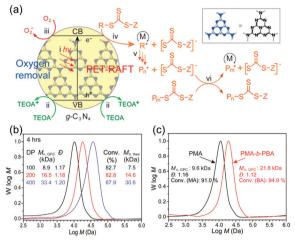

Fig. 1 (a) Schematic overview over the mechanism of deoxygenation and photoinduced electron/energy transfer-reversible addition—fragmentation chain transfer (PET-RAFT) polymerization employing $g-C_3N_4$: (i) photoinduced activation of $g-C_3N_4$, (ii–iv) electron transfers from amine to $g-C_3N_4$, from $g-C_3N_4$ to O_2 , and from $g-C_3N_4$ to the trithiocarbonate (TTC), respectively; (v) initiation and chain propagation of monomers (M); and (vi) reversible degenerative chain transfer (RAFT process). (b) size exclusion chromatography (SEC) traces of PET-RAFT polymerization derived poly(methyl acrylate) (PMA) with different degree of polymerization (DP) (DP = 100, 200, and 400). molecular dispersity (D). A work reported by Qiao and coworkers introduced g-C₃N₄/amine cocatalysts to a photoinduced electron/ energy transfer (PET) oxygen-tolerant reversible additionfragmentation chain transfer (RAFT) polymerization (Fig. 1).⁶¹ g-C₃N₄ was employed directly without prior deoxygenation of the reaction mixture to enable electron transfer from added tertiary amines (i.e. triethanolamine TEOA) to dissolved molecular oxygen. Thus, the trithiocarbonate (TTC) chain transfer agents were activated via oxygen reduction, followed by polymerization of acrylic species such as MA, n-butyl acrylate (BA) and watersoluble monomer N,N-dimethylacrylamide (DMA) (Fig. 1a). In the mechanism, molecular oxygen takes a prominent part in the photoredox cycle. Thus, benign reaction conditions under visible light, without deoxygenation of monomer solution, are achieved that are time consuming in the common case. Polymers with different polymerization degree could be achieved easily with this process as shown via size exclusion chromatography (SEC) (Fig. 1b). Moreover, block copolymers could be synthesized, e.g. PMA-b-PBA (Fig. 1c). Such PET-RAFT approach had merits of low toxicity, organic solvent tolerance and facile postpolymerization removal of the catalyst.⁶²

Very recently, our group conducted dithiol–ene click reactions between lignocellulosic biomass-derived 4-pentenoic acid (4-PEA) and different dithiols using $g\text{-}C_3N_4$ as photocatalyst. ⁶³ Visible light induced click chemistry was utilized for the reactions between 4-PEA and 1,2-ethanedithiol (EDT), 2,2-(ethylenedioxy)-diethanethiol (EDDT), and 1,4-benzenedimethanethiol (BDT) leading to polymers in high yields and purities in order to reduce the dependence on petroleum-derived monomers.

Materials Horizons Review

Moreover, g-C₃N₄ has been utilized as photoinitiator to fabricate g-C₃N₄-based polymer composites under light irradiation via a "grafting from" method, which is defined as chain growth via monomer propagation starting from a surface, i.e. here a g-C₃N₄ surface. As radicals are produced by g-C₃N₄ under visible light irradiation, the grafting occurs presumably via the presence of uncondensed -NH2 or -NH groups at g-C3N4. These groups act as active sites to initiate polymer chain growth from g-C₃N₄ surface. In such a way, g-C₃N₄-based polymer hybrid materials are fabricated, with the firmly attachment of polymer on to g-C₃N₄ surface, which facilitates further applications.

Another area where g-C₃N₄ photoinitiation is widely utilized is hydrogel formation. For hydrogel formation the same initiation mechanisms are exploited, i.e. radicals are formed on the surface of g-C₃N₄ with phototreatment and g-C₃N₄ directly participates in the hydrogelation without electron transfer or co-initiator addition. The formation of hydrogels will be covered in detail in Section 5. Most notably, hydrogels could be formed without addition of external crosslinker, which indicates initiation from the g-C₃N₄ surface and covalent incorporation of g-C₃N₄ into the gel network.⁶⁴ As such, these findings support the mechanism found for g-C₃N₄ initiated polymerization without addition of radical transfer agent.

3. Carbon nitride dispersibility

A major issue for the application of g-C₃N₄ is its poor dispersibility of the pure material. As the strong van der Waals interactions (π – π stacking) of g-C₃N₄ sheets causes the agglomeration in the liquid phase. Thus, dispersibility in organic as well as aqueous environment is rather low, 65 and results in restricted applicability as well as activity. 65,66 Especially the formation of thin (2-3 nm) semiconductor films are of great interest for optoelectronics and photovoltaics. However, to form such g-C₃N₄ films rather elaborate methods like chemical vapor deposition have to be utilized. 67,68 A solution based process would be simpler and suitable for many real life applications, and therefore, attention has been addressed to enhance dispersibility of g-C₃N₄ powder. Several researchers focused on exfoliation of the bulk g-C₃N₄ into thin sheets, in which the electrostatic repulsion between g-C₃N₄ sheets can enable the formation of well-dispersed g-C₃N₄ colloids. Hence, stable dispersions of g-C₃N₄ can be prepared, yet the achievable concentration of dispersed g-C₃N₄ is rather low. A route to disperse g-C₃N₄ is via additives or physical treatment, e.g. via addition solvents in the dispersion step, 69,70 hydrothermal treatment, 71 chemical oxidation, 72 thermal oxidation 73 or ultrasonication. 74 The other option is chemical modification via attachment of molecular moieties. On one hand, with the attachment of charged groups to the g-C₃N₄ surface, the stability of dispersed g-C₃N₄ nanosheets can be increased in aqueous environment via electrostatic repulsion. On the other hand, attachment of hydrophilic polymers can stabilize g-C₃N₄ in dispersion via steric repulsion in aqueous dispersion. In organic solvent, the dispersibility of g-C₃N₄ can be increased via

the attachment of organo soluble small molecules or polymers, where steric repulsion leads to enhanced stability of the dispersion.

A reported option is the complex formation with organic modified montmorillonite to facilitate enhanced stability in organic environment, which was utilized to form poly(styrene) (PS)/g-C₃N₄ composites.⁷⁷ Exfoliating g-C₃N₄ in 1,3-butanediol results in graphene-like g-C₃N₄ with around 2-6 layers of g-C₃N₄ with a thickness of circa 1-2 nm. However, ultrasonication for 24 hours and possibility to exfoliate only low amount of g-C₃N₄ is the drawback of the approach.³¹

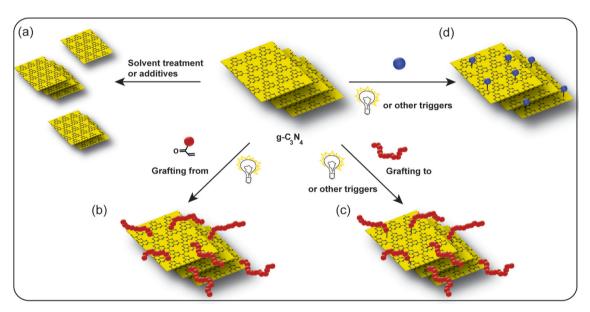

Another functionalization route to enhance dispersibility of g-C₃N₄ is by pre-condensation or post-condensation. In the case of pre-condensation a specific monomer mixture is used, for example additional phenyl moieties are introduced into the system.⁷⁸ The utilization of a phenyl-functional precursor for g-C₃N₄ synthesis prevents growth of larger g-C₃N₄ sheets which results in quantum dot structure that possess enhanced dispersibility compared to traditional g-C₃N₄ sheets. Another approach is post-condensation functionalization that allows the introduction of various functional groups via chemical treatment, e.g. oligo(ethylene glycol) (oligoEG) (Fig. 2).⁷⁵ Well dispersed colloids (Fig. 2a) with high biocompatibility and bioimaging properties could be achieved in that way (Fig. 2b). As such Kim and coworkers firstly oxidized g-C₃N₄ via KMnO₄ and exfoliated it via ultrasonication, followed by covalent modification with monomesylated oligoEG. Attachment of oligoEG resulted in oligoEG-modified g-C3N4 sheets, which exhibited water dispersibility to be utilized for bioimaging. Oxygen plasma can be employed for introducing protonated hydroxylamine functional groups to g-C₃N₄ surface, which provides extreme hydrophilic character. 79 Other functional groups such as sulfonic acid,80 hydroxyl81 or aromatic groups48 can also be introduced for enhancing dispersibility of g-C3N4 sheets. However, alternative facile and less stringent routes to enhance dispersibility with high g-C₃N₄ solid content yields would be beneficial.

To improve dispersibility, we investigated solvent mixtures (Scheme 3a). The mixture of water and EG in equal volume enabled dispersion with significant g-C3N4 weight contents of up to 4 wt%, compared to a maximum of 0.6 wt% in pure water. g-C₃N₄ is a photoactive compound that is a semiconductor and thus forms electron/hole pairs via light irradiation. This feature was exploited to perform photo-initiated polymerization reactions (Scheme 3b). Thus, to improve dispersibility of g-C₃N₄ further, a polymerization approach was introduced via g-C₃N₄ photoinitiation. DMA was added to a g-C₃N₄ dispersion in EG/water and treated with visible light, which led to a weakly associated gel. The viscous gel was formed from PDMA grafted g-C₃N₄ and could be easily dispersed in water. In addition, such dispersions possess high stability (up to 2 months) due to steric stabilization of g-C₃N₄ colloids.⁸²

Furthermore, pre-formed ene end functionalized polymers could be grafted onto g-C₃N₄ as well (Scheme 3c, refer to Section 4 as well). A way to obtain dispersible-CN via a more exact approach that does not rely on polymerization was also studied. For that, the parent g-C₃N₄ is dispersed in aqueous or organic solution, an ene-compound is added, and the mixture subjected to visible

light (Scheme 3d).⁷⁶ Due to the radical formation at the g- C_3N_4 surface, addition of the ene-compound takes place. To prevent polymerization of the added small molecule, allylic compounds were utilized as they possess no propagation tendency. Hence, the molecules are grafted on g- C_3N_4 directly. Notable, the modification of the g- C_3N_4 surface chemistry significantly influences the dispersion properties of g- C_3N_4 . For example, 3-allyloxy-2-hydroxy-1-propanesulfonic acid sodium salt (AHPA) was grafted on g- C_3N_4 to improve water dispersibility with up to 10 wt% while stable dispersions were obtained, *e.g.* for 48 hours.

Grafting of 11-decene led to organo dispersibility of up to 2 wt% g- C_3N_4 in solvents like THF, DCM or toluene. In addition, pH-sensitive dispersibility could be introduced via allylamine that leads to dispersibility in acidic solution and precipitation at basic pH (Fig. 2c). Recently, methyl vinyl thiazole was grafted onto g- C_3N_4 , which led to a significant improvement of organo dispersibility via an intrinsic electrostatic stabilization mechanism. The two components create an autonomous donor–acceptor type structure and enhance excited electron–hole separation. ⁸³ Moreover, surface functionality has a profound effect on photocatalytic activity as well.

4. Carbon nitride/polymer hybrid materials

Polymers are playing a significant role in industry as well as daily life and are widely investigated. Especially, polymer materials with functional properties are of focal interest today, such as self-healing, 84 stimuli response, 85 biodegradability 86 or electrical conductivity.⁸⁷ A combination of traditional polymers with the novel metal-free semiconductor g-C₃N₄ materials is highly worthwhile (Scheme 4). g-C₃N₄ is widely investigated as a metal-free semiconductor, but poor processing inhibits a scale-up of utilization, which is an issue for applicability.^{88,89} A combination of g-C₃N₄ with polymers appears to be a useful solution, 90,91 as properties of both material classes can be coupled via combination of the individual parts. 92 Due to g-C₃N₄, photocatalytic, photoluminescence, as well as enhanced physical and mechanical properties are obtained, while the polymers bring improved processability or conductivity. There are several ways to fabricate g-C₃N₄/polymer hybrid materials (Scheme 4a). (1) Physical absorption or deposition, mostly prepared in the liquid phase. In the same way, one can also list blending of both materials. (2) "Grafting from" method, in which monomers are polymerized from the g-C₃N₄ surface. (3) "Grafting to" method that is based on chemical bond formation between reactive sites on g-C₃N₄ and active polymer end groups.

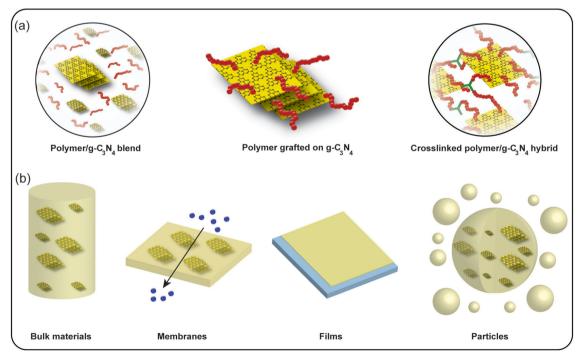

Such g-C₃N₄/polymer hybrid materials can be utilized for various applications as discussed in Section 4.1, *e.g.* photocatalytic H₂ evolution, photocatalysis, biosensors, electrochemical energy storage according to different type of the hybrids (Scheme 4b). As film and membrane materials are commonly

applied to electrochemical area and particles are mostly used in biosensors, Table 1 shows the summary of specific g-C₃N₄/polymer compositions and their application area as well as the specific enhanced properties and performance compared to the single component g-C₃N₄. In addition, polymers can be utilized to include g-C₃N₄ into specific material morphologies, *e.g.* spherical particles or thin films as presented in Section 4.2. Moreover, g-C₃N₄/hybridization enables the improvement of polymer properties, especially mechanical properties as shown in Section 4.3. As such, polymers and g-C₃N₄ can be utilized for mutual benefit. On one hand, polymers improve processing of g-C₃N₄ amongst other properties. On the other hand, g-C₃N₄ improves the properties of polymer materials, *e.g.* the mechanical properties.

A significant issue with polymer hybrids and composites is the compatibility of polymer and the mixed-in material. In the case of g- C_3N_4 , favorable interactions are present in many cases. For example, g- C_3N_4 is prone to establish π - π interactions with polymers like PS or poly(benzyl methacrylate) (PBMA). On the other hand, g- C_3N_4 contains polar groups at the edges, which allows interactions (mostly hydrogen bonding) with polar polymers like PDMA or poly(2-hydroxyethyl methacrylate) (PHEMA).

4.1 Applications of g-C₃N₄/polymer hybrid materials

g- C_3N_4 /polymer hybrids as photocatalysts for H_2 evolution and CO_2 reduction. One of the major applications of g- C_3N_4 for photocatalysis is their employment as visible-light-driven water splitting photocatalyst for H_2 evolution. Low conductivity and high recombination rates of photoinduced electrons and holes significantly limits the production of H_2 and merging g- C_3N_4 with conductive polymers is one of the efficient strategies to

Scheme 4 Approaches for polymer/g- C_3N_4 modification: (a) strategies of embedding g- C_3N_4 in polymers *via* blending, grafting as well as grafting/crosslinking approaches and (b) morphology types of g- C_3N_4 /polymer hybrids, *i.e.* bulk materials, membranes, films and particles.

Materials Horizons

overcome these issues. Due to the excellent solubility, processability and long-term stability of polymer semiconductors, such hybrid materials can significantly improve the photoelectric properties of g-C₃N₄. The combination of g-C₃N₄ with conductive polymers, e.g. poly(3-hexylthiophene) (P3HT), 93 poly(pyrrole) (PPy)⁹⁴ or poly(aniline) (PANI),⁹⁵ is usually achieved via physical interactions, self-assembly or thermal deposition methods. As g-C₃N₄ possesses a stacked 2-dimensional (2D) structure and van der Waals interactions between g-C₃N₄ sheets, with the presence of -NH₂, -NH or -OH on the edge with a slight negative surface charge, physisorption of polymers to g-C₃N₄ surface via weak van der Waals or electrostatic interactions is enabled.

For example, Yan and coworkers combined P3HT and g-C₃N₄ by impregnating g-C₃N₄ with a chloroform solution of P3HT overnight, followed by evaporation of the solvent, which resulted in physical attachment of P3HT to g-C₃N₄ surface (Fig. 3a). 96 With the increased deposition of P3HT, a remarkable increase of H₂ evolution of 300 times was achieved utilizing Na₂S and Na₂SO₃ as electron donors. The improved catalytic activity was attributed to the enhanced electron conductivity after P3HT incorporation. Later, the same group established a g-C₃N₄/Au/P3HT/Pt layer structure using a self-assembly method. 93 A tight g-C₃N₄/Au conjunction was formed by photodeposition, then P3HT/Pt was combined with g-C₃N₄/Au due to the formation of Au-sulfur association between Au on g-C₃N₄ and sulfur in the P3HT structure. Thus, chemical bonds were used instead of physical adsorption to ensure a tight junction between the individual g-C₃N₄ and P3HT layers. Such layered structures were demonstrated to be efficient for the separation of photoinduced electron-hole pairs and for H2 evolution.

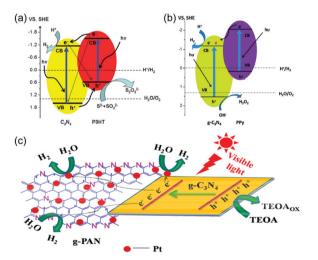

Fig. 3 (a) A proposed mechanism of visible light-induced H₂ evolution on g-C₃N₄-poly(3-hexylthiophene) (P3HT) polymer composite photocatalysts (Reprinted with permission. 96 Copyright 2011 Royal Society of Chemistry). (b) The mechanism to understand the role of the dispersed poly(pyrrole) (PPy) nanoparticles in enhancing the photocatalytic activity of PPy-g-C₃N₄ for H₂ evolution (Reprinted with permission.⁹⁴ Copyright 2013 Royal Society of Chemistry.) (c) Illustration for the enhanced photogenerated charge carriers separation and transfer in graphitized-poly(acrylonitrile) (g-PAN)/g-C₃N₄ composites under visible light irradiation ($\lambda > 400$ nm) (Reprinted with permission. 95 Copyright 2014 American Chemical Society).

Nevertheless, P3HT has the drawback of a limited processability in aqueous media, which is the preferred choice for g-C₃N₄ so far. An option to circumvent that problem is to switch to PPy, which possesses high stability in the oxidized state as well as high conductivity. For example, Chen and coworkers reported the loading of highly dispersed PPy nanoparticles onto the g-C₃N₄ surface via sonochemical approach in a physical attachment (Fig. 3b). 94 PPy-g-C₃N₄ suspension was treated with ultrasonication for 12 hours and drying at 80 °C. The addition of PPy nanoparticles showed no effects on the absorption edge of g-C₃N₄ but influenced the intensity of the g-C₃N₄ emission peak, indicating the more effective separation of photogenerated electrons and holes in PPy-g-C₃N₄ compared to pristine g-C₃N₄. The activity of H₂ evolution was dramatically improved with the increasing loading amount of PPy. Furthermore, graphitized-poly(acrylonitrile) (g-PAN) nanosheets were deposited on g-C₃N₄ via one step thermal condensation method as reported by Hao and coworkers (Fig. 3c). Simple mixing of g-C₃N₄ precursors with PAN and thermal treatment under 650 °C led to graphitization of PAN. Thus, a layered structure of g-PAN/g-C₃N₄ was obtained. Compared to aggregated polymer morphologies, the g-PAN with aromatic conjugated structure possesses more reactive sites and short diffusion distance, which decreases the recombination rate of photogenerated charge carriers. Hence g-PAN acts as an effective electron transfer channel in the g-PAN/g-C₃N₄ composites and obviously enhanced the photocatalytic performance for H2 evolution.

Very recently, hydrophobic polymer grafted g-C₃N₄ was employed as a three-phase photocatalyst for enhanced selectivity and activity of CO2 reduction.97 Hydrophobic 1H,1H,2H,2H-perfluorodecanethiol was utilized to modify poly(glycidyl methacrylate) (PGMA) grafted on CM (pDFe-PGMA/CM) via thiol-epoxy addition reaction. Subsequently, an in situ photoloading method was applied for loading Pt on the pDFe-PGMA/CM surface. A threephase contact photocatalyst of CO2 (gas), H2O (liquid) and catalyst (solid) was fabricated to enable a high concentration of CO2 molecules on the catalyst surface directly. Moreover, the mass transfer limitation of CO2 was overcome due to the hydrophobic catalytic surface, which contributed to an enhanced CO₂ reduction reaction and suppressed hydrogen evolution reaction. The observed efficiency was about 34 times higher than commonly achieved by hydrophilic catalysts. Reisner and Roy showed an avenue to CO2 reduction as well. 98 In their experiments, mpg-C3N4 was combined with a polymeric cobalt phthalocyanine catalyst. To obtain a good interfacial contact, 1,2,4,5-tetracyanobenzene together with Co²⁺ was polymerized directly in the presence of mpg-C₃N₄. A synergistic effect of CN porosity, solar energy harvesting and photosensitization facilitated remarkable activity of the phthalocyanine catalyst in CO2 reduction under visible light.

g-C₃N₄/polymer hybrids as photocatalysts for water contamination degradation. In addition to H₂ evolution, other photocatalytic tasks can be performed with g-C₃N₄/polymer hybrids as well. g-C₃N₄/polymer hybrid materials show improved performance towards water contaminant degradation too. 99 For example, organic dyes like Methyl red, Congo red or methylene blue (MB)100 are responsible for wastewater contamination, as they have been

used for dyeing fabrics. Due to their high solubility in water, effective purification processes are needed as otherwise these dyes cause significant contamination in wastewater. Moreover, they act as easy recognizable substances to probe photocatalytic activity. Several strategies were attempted to degrade dyes so far, such as ion exchange, electrochemical treatment, adsorption, membrane separation and catalytic reduction. 101-103 Amongst the approaches to degrade dyes in water, g-C₃N₄ based polymer hybrid composites via photocatalytic means show remarkable advantages such as being low-cost, ease of processability and recyclability as well as activity under visible light. 104,105 Zhu and coworkers synthesized PANI nanofibers between g-C₃N₄ nanosheets by polymerizing aniline in the presence of ammonium persulfate (APS). 106 Coral-like PANI nanofibers were grown between g-C₂N₄ sheets as monomers were in situ polymerized on the surface of g-C₃N₄ to form a hydrogel material (Fig. 4a). Thus, a 3D hierarchical structure of the composite hydrogel was constructed with excellent contaminants degradation properties, 5.1-fold higher than that of pure g-C₃N₄ (Fig. 4b). In a similar way, Liu and coworkers fabricated PANI-g-C₃N₄ composite photocatalysts by in situ oxidative polymerization of aniline onto g-C₃N₄ powder in the presence of APS as initiator. 107 There, g-C₃N₄ was employed as a substrate and to serve as loci for monomer propagation and polymer chains propagated on the g-C₃N₄ surface. Finally, improved photodegradation properties toward MB were found due to the enhanced electron-hole separation induced by the synergistic effect between PANI and g-C₃N₄. Another hybrid material of PANI and g-C₃N₄ was synthesized by Prakash and coworkers, who used sulfur and phosphorous co-doped g-C₃N₄ (SP-g-C₃N₄) and covalently grafted PANI via oxidative polymerization. The SP-g-C₃N₄-grafted with PANI also featured a tuned band gap structure with extended light absorption. Hence, more active sites for photogeneration of charge carriers at the interfaces were formed. Moreover, PANI possesses unique electron and hole transport property and excellent chemical stability, which leads to an improved utilization of visible light.

Therefore, the as-prepared metal-free nanocomposite showed

an outstanding photocatalytic activity for the degradation of MB. 108 Other water contamination can also be removed by g-C₃N₄/polymer composites. Qian and coworkers combined porous g-C₃N₄ foams with acrylic resin for efficient oil and organic solvent capture. 109 The g-C₃N₄/acrylic resin showed high adsorption capacity, fast capture rate and good recyclability toward removing oils and organic solvent from water.

A good way to improve efficiency of g-C₃N₄-based waste water remediation by improved transport engineering is the incorporation into fiber structures. The group of Chen fabricated visible light responsive nanofibers based on PAN dispersed g-C₃N₄ via electrospinning, to disperse g-C₃N₄ and immobilized by PAN fiber structure. 110 The g-C₃N₄/PAN hybrids demonstrated efficient photocatalytic properties of Rhodamine B (RhB) degradation over a wide pH range and were recycled in a simple way. Othman and coworkers incorporated g-C3N4 into PAN nanofibers using electrospinning as well. 111 A liquid-permeable self-supporting photocatalytic nanofiber was fabricated, demonstrating 85% degradation capability for purification of oil contaminated water under visible light irradiation. Liu and coworkers utilized electrospun PAN nanofibers to immobilize a g-C₃N₄/BiOI heterojunction via a facile in site synthesis strategy. 112 The efficient separation of the electron-hole pairs and strong absorption in the visible region of PAN/g-C₃N₄/BiOI hybrids resulted in superior photocatalytic activity in the degradation of RhB and toxic Cr(vi) ions under visible-light. Moreover, the film-like and selfsupporting nanostructure enabled the hybrids for floating photocatalyst application.

An issue of growing interest is the removal of antibiotic contaminations in water, which can be tackled via g-C₃N₄ photocatalysis as well. For example, g-C₃N₄@poly(ethylene terephthalate) nanofibers were fabricated using poly(ethylene terephthalate) as a support and polyethylene glycol (PEG) as a porogen via electrospinning, 113 which is beneficial for catalyst-substrate contact. This work demonstrated high photocatalytic activity for the degradation of antibiotics such as sulfaquinoxaline and sulfadiazine under solar irradiation. Polyester fibers (from poly(ethylene terephthalate))

Materials Horizons

were utilized to support cellulose (CA) containing nanosheet g-C₃N₄ in another work as well, 114 aerogel g-C₃N₄@CA/poly(ethylene terephthalate) for enhanced photocatalytic activity towards the removal of hexavalent chromium and antibiotics, simultaneously. Chen and coworkers used poly(ethylene terephthalate) as support for g-C₃N₄ *via* electrospinning and subsequently hydrothermal treatment, which enabled the exposure of g-C₃N₄ on the poly(ethylene terephthalate) surface, avoided aggregation and improved recyclability. 115 Low melting sheath-core composite polyester fibers were immobilized with g-C₃N₄ to induce recyclability as well as enhanced photocatalytic degradation capability. 116

g-C₃N₄/polymer hybrids as photocatalysts for sterilization. The combination of polymers and g-C₃N₄ leads to improved antibacterial performance. In addition to the antibacterial properties of g-C₃N₄, ¹¹⁷ polymer fibers improve recyclability and sterilization ability as well. Zhang and coworkers fabricated self-cleaning and antibacterial membranes via filtering g-C₃N₄ nanosheets onto PAN porous substrates. 118 The membrane showed high water permeability (11.7 L m⁻² h⁻¹) and good antibacterial activity. Moreover, the g-C₃N₄/PAN membrane preserved its original permeability, e.g. rejecting dyes, and the surface was close to its initial color after three cycles via post treatment under visible light irradiation. A poly(ether sulfone) (PES) microfiltration membrane was combined with g-C₃N₄ and Ag₃PO₄ by Vatanpour and coworkers. ¹¹⁹ Significant antifouling behavior was observed that was ascribed to the synergistic effects of photocatalytic activity, hydrophilicity and porosity.

g-C₃N₄/polymer hybrid materials for biosensors. Although the formation of g-C₃N₄ hybrids has been widely investigated, the applications of g-C₃N₄ in the field of sensing are still in the initial stage. Since the first report of the cathodic electrochemiluminescence (ELC) behaviors of g-C₃N₄ nanosheets, ¹²⁰ it has attracted an increasing attention as a promising luminophore candidate for ELC biosensor systems. Especially as g-C₃N₄ presents many favorable advantages, such as nontoxicity, excellent biocompatibility, high thermal and chemical stability, 53,121 polymer functionalized g-C₃N₄s are investigated for improving the sensitivity and selectivity of ECL sensors. A combination of g-C₃N₄ with phenoxy dextran (DexP) and bovine serum albumin was applied to obtain a ECL sensor for concanavalin A by Wei and coworkers. 122 In this study, DexP and g-C₃N₄ nanocomposites were fabricated via simple overnight stirring to induce physical adsorption via π - π stacking between g-C₃N₄ and DexP. Later, biosensor performance was investigated, and it was shown that the DexP-g-C₃N₄ composites not only serve as an excellent ECL signal probe, but also form specific carbohydrate-Con A interaction, which demonstrated a novel sandwichtype scheme with a signal-on ECL detection strategy. Chen and coworkers introduced PANI to the g-C₃N₄ sheet structure by an in situ deposition oxidative polymerization using APS as initiator, then gold nanoflowers (AuNF) were in situ formed on the g-C₃N₄-PANI composite to achieve AuNF@g-C₃N₄-PANI hybrids. 123 The hybrid components were utilized for ECL biosensor construction, showing high sensitivity and low limit of detection for dopamine. Hence the sensors might be a potential material for determination of dopamine in the field of clinical disease diagnosis. Kim and

coworkers attached cylindrical spongy shaped PPy onto protonated g-C₃N₄ (g-C₃N₄H⁺) *in situ* using oxidative polymerization. 124 Cholesterol oxidase (ChOx) was immobilized on the as-prepared nanohybrids to construct cholesterol biosensor electrodes. Various features were demonstrated, *e.g.* long-term stability and good selectivity for cholesterol detection during electrochemical characterization. Wei and coworkers presented a CdS/PPy/g-C₃N₄ aptasensor for adenosine detection. 125 Therefore, a SH-aptamer was adsorbed on CdS/PPy/g-C₃N₄ modified electrodes that formed bioaffinity complexes with adenosine. The readout of photocurrent changed according to adenosine concentration in a linear fashion in the range of 0.3 nmol $\rm L^{-1}$ to 200 nmol $\rm L^{-1}$

g-C₃N₄/polymer nanocomposites applied in electrochemical energy storage and solar cells. Electrochemical energy storage and energy generation is one of the major current research areas. Hence, also g-C₃N₄ has found its way into materials for fuel cells, batteries and solar cells. Fuel cells are one of the main devices that can convert chemical into electrical energy. In particular, polymer electrolyte membrane fuel cells (PEMFCs) are of interest for electrochemistry and polymer chemistry. Commonly utilized polymers include poly(benzimidazole) (PBI), 126 poly(vinyl pyrrolidone) (PVP), 127 PVP-poly(vinyl alcohol) (PVP-PVA) 128 or PVP-PES. 129 However, PEMFC research faces several challenges. For example, high cost, low durability and degradation of PEMFCs, which are due to the instability of membrane materials, seriously inhibit the widespread utilization of the technique. 130,131 Regarding these challenges, researchers introduced g-C3N4 nanosheets to the polymer matrix. 132 One particular reason to employ a combination with g-C₃N₄ is its decent thermal stability with chemical bond energy of C-N and C=N of 305 kJ mol⁻¹ and 615 kJ mol⁻¹, respectively. 133 Another reason is that the amino (-NH₂) and imino (-NH) groups of g-C₃N₄ can interact with acid groups in the polymer matrix, which leads to enhancement of the Grotthuss-mechanism proton transfer. For instance, Zhou and coworkers blended PVPphosphonated-poly(2,6-dimethyl-1,4-phenylene oxide) (PVP/pPPO) with g-C₃N₄ nanosheets via a solution casting method, ¹³³ by mixing a certain amount of g-C₃N₄ in 70% PVP/pPPO solution, then the solution was casted onto a glass plate to obtain the nanocomposite membranes. Improved proton conductivity and mechanical properties were realized due to the proton accepting sites provided by NH₂ and the interaction of g-C₃N₄ with polymer chains, thus leading to higher proton conductivity (74.4 mS cm⁻¹) and power density (294 mW cm⁻²) at 180 °C with a content of g-C₃N₄ nanosheets of 5 wt%.

To improve the proton conductivity of PA doped PES-PVP membrane material, Lu and coworkers introduced g-C₃N₄ nanosheets to the polymer composite matrix through a blending method (Fig. 5).¹³⁴ The as-prepared nanocomposites have shown a significantly improved proton conductivity of 0.104 S cm⁻¹ and power density of 512 mW cm⁻² with 0.5% content of g-C₃N₄. Meanwhile, due to the physical reinforcement effect of 2D g-C₃N₄ nanosheets, the mechanical properties of the composite membranes were enhanced compared to PES-PVP without g-C₃N₄. Jiang and coworkers introduced g-C₃N₄ nanosheets to sulfonated poly(ether ether ketone) composites (SPEEK),¹³⁵ exhibiting a 68% increase of tensile strength of nanocomposite membranes with

Review Materials Horizons

g-C₃N₄ content of 0.5 wt% due to the intrinsic mechanical stability of g-C₃N₄ nanosheets and favorable interfacial interactions of g-C₃N₄ nanosheets with the SPEEK matrix. The g-C₃N₄/ SPEEK composites were applied to PEMFCs demonstrating a 39% increase in maximum power density at a g-C₃N₄ content of 0.5 wt%.

Other energy storage devices such as vanadium redox flow battery (VRB), lithium metal batteries and supercapacitors were also combined with g-C₃N₄ for improved stability and battery efficiency. Particularly, for VRB, sulfonated aromatic polymers such as SPEEK, 136 sulfonated poly(sulfone) (SPSF) 137 or sulfonated polyimide (SPI) 138 are widely used for fabrication of membranes due to excellent proton conductivity and mechanical properties.

However, improved proton conductivity and ion selectivity are still required. Incorporation of g-C₃N₄ regulates the interfacial interaction of the membrane materials, thus the ion selectivity, and vanadium ion permeation and structure stability could be effectively controlled. 139-141 Xiang and coworkers introduced g-C₃N₄ nanosheets into a Nafion matrix membrane to reduce vanadium ion crossover (Fig. 6a). 142 Crosslinking interaction between Nafion matrix and g-C₃N₄ nanosheets efficiently induced the shrinkage of the Nafion membrane (Fig. 6b and c), resulting in a lamellar structure, thus the vanadium ion crossover is significantly reduced. An improved coulombic efficiency of 97% and energy efficiency of 85% at a current density of 80 mA cm⁻² was achieved (Fig. 6d). Moreover, Li and coworkers proposed a lightweight polymer-reinforced electrolyte based on g-C₃N₄ mesoporous microspheres as electrolyte filler in lithium metal batteries. 143 Due to the high mechanical strength and nanosheet-built hierarchical structure of g-C₂N₄, this electrolyte can effectively suppress lithium dendrite growth during cycling. The Li/Li symmetrical cell based on this electrolyte exhibited a long-term cycling of at least 120 cycles with a high capacity of 6 mA h cm⁻². Additionally, g-C₃N₄ was embedded onto conductive polymers as an efficient electrode material for supercapacitors to improve electrochemical and mechanical stability. 144-146 Yang and coworkers prepared a novel electrode material for supercapacitors composed of poly(3,4-ethylenedioxythiophene) (PEDOT):poly(styrenesulfonate) (PSS) and g-C₃N₄ by the layer-by-layer assembly method. 147 Compared with pure PEDOT, the PEDOT/g-C₃N₄ composite demonstrated excellent electrochemical stability in neutral electrolyte and enhanced electrochemical performance of capacitance of 137 F g⁻¹ in H_2SO_4 and 200 F g^{-1} in Na_2SO_4 , respectively.

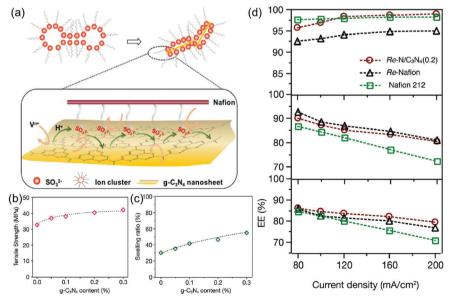

Fig. 6 (a) Proton and vanadium ion transport behaviors of the Re-N/CN(x) composite membrane. Materials Horizons Review

Additionally, few studies reported the combination of g-C₃N₄ with polymers for solar cell utilization. 148 Yang and coworkers for the first time introduced g-C₃N₄ quantum dots (C₃N₄QDs) into the active layer of bulk-heterojunction (BHJ) polymer solar cells (PSCs). 149 Solution-processable C₃N₄QDs were prepared by acid treatment of bulk g-C₃N₄, followed by a solvothermal treatment. Finally, they were doped to the active layers of the PSC with a doping ratio of 0.2 mg mL⁻¹. The different active layers of the C₃N₄QDs doped BHJ-PSC device demonstrated an obvious enhancement of power conversion efficiencies from 17.5% to 11.6%, depending on the utilized active layer compared to the reference device in the absence of C₃N₄QDs. The effect of C₃N₄ODs on surface morphology, optical absorption, PL properties as well as charge transfer properties was specifically studied, hence the mechanism for such efficiency enhancement was proposed. Very recently, following our recent discovery of modifying g-C₃N₄ with 4-methyl-5-vinylthiazole (vTA), in which the grafting of vTA led to spontaneous polarization and migration of negative charges on thiazole rims whereas g-C₃N₄ remained positive. Thus significantly influencing the electron transport process,83 which was exploited in another work of our group that applied vTA-grafted g-C₃N₄ nanosheets (g-C₃N₄-vTA) as interfacial transporting layers (ETLs) for inverted perovskite solar cells (PVSCs).²⁹ Homogenous films of g-C₃N₄-vTA were formed via facile spin-coating on two different layers to study the influence of g-C₃N₄-vTA on the electronic properties of methylammonium lead iodide based PVSCs. The implementation of g-C₃N₄-vTA enabled interface enhancement via suppression of charge recombination, achieving 1.09 V in V_{oc} and a rise to 20.17 mA cm⁻² in short circuit current. Besides, enhanced carrier collection due to the extra light absorption at short wavelengths was observed. Moreover, the introduction of g-C₃N₄-vTA as alternative interface layer featured metal-free, cheap and benign photophysical properties with high tenability.

4.2 g-C₃N₄/polymer hybrids for designed material morphologies

g-C₃N₄/polymer hybrid film materials. As g-C₃N₄ is a very promising photocatalytic material, application of g-C₃N₄ in films is of significant interest,⁶⁷ especially in the utilization of solar cells, 150 sensors 151 or in ionic transport. 25,152 Nevertheless, common methods of film formation and processing, e.g. spin coating or inkjet printing,153 have been achieved with minor success only for a longer time, which is to a large extent due to the limited colloidal dispersibility of g-C₃N₄ and necessity of harsh processing conditions. 154 Thus several studies investigated formation of g-C₃N₄ film materials.⁶⁸ One effective strategy is to combine g-C₃N₄ with polymers for improved dispersibility and processability. In such a way, thin films and coatings based on g-C₃N₄ could be fabricated, which enables processing of g-C₃N₄ and access to novel applications. One way for such combination is "grafting to", which used surface functionalities on g-C₃N₄ (e.g. -NH₂, -NH or -OH) for amide formation or hydrogen bond formation. The other way is "grafting from" method, which was described above (Section 3).

For example, Hu and coworkers fabricated a series of sodium alginate (SA) nanocomposite films with different g-C₃N₄ loading

levels via casting technology. 156 A physical adsorption method was utilized here to fabricate SA/g-C₃N₄ composites, SA and g-C₃N₄ mixture were ultrasonicated at 40 °C to form hydrogen bonds between -OH on SA and uncondensed -NH2 on g-C3N4. Subsequently, the mixture was poured onto a transparent flat dish and left undisturbed for 36 h at 40 °C. The hydrogen bonding behaviour, thermal stability and mechanical performance of the g-C₂N₄/SA film were studied. Recently, our group investigated a "grafting to" method to graft allyl-end functionalized polymers onto g-C₃N₄ under visible light irradiation (Fig. 7). Decene end functionalized PMMA, poly(isobornyl methacrylate) (PIBA) and PGMA were firstly synthesized via ATRP. 155 In the next step the polymers were mixed with g-C₃N₄ dispersed in THF and irradiated with visible light to form a covalent bond. The as-prepared polymer/g-C3N4 with different grafting density could be easily processed for fabrication of polymer/g-C₃N₄ film by dispersing the composites in THF and spin coating on glass slides (Fig. 7b). As such, smooth thin polymer/g-C₃N₄ films with thicknesses in the range of 60 nm were obtained (Fig. 7c). In addition, the PGMA-based materials could be further modified via nucleophilic ring-opening of the epoxides with thiol compounds (Fig. 7d). In such a way, sodium 2-mercaptoethanesulfonate or 1H,1H,2H,2H-perfuorodecanethiol were further grafted on the g-C₃N₄-brushes, which led to significant changes in surface hydrophilicity as shown via contact angle measurements after film formation.

Another work from our group described a g-C₃N₄-based polymer thermoset coating, and thicker films were obtained via a prepolymer route, which is similar to already discussed g-C₃N₄-PDMA prepolymers. 157 In this case, a prepolymer of PHEMA on g-C₃N₄ was formed in EG/water mixture that led to the formation of a viscous precursor material composed of PHEMA grafted g-C₃N₄, EG and water. The viscosity of the precursor was tuned in way that injectable material was obtained. As such, the precursor could be applied to various surfaces, including PS, wood and copper, with spatial control. After addition of citric acid and film formation on a glass slide, crosslinking was performed via heating. The so-formed thermosets formed smooth hydrophobic coatings that could be used for further processing. As the g-C₃N₄ in the coating retains its photoactivity, PDMA or PS could be modified to the surface via the "grafting from" method to tailor the surface polarity, as shown via contact angle measurements. Moreover, the photoactive surfaces could be used in dye degradation experiments as well as photoelectrochemistry.

g-C₃N₄/polymer nanoparticle composites. A very common and useful structure in polymer and materials science are latexes based on nanoparticles. Therefore, research regarding the introduction of g-C₃N₄ into or onto polymer particles is another major topic. As it was found that g-C₃N₄ can act as emulsifier to stabilize oil in water (o/w) emulsions, 30,158 one way to fabricate g-C₃N₄/polymer nanoparticles is to utilize g-C₃N₄ as stabilizer in a Pickering emulsion polymerization. 159 The approach was utilized by Li and coworkers to form g-C₃N₄ based latexes.⁵³ Pickering emulsion polymerization was conducted using g-C₃N₄ as stabilizer and potassium persulfate (KPS) as initiator.

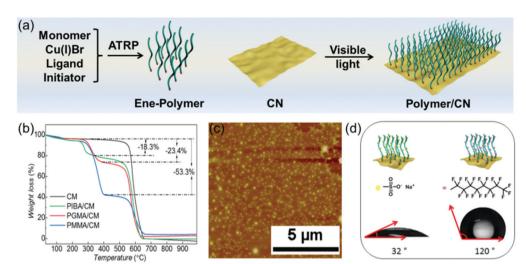

Fig. 7 (a) Overview for atom transfer radical polymerization and grafting of polymer brushes onto g-C₃N₄ under visible light irradiation, (b) thermogravimetric analysis of cyanuric acid-melamine-derived g-C₃N₄ (CM) precursor and ene-polymer grafted CM, (c) atomic force microscopy profile of spin coated poly(isobornyl acrylate)(PIBA)/CM film, (d) modification of poly(glycidyl methacrylate)(PGMA)/CM via thiol-addition mediated epoxy ring-opening, with sodium 2-mercaptoethanesulfonate and 1H,1H,2H,2H-perfluorodecanethiol, respectively (Licensed under CC-BY). 155

Hence, monodisperse PS microspheres with tunable size down to the 100 nm diameter region, surface charge and morphology were obtained. Herein, g-C₃N₄ located in the continuous phase and adhered to the monomer droplet surface forming a network structure preventing the emulsion from coalescence. The as-prepared PS/g-C₃N₄ possessed photoluminescence properties owing to the existence of g-C₃N₄ sheets, and both g-C₃N₄ and PS latex showed excellent biocompatibility during standard MTT assays. Nanoparticles were incubated with HeLa cells for 12 h and observed with confocal laser scanning microscopy. The particles were internalized by HeLa cells, indicating that the fluorescent PS/g-C₃N₄ hybrid particles are promising materials for bioimaging. Recently, sialic acid was introduced into the g-C₃N₄ stabilized Pickering polymerization system, which is an important indicator of some types of cancer. The g-C₃N₄ contained and sialic acid-imprinted polymer nanoparticles exhibited good biocompatibility and excellent targeted image of DU 145 cells (sialic acid-overexpressed surface). 159

Additionally, as discussed in Section 2, g-C₃N₄ can effectively produce radical species under visible light irradiation, thus polymerization can be conducted on g-C₃N₄ and g-C₃N₄/polymer nanocomposites can be obtained. For example, Weber and coworkers reported the formation of g-C₃N₄-based PBA composites via an aerosol polymerization process (Fig. 8a). 160 Spherical mesoporous g-C₃N₄ (SMCN) was initially prepared with mesoporous silica nanoparticles as template (Fig. 8b), then monomer was continuously added via the gas phase and polymerized in proximity of g-C₃N₄ via photoinitiation under UV light irradiation. Later, spherical g-C₃N₄/polymer composite particles (Fig. 8c) were obtained without solvent or surfactant. Such a strategy is suitable for fabrication of spherical nanocomposites with hydrophobic polymers. The as-prepared mesoporous CN acts not only as photoinitiator but also as filler and template.

Very recently, our team attempted to utilize g-C₃N₄ as emulsifier and photoinitiator at the same time to conduct emulsion

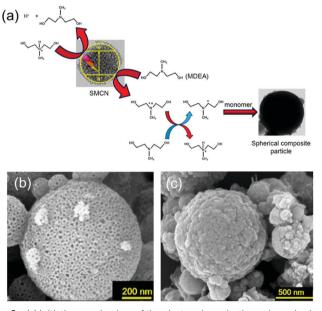

Fig. 8 (a) Initiation mechanism of the photopolymerization using spherical mesoporous q-C₃N₄ (SMCN) in the presence of the methyl diethanolamine (MDEA) as co-initiator. (b) SEM image of SMCN replicas. (c) SEM image of PBA-SMCN composites produced by aerosol-photopolymerization (Reprinted with permission. 160 Copyright 2016 American Chemical Society).

photopolymerization.⁵⁸ Herein, the emulsion photopolymerization of styrene was studied with non-functionalized g-C3N4, which led to PS latexes with particle diameters around 170 nm. Nevertheless, no satisfying MMA latexes could be obtained that way albeit BMA formed latexes with narrowly distributed particle sizes. Apparently, the monomer structure has a significant impact on the polymerization process, i.e. the interactions of monomer and g-C₃N₄ seem to play a significant role to create the particle nucleation site. It is very likely that styrene and BMA feature enhanced interactions with g-C₃N₄ due to π - π interactions, while MMA interacts to a lesser extent. Notably, the utilization of decene-functionalized g-C₃N₄ enabled the formation of PMMA latexes, probably due to the improved interaction of the initiating stabilizer with the monomer. The formed latexes feature polymer particles that incorporated g-C₃N₄ and were crosslinked directly. The specific location of g-C₃N₄ was investigated, demonstrating that g-C₃N₄ nanosheets ranging from 50–100 nm appeared to be inside of the latex with STEM tilt observation, and small pieces attached outside of latexes with a negative surface charge that grants a stable emulsion latex/g-C₃N₄ composite. The combination of the traditional PS latex with the outstanding features of environmentally friendly g-C₃N₄ provides novel polymer composites with multifunctional modern applications, *e.g.* in bioimaging or 3D printing.

4.3 Improved properties of polymer materials via combination with g-C₃N₄

It is reported that hybridizing g-C₃N₄ and polymers on one side significantly improves surface and photocatalytic properties of g-C₃N₄, on the other side also enhances the thermal and mechanical properties of polymers as well as surface properties. 162-164 Few studies reported that the introduction of g-C₃N₄ to polymers also lead to the improvement of mechanical properties of polymers. 165 Myllymaa and coworkers deposited Si-doped CN (CN-Si) on poly(propylene) (PP) disc samples via pulsed laser deposition. 166 The coating of CN-Si can significantly convert the PP surface from being hydrophobic to hydrophilic, leading to enhanced adherence of Saos-cells on PP. Hu and coworkers reported a mix of PP-grafted maleic anhydride (PP-g-MA) with g-C₃N₄ by refluxing the mixture for 4 hours in xylene. 167 It was reported that the incorporation of g-C₃N₄ with PP-g-MA significantly improved the storage modulus, i.e. 2445 MPa for neat PP-g-MA and 2784 MPa for pp-g-MA/g-C₃N₄, respectively. Moreover, optical results showed that the hybrid materials possessed fascinating UV absorption. Cai and coworker introduced g-C3N4 as reinforcing filler for wood plastic compositions (WPCs), pp-g-MA was added as a coupling agent to increase the interaction between different components. 168 The tensile modulus indicating an increase of 143% with g-C₃N₄ contents of 5 wt%, and the thermal tests demonstrated that the degradation temperature shifted to higher values after g-C₃N₄ addition. Lin and coworker fabricated g-C₃N₄/poly(vinyl alcohol) (PVA) nanocomposites by solution casting using water as solvent, demonstrating that the g-C₃N₄ could be well dispersed in PVA matrix. 169 The introduction of g-C₃N₄ nanosheets increased the glass transition temperature and crystallinity of the nanocomposites, leading to improved mechanical performance with \sim 71% enhancement of tensile strength. 169 Very recently, Guo and coworkers synthesized g-C₃N₄ on carbon fiber surfaces in situ in order to enhance interfacial properties of carbon fiber reinforced epoxy resin composites.¹⁷⁰ The g-C₃N₄ on the carbon fiber surface greatly increased the roughness, the content of polar functional groups and wettability of carbon fibers. Thus, significant enhancement of interfacial properties of the composites was obtained.

5. Carbon nitride-based hydrogels

Hydrogels constitute an important class of polymeric materials due to their unique features such as swelling properties or soft character while being shape persistent.¹⁷¹ Consisting of a crosslinked hydrophilic network, hydrogels contain significant amounts of water. Their similarity to natural tissues is another important point for the frequent investigation of hydrogels, especially when biomedical applications like tissue-engineering or drug-delivery are targeted. 172,173 Other discussed applications comprise actuators, 174 self-healing, 175 absorption of contaminants 176 or shape-memory materials. 177 Commonly, hydrogels possess rather weak mechanical properties but research has introduced reinforced hydrogels with partly extraordinary properties. For that, several methods are utilized, e.g. double network hydrogels, 178,179 topological (slide-ring) gels, 180,181 nanofiber reinforced hydrogels 182 or the introduction of charged supports. 183-185 Especially, the introduction of particles as reinforcer provides increased stress dissipation, in some cases charge-charge repulsion between the single filler particles or sheets leads to an additional stabilization especially against compression.²⁰ One common example are clay nanosheets that combine ionic interaction and hydrogen bonding with polymeric chains acting as additional crosslinking points. 186-188

As mentioned before, g-C₃N₄ can be utilized as photoinitiator for polymerization reactions. As such g-C₃N₄ can be utilized as well for the formation of hydrogels under visible light. Most notably, these hydrogels incorporate g-C₃N₄, which might have various effects on materials properties.¹⁸⁹ For example, g-C₃N₄-based hydrogels feature remarkable mechanical properties like compressibility and high storage moduli as discussed in Section 5.1. In addition, g-C₃N₄-based hydrogels retain the photocatalytic properties of g-C₃N₄, which allows utilization in contaminant degradation or H₂ evolution (Section 5.2). Besides the formation of hydrogels *via* covalent bonds, g-C₃N₄ can be utilized in supramolecular hydrogels as well as blended into hydrogel scaffolds to improved mechanical properties for instance, which is discussed in Section 5.3.

5.1 Hydrogels with tailored mechanical properties

It was already stated that the photoactive properties of g- C_3N_4 enable the formation of radicals in aqueous dispersion. Thus, after addition of monomer and crosslinker, hydrogels can be formed with greatest ease via visible light irradiation (Scheme 5a and Table 2). For example, water-soluble acrylamide-derivatives can be utilized, which feature fast gelation rates and a broad spectrum of functionalities. g- C_3N_4 then indeed does not only act as photoinitiator but also as reinforcer. The reinforcement effect is due to the lateral extension of the g- C_3N_4 sheets that dissipate mechanical stress throughout the network and thus improve mechanical properties, very similar to the previously mentioned clay nano sheets.

As a first example our group employed DMA and *N,N'*-methylene bisacrylamide (MBA) with a dispersion of 0.6 wt% CM in water for hydrogel formation.¹⁹¹ Hydrogels were obtained after several hours of visible light irradiation. Notably, the hydrogels retained the photocatalytic properties of g-C₃N₄. In addition,

Scheme 5 Overview of $g-C_3N_4$ based hydrogels: (a) formation via visible light induced polymerization of a water-soluble monomer and crosslinker, (b) spatially controlled hydrogel formation via application of a photomask leading to polymerization in the illuminated part only and (c) formation via physical interactions (DMA: N,N-dimethylacrylamide; NIPAM: N-isopropylacrylamide; MBA: N,N'-methylene bisacrylamide; AAm: acrylamide; SPMA: 3-sulfopropyl methacrylate potassium salt; FMOCDPA: Fmoc-diphenylalanine; SA: sodium alginate).

EMOCDPA

remarkable mechanical properties were observed, such as superstretchability or being very tough and flexible at the same time. Such behavior opens up a completely new field of applications. In the next step the mechanical properties and origin of gel formation were studied in more detail (Fig. 9).⁶⁴ To investigate the role of g-C₃N₄ in the network formation, control reactions were performed, i.e. hydrogel formation with a common photoinitiator/without g-C₃N₄ (Fig. 9a), which lead to very weak hydrogels. Furthermore, hydrogelation employing g-C₃N₄ without external crosslinker and non-nitrogen containing monomers was investigated as well. Indeed, hydrogelation took place even without addition of external crosslinker, which indicates the incorporation of g-C₂N₄ into the network, Moreover, hydrogels could be formed from non-nitrogen containing monomers and crosslinkers, which indicates that the reaction is not dependent on radical transfer from g-C₃N₄ to amines as instrumentalized in various other reactions. 56,57 Moreover, remarkable mechanical properties were obtained (G' up to 8.3 kPa at solid contents of 11 wt%) (Fig. 9c). One reason is the particular structure of g-C₃N₄ that acts as colloidal filler via formation of a secondary network of inorganic sheets inside of the hydrogel providing additional strength to the structure. In addition, g-C₃N₄ introduces additional crosslinking points, which strengthens the hydrogel further. This effect could be analyzed via a control experiment of hydrogel formation in g-C₃N₄ dispersion but with redox initiation in the absence of light (Fig. 9b). Compared to a reference sample without g-C₃N₄, improved mechanical properties were found albeit the mechanical properties from visible light g-C₃N₄ mediated hydrogels were not reached. Thus, both reinforcement via inorganic secondary network as well as via additional crosslinking points are important. The fabricated hydrogels showed a significant shear thinning effect. Such an effect is common to reinforced hydrogels as shear leads to alignment of the polymer network as well as g-C₃N₄ particles, and such ordering is weakening the g-C₃N₄-g-C₃N₄ interactions.

Liu and coworkers showed the formation of a g- C_3N_4 /NIPAM hydrogel. ¹⁹⁰ A hydrogel was formed *via* visible light mediated photopolymerization albeit no external crosslinker was added. The NIPAM-based hydrogels showed thermoresponsive properties. For example, the viscosity, storage and loss modulus of the obtained hydrogels decreased until the lower critical solution temperature (LCST) of PNIPAM and increased again above the LCST. Moreover, the authors could form the hydrogels in specific patterns that changed transparency reversibly according to temperature (Fig. 9d). Farzaneh and coworkers physically

Table 2 Hydrogels based on $g-C_3N_4$ and their properties

Synthesis method	Monomers/gelators	Properties/applications	Ref.
Photopolymerization	DMA/MBA	Photocatalytic dye degradation and H ₂ evolution	191
Photopolymerization	DMA/MBA	High G' (up to 8.3 kPa), salt and pH response	64
Photopolymerization	NIPAM/MBA	Thermoresponse	190
Photopolymerization	AAm/DMA/MBA	High compressibility	193
Photopolymerization in water/EG	DMA/MBA	High G' (up to 729 kPa)	196
Photopolymerization with g-C ₃ N ₄ prepolymer	DMA/SPMA/MBA	Low friction	197
Photopolymerization	AAm/MBA	Tetracycline degradation	200
Photopolymerization	AAm/MBA	Photooxidation of Cr(v _I)	201
Redox polymerization	AAm/MBA	Gel electrophoresis	192
Thermal polymerization	AAm/acrylic acid/MBA	Ag ⁺ sensing and pH sensitivity	203
Blending	Graphene/PPy	Photooxidation of Cr(vi) and degradation of phenol	202
Blending	FMOCDPA	Photo- and enzymatic catalysis	204
Blending	SA	3D printing and photocatalysis	205
Blending	IL	H ₂ S gas sensor	206
Blending	Agar	Photocatalytic dye degradation	208 and 209
Supramolecular	Partially hydrolyzed g-C ₃ N ₄	Selective dye adsorption	207

Materials Horizons Review

(d) Pictures of a monolithic NIPAM/g-C₃N₄ hydrogel at ambient temperature and elevated temperature, respectively (Licensed under CC-BY). 190

incorporated g-C₃N₄ into acrylamide hydrogels for gel electrophoresis via a redox polymerization of AAm and MBA. 192 Due to the thermal conductivity of g-C₃N₄, Joule heating in the hydrogels was reduced and band broadening in the electrophoresis was lowered. Moreover, the presence of g-C₃N₄ allowed to refrain from utilization of tetramethyl ethylenediamine as polymerization catalyst, which can be a disadvantage for some analytes.

As g-C₃N₄ provides the opportunity to modify the surface charge (zeta potential), surface area and light absorption via variation in the precursor composition, 43,194,195 effects of the precursor composition on mechanical properties were investigated as well. Notably, the zeta potential had a profound effect on storage modulus. It was found that stronger negative zeta potential g-C₃N₄ compounds led to stronger hydrogels.⁶⁴ Such an effect can be explained by g-C₃N₄ sheet repulsion that increases with more negative zeta potentials. A similar effect was already described in the literature for other reinforcing particles. 185,188 The effect of surface charge was further investigated by our group employing AHPA-modified g-C₃N₄, which features significantly lower zeta potentials and high dispersibilities due to the sulfonic acid group. 193 A mixture of AAm, DMA and MBA were used as monomers together with CM-AHPA as initiator. The hydrogels obtained were rather soft with G' in the range of 100-200 Pa and contained solid contents below 10 wt%. However, the hydrogels featured remarkable compression properties, e.g. withstand loads above 12 MPa (Fig. 10) and resisted multiple hits with a hammer. Probably, the extreme compressibility is due to the fact that the gels contained highly negatively charged g-C₃N₄, which shows significant repulsion of the g-C₃N₄ sheets in compression. In addition, the gels were soft and could dissipate

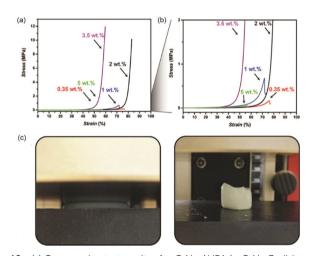

Fig. 10 (a) Compression test results of g-C₃N₄-AHPA (g-C₃N₄-3-allyloxy-2hydroxy-1-propanesulfonic acid sodium salt)-based hydrogels (red: 0.35 wt%; blue: 1 wt%; black: 2 wt%; violet: 3.5 wt%; green: 5 wt%), (b) magnification of compression test results of g-C₃N₄-AHPA hydrogels, (c) images of 2 wt% g-C₃N₄-AHPA hydrogel during (left) and after (right) compression (Reproduced with permission. 193 Copyright 2019 John Wiley and Sons).

the compressive force over the whole structure by electrostatic coupling. Compression led to a complete flattening of the structure and a return to the initial shape after release of the force. In order to get further insights into the origin of the remarkable compression properties, hydrogels were formed from the individual monomers with MBA. It was found that the DMA-based hydrogels were stronger but less compression resistant, while the AAm-based hydrogels were weaker but more resistant to compression. Swelling the AAm/DMA

(a) (b) (c)

Fig. 11 Spatially controlled photopolymerization for gel formation: (a) formation of a self-standing half-circle, (b) self-standing club shape and (c) photopatterning of stripes on a glass slide (Licensed under CC-BY). 196

hydrogels with salt solution (NaCl or $CaCl_2$) showed increased strength but less compressibility, which might be due to the screening of the negative charges on the g- C_3N_4 surface. Hence, the surface charge of g- C_3N_4 is certainly the main reason for the enhanced compressibility, while the monomer mixture supports compressibility due to enhanced elasticity, which leads to improved distribution of the stress in the network.

Regarding the mechanical properties of the hydrogels, not only the charge on the g-C₃N₄ matters but also the amount of incorporated g-C₃N₄. Therefore, EG/water mixtures were used to increase the amount of non-functionalized g-C₃N₄ during hydrogel formation. 196 Incorporating g-C₃N₄ contents up to 4 wt% led to hydrogels with G' of 88 kPa for 2 wt%, 430 kPa for 3 wt% and 729 kPa for 4 wt% of g-C₃N₄ at 0.1% strain, which is a remarkable increase of two orders of magnitude compared to the first hydrogels with 0.6 wt% g-C₃N₄. In addition to enhanced mechanical performance, hydrogelation was much faster with higher g-C₃N₄ content which proves g-C₃N₄ acts as photoinitiator. As the hydrogel formation is photoinitiated, patterning was investigated as well. For that, parts of the reaction mixture were covered with a photomask to obtain an inversely shaped hydrogel (Scheme 5b and Fig. 11). The success of such experiments also proves that there is no significant radical transfer to dark area (solution) and the polymerization takes place only in the illuminated area via g-C₃N₄ initiation. In order to enable the fabrication of hydrogels with a broader range of monomers, e.g. charged monomers, our group utilized g-C₃N₄-PDMA prepolymer formed in EG/water mixture without crosslinker.⁸² With prepolymer, hydrogels from 3-sulfopropyl methacrylate potassium salt (SPMA) and DMA were obtained. The SPMA monomer introduces negative charges into the hydrogel structure, which is a useful feature for low friction surfaces. 197 Hence, hydrogels with both very low friction coefficients (around 0.03) and remarkable compression properties due to g-C₃N₄ incorporation were obtained. This combination of properties is rather uncommon and challenging to achieve but of particular interest for applications, e.g. in artificial cartilage. 198

5.2 Utilization of photophysical properties

The incorporation of g- C_3N_4 into hydrogels occurs under retention of its photophysical properties in the dispersed state inside of the network (Table 2). As such, various properties are accessible, *e.g.* photocatalysis or water contaminant degradation. Dong and coworkers obtained acrylamide-based hydrogels for "light filtering" applications.¹⁹⁹ AAm was utilized as monomer in a visible light

induced polymerization. Due to the hydrogen bonding interactions between g- C_3N_4 and PAAm in the hydrogel self-healing was observed after cutting the hydrogel. Similar mechanical properties (compression and tensile) were observed before and after healing. The hydrogels featured high photostability and could be utilized for UV shielding due to the broad absorption of g- C_3N_4 in the gel. For example, for UVA, UVB and UVC a transmittance of 0 to 28% was observed, while at 550 nm a transmittance of 89% was measured. Thus, these gels might be used as sun-light blockers.

H_2 Copyright 2017 American Chemical Society).

Materials Horizons

Shalom and coworkers formed g-C₃N₄-based hydrogels for photocatalytic applications (Fig. 12a). 191 For example dye degradation reactions could be performed easily. Several dyes were probed as reference compounds for other impurities in waste water. Depending on the type, absorption in the gel proceed with different efficiency, which was mainly attributed to ionic interactions. In addition, hydrogen evolution could be performed after addition of platinum cocatalyst (Fig. 12b) and the catalytic hydrogel could be recycled easily (Fig. 12c). Another hydrogel for waste water treatment was described by Yao and coworkers. 200 In this case, bentonite, g-C₃N₄, AAm and MBA were combined to form hydrogel monoliths via thermal polymerization. Finally, the monoliths were cut into small cubes, and adsorption of tetracycline was tested. The incorporation of bentonite led to enhanced adsorption of the organic contamination. In the next step, tetracycline was degraded via visible light irradiation. Furthermore, adsorption and degradation were studied in the flow process that showed a high removal efficiency and cycling stability.

Another photocatalytic process employing g-C₃N₄-based hydrogels was presented by Lamkaho and Randorn. 201 A PAAm hydrogel was formed via photopolymerization of AAm and MBA under UV light. Finally, the hydrogel was utilized for the photocatalytic reduction of Cr(vI) to Cr(III). Cui and coworkers described a hydrogel formed from g-C₃N₄, graphene and PPy.²⁰² Improvements of the photocatalytic properties were obtained *via* graphene as electron transporter and PPy as hole transporter. The obtained hydrogels were utilized for photodegradation of phenol and reduction/adsorption of Cr(VI). Tu and coworkers introduced another application of g-C₃N₄ based hydrogels. An AAm/acrylic acid-based hydrogel was formed via thermal initiation that could be utilized as sensor for Ag+ ions.203 Due to the acrylic acid incorporation, the hydrogels were pH sensitive, i.e. the swelling state changed according to pH. Moreover, the hydrogels showed fluorescent behavior because of the g-C₃N₄ incorporation. The fluorescence could in turn be utilized for sensing. The change in fluorescence after addition of various metal ions was tested, and in the case of Ag⁺ a significant quenching effect was observed down to concentrations of 6.31 μM. Notably, the detection of Ag⁺ was still possible when other contaminant ions were present.

Blending and supramolecular hydrogels

In addition to covalent hydrogels formed via polymerization, g-C₃N₄ was incorporated into hydrogels via blending or supramolecular interactions as well (Scheme 5c and Table 2). For example, Park and coworkers presented the combination of g-C₃N₄ and peptide materials.²⁰⁴ In those experiments, Fmocdiphenylalanine (FMOCDPA) was utilized to undergo self-assembly in the presence of g-C₃N₄ yielding a hydrogel. The formed hydrogel was utilized to reduce NAD⁺ to NADH. Moreover, the incorporation of an enzyme facilitated the combination of photo and enzymatic catalysis. A remarkable hydrogel was described by

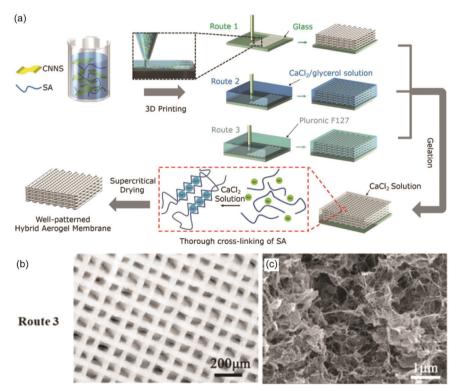

Fig. 13 (a) Schematic illustration of the 3D fabrication process: a highly concentrated homogeneous CNNS-SA ($g-C_3N_4$ nano sheet-sodium alginate) ink was extruded and directly printed onto a glass substrate covered with a layer of Vaseline (Route 1), into a reservoir composed of a CaCl₂/glycerol solution (Route 2) or Pluronic F127 (Route 3). Subsequently, the printed lattices were submerged in a CaCl₂ aqueous solution overnight to crosslink the SA. (b) Optical image of a woodpile structure (mass ratio CN: SA = 1:2) printed via Pluronic F127 (Route 3) and (c) a cross-sectional SEM image (Reprinted with permission. 2015 Copyright 2018 John Wiley and Sons).

Fan and coworkers, who combined g-C₃N₄ with the Ca²⁺/alginate supramolecular hydrogel and 3D printing (Fig. 13a).²⁰⁵ Hence, 3D hydrogel scaffolds were obtained that could be utilized for photocatalytic tasks. A carbon nitride nanosheet/sodium alginate (CNNS-SA)-based ink was printed and crosslinked in CaCl₂/glycerol solution (Fig. 13b and c). Inclusion of gold nanopyramids in such 3D scaffolds boosted the photocatalytic activity for solar wastewater remediation. Thus, the gel architecture could be utilized to tailor the catalysis efficiency via enhanced substrate transport. Ayajan and coworkers presented a gel from g-C₃N₄ and ionic liquids (IL) forming an amphiphilic network that was utilized as H₂S gas sensor at ambient temperature. ²⁰⁶ ILs served as exfoliating agent for g-C₃N₄ sheets at high temperatures, and gel formation was observed at 200 °C after 24 h, where exfoliated g-C₃N₄ nanosheets assembled in the IL matrix.

A hydrogel solely formed from g-C₃N₄ was investigated by Zhang and coworkers. 207 Here, g-C₃N₄ was partially hydrolyzed in sodium hydroxide solution. The obtained material formed reversible hydrogel structures via bubbling with CO2 or N2 that could be utilized for selective dye absorption. In the presence of agar, heating-cooling polymerization yielded hydrogels including g-C₃N₄.²⁰⁸ The agar-based hydrogels were further utilized for effective photocatalytic degradation due to enhanced adsorption capacity. In a similar way, Zhu and coworkers utilized a g-C₃N₄/ agar hydrogel for photocatalytic tasks.²⁰⁹ Therefore, g-C₃N₄ and agar were dispersed in water and heated. After cooling a hydrogel was obtained that was used for the photodegradation of MB and phenol. A significant activity was obtained due to the adsorptive behaviour of the hydrogel.

6. Conclusion and outlook

Combining exfoliated g-C₃N₄ nanosheets with polymers is a recent hotspot of materials research, thus enabling many advanced functionalities and hybrid materials with unusual properties extending the previous range of the possible. The development is mainly driven by typical g-C₃N₄ properties, such as photoinitiation, photocatalysis, or photoluminescence. However, it turned out that these properties are significantly improved or optimized in the polymer hybrids, which is due to improved delamination, but also due to synergies of the two sides. Introducing for instance conducting polymers to g-C₃N₄ enables overcoming the drawback of low electron conductivity of g-C₃N₄, and hence the photocatalytic or H₂ evolution properties of g-C₃N₄ are promoted. In biosensor systems, polymer functionalized g-C₃N₄ has shown an improved sensitivity and selectivity, which we attribute to improved dispersion and access to the sensing sites. Polymer modified g-C₃N₄ showed enhanced dispersibility and processability, and for instance can be employed in film formation.

On the other hand, g-C₃N₄ with its multiple properties brings advantages to polymer materials as well. For example, doping the polymer matrix with g-C₃N₄ enhances the performance of electrode materials in energy storage and improves stability as well as efficiency compared to the pure polymer matrix. Photoinitiation with g-C₃N₄ facilitates polymerization in solution and on g-C₃N₄ to obtain g-C₃N₄/polymer nanocomposites with inherent photoluminescence that can be applied for various applications. In addition, combination of g-C₃N₄ with polymers enhances the thermal and mechanical properties of polymer materials. In the realm of bulk soft materials, g-C₃N₄ is particularly useful as reinforcer in hydrogels and g-C₃N₄/hydrogel hybrids can be obtained. Overall, the plethora of monomer combinations and g-C₃N₄ types allows the fabrication of tailored hydrogel materials with very unusual and most useful properties, e.g. ultralow friction, being thermoresponsive, or tough but compressible. Indeed, the storage modulus of hydrogels could be varied over a broad range (approximately 7 kPa to 700 kPa) via g-C₃N₄ content and type, only, while the toughness of the material could be adjusted by monomer mixtures, e.g. AAm and DMA. By inherent photopolymerization, reinforced hydrogels can be obtained also in a spatially controlled way and directions of additive manufacturing are certainly a promising approach a toolbox is needed for. 210,211

Polymers might pave the way for novel applications for g-C₃N₄, however some main issues still need to be addressed. Although promising results were reported so far, the research for g-C₃N₄/polymer hybrids is still in the infant stage, and further investigations and developments are still required. To date, there are a number of issues, which need to be resolved for improved combination of g-C₃N₄ and polymer. For example, most of the research reported utilizes the simple blending method of fabrication, thus connection between polymer and g-C₃N₄ is enabled by physical interaction, only, which may cause restrictions for the future commercial application. Moreover, the synthesis process mainly depends on organic solvents, which is not environment friendly when expanded to commercial scale, thus solvent-free, mechanochemical and green routes should be developed in the future research. In oxygen evolution and organic synthesis, g-C₃N₄ is also of great significance as a photocatalyst. Nevertheless, g-C₃N₄/polymer hybrids are rarely applied in these areas so far. As such, one can expect significant outcomes in the future in organic synthesis and oxygen evolution. Overall, g-C₃N₄ has a promising future especially in energy conversion and storage, and enhancing surface area of g-C₃N₄ by polymers might become key for utilization of g-C3N4 in batteries, supercapacitors and other high-efficiency energy conversion devices.

Polymers have opened up new doors for g-C₃N₄ which could not be imagined seven years ago. Previously, dispersibility and processability issues were the main problems for integration of g-C₃N₄ materials, however with the current ideas in mind dispersibility becomes less of an issue. Ultimately, g-C₃N₄ is a sustainable and cheap alternative for other semiconductors, and we believe that with precise tailoring of both g-C3N4 properties and design of a surrounding polymer, g-C₃N₄ will play an increasingly important role both in academia and in the industry of the future.

Conflicts of interest

There are no conflicts to declare.
